INTRODUCTION

The development of therapeutics is limited by its ability to localize and be delivered to the site of interest. Among all drug delivery techniques to the central nervous system, the brain is notorious for low drug penetration due to a structure known as the blood brain barrier (BBB). The BBB is maintained by a population of cells, including endothelial cells, astrocytes, and pericytes collectively called the neurovascular unit (NVU), which regulates passage into the brain. Classes of drugs which are developed to treat central nervous system disorders are severely limited since molecules that are large (over 400 Daltons), highly polar and hydrophilic are prohibited from passively diffusing across the barrier. Among the current methods aiming to bypass the BBB, focused ultrasound (FUS) and microbubble assisted blood brain barrier disruption (BBBD) has proven to be one the safest noninvasive methods to guide the delivery of drugs past the BBB and into the parenchyma [1, 2]. Microbubbles (MBs) are ultrasound contrast agents ranging from 1-10 μ m in diameter which oscillate in an event known as cavitation in an acoustic field. Mechanical forces generated from cavitation are able to pry apart tight junctions between endothelial cells creating fenestrations along the blood vessel endothelium. This procedure has been demonstrated irreversibility and success in targeted delivery to the site of interest with millimeter precision and relative safety [3].

A caveat is that inflammation can be triggered in response to BBBD known as the sterile inflammatory response (SIR), recruiting microglia and catalyzing inflammatory cascades (Figure 1). Occurring shortly after disruption, damage associated molecule proteins can be upregulated along with the activation of the inflammatory pathways such as NF κ B [4, 5]. Despite molecular characterizations, little work has been done investigating the degree of inflammation that can occur between BBBD and the onset of SIR dubbed the “therapeutic window”. As the intensity of BBBD can be manipulated through mechanical index (MI), a measurement of ultrasonic energy delivered, and microbubble volume dose (MVD), a dose unifying parameter of microbubbles being injected [6], the objective of our study is to establish the boundaries of the therapeutic window by modulating these

parameters in order to be able to more accurately predict the degree of SIR occurring after disruption.

METHODS

Lipid films were prepared with a 90:10 ratio of lipid 1,2-Distearoyl-sn-glycero-3-phosphocholine (DSPC) and a PEG40S emulsifier. Lipid films were hydrated at 65°C for 40 minutes with sterile 1x PBS and diluted to a final concentration of 2 mg/mL. After rehydration, films were sonicated using a 20 kHz probe, cooled to room temperature (25°C) and re-sonicated with perfluorobutane gas to produce polydisperse microbubble concentrations. Microbubbles were differentially centrifuged down to diameters of 3 μ m and distribution and concentration sizes were measured using the Beckman Coulter Multisizer 3 counter. After successful isolation, microbubbles cakes were stored at 4°C and used within a week to avoid major distribution and concentration changes.

Figure 1: Recruitment of inflammatory markers (SIR) following microbubble-assisted blood brain barrier disruption (BBBD).
Copyright 2023 SB³C Foundation, Inc.

To establish the boundaries of the therapeutic window 5 MVD values were chosen ranging from lowest (0.01 $\mu\text{l/kg}$) to highest concentration (40 $\mu\text{l/kg}$) of microbubbles, these values are indicated in Table 1. All tests for MVDs were performed with a MI of 0.5. CD-1 mice were initially imaged with a 9.4T MRI scanner on the T2 weighted channel to determine correct anatomical targeting of the striatum. MRI coordinates were then transferred to a focused ultrasound machine (RK50, FUS instruments) where mice were retro orbitally injected with a Gadolinium based contrast agent (gadobenate dimeglumine, 4mmol/kg) and sonicated under these conditions: 1.5 MHz pulse frequency, 0.5MI, 0.615 MPa peak negative pressure (accounting for 20 percent skull attenuation), 10 ms pulse length, 1 Hz pulse repetition frequency, and a 5 minute sonication time. Directly after FUS treatment, animals were imaged with a T1+CE MRI where BBBD could be visually confirmed with gadolinium enhancement.

RESULTS

For our BBBD experiments, the mouse striatum was chosen due to its largest anatomical presence and ease of resectability. An MVD of 40 exerted the greatest degree of disruption evident through the intense gadolinium contrast enhancement shown (Figure 2). Interestingly, we observed that disruption occurred at a dose as low as 0.10 A MVD of 0 was selected as a control against BBBD with no visible gadolinium enhancement indicative of barrier impermeability. A linear trend of BBBD is observed over a range of MVDs measured arbitrary units of intensity. To a lesser extent this is also demonstrated in Song KH et al [6].

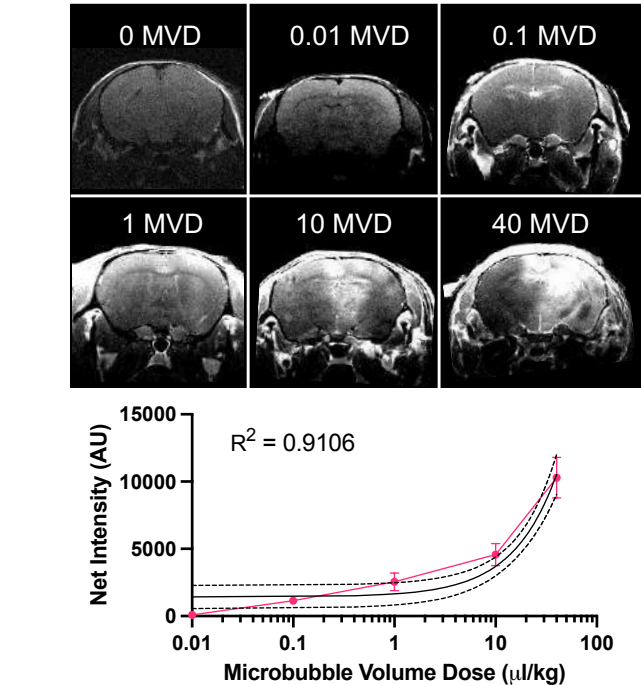

Figure 2: Gadolinium contrast enhancement of BBBD. The solid black indicates a best fit curve with the dashed lines above and below representing 95 percent confidence intervals. X-axis is shown as a logarithmic scale of microbubble doses. R squared values represents disagreement between the best fit line and experimental data

Table 1: Experimental groups

	Mechanical Index	Microbubble Volume Dose
Group 1	0.5	0.01
Group 2	0.5	0.1
Group 3	0.5	1
Group 4	0.5	10
Group 5	0.5	40

DISCUSSION

Preliminary results of this study highlight a relationship between our tested MVD values and MI which can be manipulated to influence the degree of BBBD. At higher MB concentrations of 40 and 10 MVD, larger gadolinium extravasation was observed as compared to the contralateral hemisphere which experienced no FUS treatment. Previous work in microbubble pharmacokinetics have shown that concentration decays exponentially immediately after injection [7] , supporting the case that higher MVDs contribute to longer persistence therefore allowing for more circulating microbubbles to participate in BBBD. This is observed in works of McMahon et al. where similarly, greater doses of microbubbles lead to greater BBBD and thus greater sterile inflammatory responses [8]. Interestingly, at MVDs as low as 1 and 0.1 MVD, slight disruption was detected via gadolinium contrast enhancement when measured against contralateral controls, exceeding our expectations for was what the lowest possible MVD at 0.5 MI to achieve successful disruption. Future work will aim to test more mechanical indices with MVDs and analyze transcriptomic changes at the level of RNA to assess gene regulation in response to the disruption.

Commercial brand microbubbles such as Definity and Optison are commonly used to test clinical doses of microbubble concentrations for BBBD, however, these are manufactured as polydisperse MB populations which may contribute to batch-to-batch variability. Using monodispersed MBs to calculate microbubble gas fractions allows us to measure the concentration of MBs systemically delivered more rigorously. This can be especially advantageous for future directions aiming to gauge or anticipate the amount of inflammation incurred by disruption by exploring various microbubble volume doses tested with different experimental mechanical indices. Currently, there is no method that aims to completely define the therapeutic window by manipulating MVD vs MI which measures the time between disruption and the severity and onset of SIR. Creating a wide range of parameters will create a more defined therapeutic window in which an immune response can be predicted, giving key insights into the safety of blood brain barrier disruption for future clinical translation.

BIOMECHANICAL IMPROVEMENTS IN GAIT WITH CARBON-FIBER ORTHOTIC INSOLE FOR POST-OPERATIVE TIBIOTALAR ARTHRODESIS PATIENTS

Adam J. Bradshaw (1), Austin J. Carcia (1), Colin R. Smith (1), Thomas O. Clanton (1),
Scott Tashman (1)

INTRODUCTION

Despite the high success rate of tibiotalar arthrodesis (TTA) for patients with degenerative ankle arthritis, many patients still experience functional limitations during daily activity, including reduced sagittal ankle range of motion, plantarflexion moment and power, and increased gait asymmetry [1,2]. Several consumer orthotics and footwear options are available to TTA patients, including rocker-bottom shoes, heel lifts, and solid ankle cushion heels, though none have been shown to restore normal gait biomechanics [3]. Recently, carbon-fiber plates inserted into high-performance running shoes to increase longitudinal bending stiffness have been shown to increase running economy, up to 3% [4]. To our knowledge, no studies have been performed investigating the use of carbon-fiber orthotic insoles for TTA patients.

This study aimed to determine whether a 3-layer carbon-fiber orthotic insole could improve gait biomechanics for TTA patients. Our central hypotheses were that 1) gait asymmetry in joint kinematics and kinetics, 2) ground reaction force (GRF) at heel strike, and 3) muscular activation would each be reduced in TTA patients while wearing the orthotic insole device.

METHODS

Seven participants (2 females; age: 55 ± 9.9 years; weight: 84.7 ± 19.9 kg; height: 1.78 ± 0.11 m) who were at least 29 months removed from single-leg total ankle fusion surgery (mean 77.1 ± 27.9 months) were recruited from the patient population at The Steadman Clinic (Vail CO). This study was IRB-approved and all subjects gave their written informed consent prior to data collection. Three footwear conditions were evaluated, each in standardized shoes: a control condition with no orthotic (NO), a regular orthotic condition (RO, Fig. 1b), and a stiffened orthotic condition (SO, Fig. 1c). To create the SO condition, a compressible foam wedge was inserted behind the middle and bottom layers of the device, providing increased resistance to compression of the orthotic.

Gait analysis was performed in each condition on a split-belt instrumented treadmill with a 16-camera motion-capture system and surface EMG at two different walking speeds: a self-selected pace (Normal: 1.01 ± 0.11 m/s), and a speed that was 20% faster (Fast: 1.22 ± 0.13 m/s). Twenty-six retroreflective markers were placed on the shoes, legs, hips, and trunk of each participant for motion capture. Participants were fitted bilaterally with wireless EMG sensors on their medial gastrocnemius.

Figure 1: (a) Oblique view of the 3-layer carbon-fiber orthotic insole (OI). (b) Lateral view of regular orthotic (RO). (c) Lateral view of stiff orthotic (SO) achieved using foam wedge. (d-f) A simulated loading response by the OI during stance, showing energy management function.

Nine gait cycles were selected as representative of each condition for analysis, and statistical tests evaluating the effect of the orthotics were performed independently for the Normal and Fast walking speeds. All kinetics, kinematics, and EMG data were normalized to 0 to 100% of stance phase and filtered with a zero-phase low-pass fourth-order 6Hz Butterworth filter. Joint moments and powers were normalized to the product of each participant's height and weight, and ground reaction forces were normalized to weight. Paired t-tests using Statistical Parametric Mapping (SPM) were implemented in MATLAB using

open-access SPM1D functions to assess the effect of each orthotic condition on the data of the affected leg [5]. Gait asymmetry was quantified using a symmetry ratio of affected versus contralateral leg swing time, as a percentage of cycle time [6].

RESULTS

SPM paired t -tests showed statistically significant reductions in ankle plantarflexion moment (Fig. 2a), knee extension moment (Fig. 2b), and gastrocnemius activity (Fig. 3a) during midstance (~30-70% stance) in the SO condition when compared to the control. Significant effects were still seen in the RO condition compared to the control, though to a lesser degree than SO. Significant reduction in impact force (Fig. 3b) occurred at heel-strike (0-10% stance) in the SO condition, though not in the RO condition. Non-parametric paired t -tests showed significant reductions in gait asymmetry at both walking speeds for the SO condition, decreasing gait asymmetry by between 1.1% and 2.6% across all comparisons.

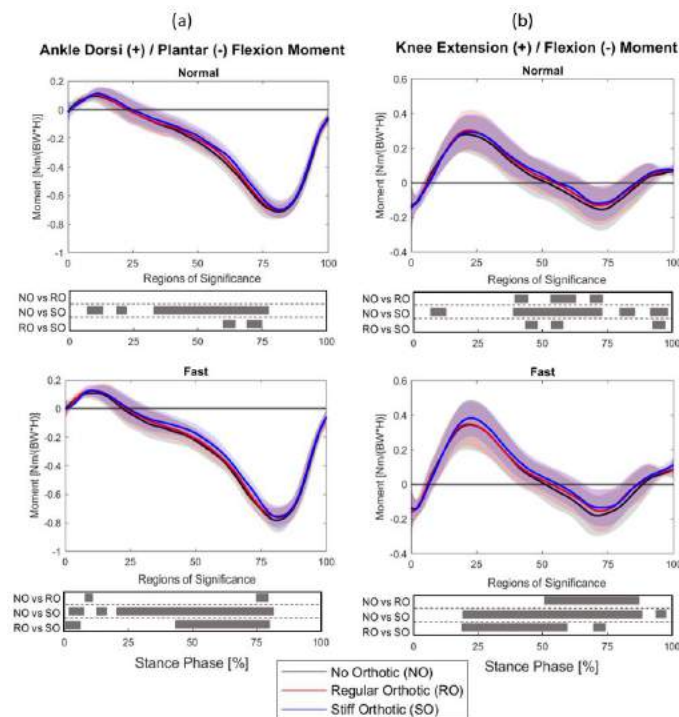

Figure 2: (a) Mean sagittal ankle moment and (b) mean sagittal knee moment of affected leg during gait. The shaded areas indicate one standard deviation from the mean across all subjects. Shaded blocks below the curves indicate regions of significant difference between the conditions ($p < 0.05$), based on the SPM paired t -tests.

DISCUSSION

The stiff orthotic (SO) condition showed the most statistically significant changes in gait compared to the control. Reductions in sagittal knee and ankle moments and gastrocnemius muscle activity during mid-stance suggests savings in muscular effort for the participants. Ground reaction forces were also reduced at heel-strike in both orthotic conditions, indicating a level of energy absorption by the orthotic device at impact. The SO condition, with the additional foam wedge inserted between the carbon-fiber spring system, acts as a better shock absorber than the carbon-fiber on its own, dampening the impact of the foot at heel-strike. Vertical GRFs were also reduced in terminal

stance in both RO and SO as compared to the control, near the point of peak push-off force, indicating that the energy absorbed at heel-strike was not released at toe-off. Previously discussed reductions in knee and ankle moments and gastrocnemius EMG indicate the energy may have been returned during mid-stance instead, although the viscoelastic properties of the foam may lead to overall loss of some of the energy absorbed at impact, resulting in less energy returned overall. Lastly, reductions in patient gait asymmetry in the SO condition can be seen as a positive impact of the device. Further research is needed on the optimal stiffness of the orthotic device, and on patient comfort and quality of life with long-term use.

No options are available to ankle fusion patients that can restore normal gait biomechanics post-surgery. Though this study only investigates the effects of an orthotic device on a small sample size, significant results in important gait metrics are promising for future tibiotalar arthrodesis patients.

ELASTIC FIBERS CONFER TENSILE STIFFNESS TO THE DORSAL MESENTERY, DRIVING BUCKLING MORPHOGENESIS OF THE SMALL INTESTINE

Elise A. Loffet, John F. Durel, Hyunjee Lim, Richard Kam, Nandan L. Nerurkar

Department of Biomedical Engineering, Columbia University, New York, USA

INTRODUCTION

Buckling has emerged as a core mechanism shaping a broad range of tissues during embryonic development [1]. However, integration of tissue mechanics with underlying cell behaviors and molecular cues has been limited. Looping of the small intestine – the process by which the initially straight intestinal tube is bent into tightly packed loops within the body cavity – is among a handful of examples of buckling morphogenesis where the underlying biological cues have begun to be revealed [2]. Differential elongation rates between the initially straight intestinal tube and the dorsal mesentery – a thin membranous tissue attaching the tube to the dorsal body wall – result in buckling of the gut into loops as the slowly elongating mesentery compresses the rapidly elongating tube [3][2]. The resulting wavelength and curvature of intestinal loops can be fully predicted from experimental measurement of growth rates, geometry, and mechanical properties of the gut and the mesentery [3]. Effectively, the mechanical properties of the mesentery determine how differential growth between the two tissues is converted to compressive forces that buckle the tube. Here, we focus on looping of the chick small intestine to understand how tissue stiffness is controlled during buckling morphogenesis.

The biological effectors involved in the mechanical properties of the mesentery remain largely unexplored. More broadly, the biological basis of tissue stiffness during embryonic development has received far less attention than other aspects of the mechanics of morphogenesis, such as regulation of acto-myosin activity [4] or cell migration [5]. In this study, we observed that changes in mechanical properties of the mesentery during the looping process correlate with changes in the expression of genes related to extracellular matrix (ECM), and elastic fibers in particular. Focusing on the functional role elastic fibers in looping, we enzymatically depleted elastin in the mesentery to observe the effects on tensile properties of the mesentery.

METHODS

Bulk RNAseq was carried out on mesentery tissues from White Leghorn chicken embryos (*gallus gallus*) embryos at embryonic day (E) 8, 12, and 16. Fastq files went through quality control (FastQC), residual adapter cleaning (cutadapt), genome alignment (hisat2) and read counting (htseq2). Subsequent analyses were done using R using package DESeq2 for differential expression and clusterprofiler for Gene Ontology analysis.

Elastase treatment: samples were incubated in PBS + 0.1 mg/ml SBTI (Sigma-Aldrich) and elastase (Elastin Products Company) for 4h at 37°C under agitation.

Immunostaining: Fixed samples were cryosectioned (16 μ m) and immunostained for elastin (Millipore Sigma MAB2503) [2]. Sections were counterstained with DAPI, mounted in and imaged using a LSM880 confocal microscope (Zeiss).

qPCR: Total RNA was extracted using RNeasy mini kit (Qiagen) ND reverse transcribed using SuperScript III Reverse Transcriptase (Life Technologies). Real-time quantitative PCR was performed using a C1000 thermocycler (Biorad) with a Sybr green mix kit (Applied Biosystems). The relative expression of the gene of interest was measured by the $2^{-\Delta\Delta C_t}$ method and normalized for the housekeeping gene ACTB.

Figure 1: Mechanical testing of mesentery

Mechanical testing of the mesentery was performed in uniaxial tensile testing on a custom micromechanical tester [2]. 1 mm wide

samples were hooked to a tungsten cantilever attached to a linear actuator, stretching the sample (fig 1.a.). Fluorescent dyes placed on the tissue and tungsten cables were used to measure strain. Bi-linear curve fits were applied to quantify the toe-region modulus E^{toe} , the linear region modulus E^{lin} , and the transition strain ϵ^* (fig.1.b.).

RESULTS

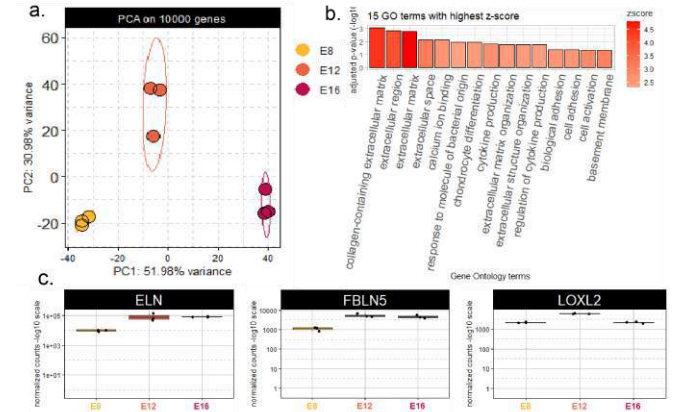

Figure 2: Bulk RNAseq of mesentery at E8, E12 and E16. a. Principal Component Analysis b. 15 Gene Ontologies with highest z-score (up-regulation association score) at E12 vs E8 c. Boxplots of gene expression for ELN, FBLN5 and LOXL2

Principal Component Analysis (PCA) showed significant difference between the three time points (fig 2.a.). Gene Ontology analysis of differentially expressed genes showed an upregulation of several ontologies related to ECM gene expression (fig 2.b.). Upregulated genes included collagen genes, as well as genes involved in elastic fiber formation: ELN (tropo-elastin), FBLN5 (fibulin-5) and LOXL2 (lysyl-oxidase, a cross-linking enzyme) (fig 2.c.).

Figure 3: Elastin and the buckling the gut tube. a. Immunofluorescence staining for elastin and DAPI on E8, E12 and E16 sections (scale bar = 100µm) b. qPCR for ELN in the mesentery at E8 to E16 c. Linear modulus for mesenteries at E8 to E16 d. Correlation of Elin and qPCR expression of ELN in the mesentery from E8 to E16.

Immunostaining revealed a progressive increase in elastin staining from E8 to E16, in the outside wall of the gut tube and in the mesentery (fig 3.a.). In untreated embryos, the linear modulus of mesentery tissue increased from E8 to E16 (fig 3.c.), correlating with qPCR expression for ELN (fig. 3.b) at these same time points ($R^2=0.7435$) (fig 3.d.). We did not measure a significant change in toe modulus or transition strain.

We treated mesentery and gut tube segments with 0, 2 or 4 U/mL of elastase for 4 hours at 37°C (fig. 4.a.). Controls showed no significant cell death or loss of collagen network and content. The treatment resulted in a down-regulation of the linear modulus at 2 and 4 U/mL (fig. 4.b.), but no significant difference in transition strain or toe modulus (data not shown).

Figure 4: Elastase depletion. a. Whole-mount immunofluorescence staining for elastin and DAPI on control and elastase-treated mesenteries (scale bar = 50 µm) b. Linear modulus.

DISCUSSION

In this study, we show that elastic fiber formation is closely associated with looping of the small intestine and that elastin depletion changes the mechanical properties of the mesentery.

Enzymatic digestion has been used to probe mechanical contributions of elastic fibers in a range of adult tissues, revealing some behaviors shared by the mesentery in the present study. For example, elastase treatment reduced linear modulus of the mesentery as it does in several tissues [6][7], and in synthetic matrices [8]. Elastase treatment has also been shown to result in lower capacity to withstand load, resist fatigue loading, and recover after loading in equine ligament [9]. However, disparities between our findings and those from other tissues may help explain the physical mechanism by which elastic fibers resist elongation of the mesentery to drive looping. Unlike porcine ligamen and human inter-vertebral disc, which experience a reduction in toe modulus as well [6][7] and an increase in transition strain for the intervertebral disc [7], the mesentery experiences an ~80% reduction in the linear modulus with no changes in toe modulus or transition strain. One explanation may be that elastin in the mesentery functions primarily to permit load transfer across stiff collagen fibers, and removal of elastin attenuates the influence of collagen in the linear region, where conventionally it is thought to dominate the properties of adult connective tissues. This is supported by the observation that elastase treatment increases the Poisson’s ratio of the mesentery (not shown), which has been suggested to reflect a reduction of load transfer between fibrous components in a matrix [10].

Altogether, our data shows that elastic fibers play a previously unappreciated role in resisting passive stretching of the mesentery, in turn contributing the compressive forces that buckle the intestinal tube into loops. Future work will aim to address the underlying mechanisms, and to ask whether tissue tension regulates elastic fiber deposition to provide feedback controls on looping of the intestine.

ELUCIDATING THE LONGITUDINAL IMPACT OF SOLID MECHANICS ON ATHEROSCLEROTIC PLAQUE IN PATIENT-SPECIFIC CORONARY ARTERIES

Jeremy L. Warren (1), Clark A. Meyer (1), Heather N. Hayenga (1)

(1) Department of Bioengineering, University of Texas at Dallas, Richardson, TX, United States

INTRODUCTION

In 2020 the CDC reported that approximately one in five deaths were attributed to cardiovascular disease (CVD) from 1999-2020 [1], [2]. In particular, coronary artery disease (CAD), also called atherosclerosis, accounted for roughly 55% of CVD-attributed deaths in 2020 alone, making it the leading cause of death across all CVD [2]. CAD is an inherently complex and heterogeneous disease wherein fatty plaque forms and accumulates within the artery wall. It is known that the growth and progression of plaque in coronary arteries is largely influenced by low or oscillatory wall shear stress at the luminal interface which causes inflammation [3], increased leukocyte transendothelial migration [4], and low-density lipoprotein (LDL) transport across the endothelium [5]. What is less known is how solid mechanics within the lesion augments atherosclerosis. Untreated plaque growth results in luminal narrowing which impairs blood flow hence, increasing the chance of adverse ischemic events downstream of the blockage. Moreover, a narrowed morphology results in large mechanical stresses in the cap and shoulder of the plaque, causing a sudden and life-threatening biomechanical failure known as plaque rupture [6]. However, the unpredictable nature of plaque rupture makes it difficult to clearly identify the magnitude or threshold of the mechanical stresses or strains that cause rupture. Therefore, we investigated how artery wall mechanics influence plaque growth pre-rupture. To do so, we use patient-specific data and in-silico methods to correlate the biomechanics of real-patient arteries with morphological features of plaque remodeling over 6 months. The outcomes of this work will further the current understanding of mechanically mediated plaque growth with implications in personalized treatment to minimize disease progression.

METHODS

Current imaging modalities such as coronary angiography and virtual histology intravascular ultrasound (VH-IVUS) are utilized to diagnose plaque severity and uncover locational and compositional features.

Recently, we published our work on an automated algorithm that is capable of using patient-specific VH-IVUS images and coronary angiography data to generate volumetric 3D meshes of coronary arteries for in-silico biomechanical modeling [Figure 1] [7]. Utilizing the model and in collaboration with a medical center, Emory University, we processed a 16-patient dataset of paired VH-IVUS and angiography images at baseline (BL) and 6-month follow-up (FU). MATLAB was used to generate the meshes and extract image derivable features.

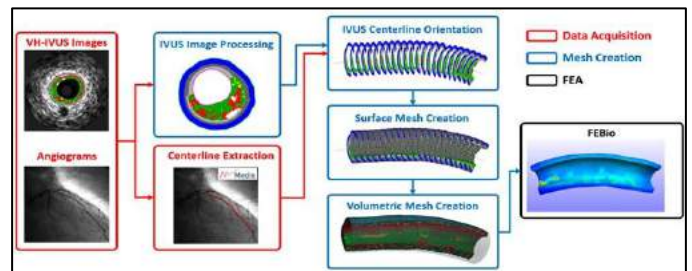

Figure 1. Simplified mesh generation flowchart.

Mesh Reconstruction and FEA. We used our reconstruction algorithm to generate straight meshes using BL patient data. Each mesh comprises quadratic 10-node tetrahedral element shapes with edge length of approximately 0.2mm. This mesh resolution is suitable to accurately represent semi-fine details present in the VH-IVUS images. Subsequent finite element analysis (FEA) simulations were performed using the open-source FEBio FEA software. Patient-specific blood pressure were applied to luminal surfaces. Nonlinear Neo-Hookean material model was utilized with heterogeneous literature-derived material properties pertaining to each plaque constituent. Mean elemental effective stress and strain corresponding to each pair of BL and FU VH-IVUS image was calculated from the FEA results.

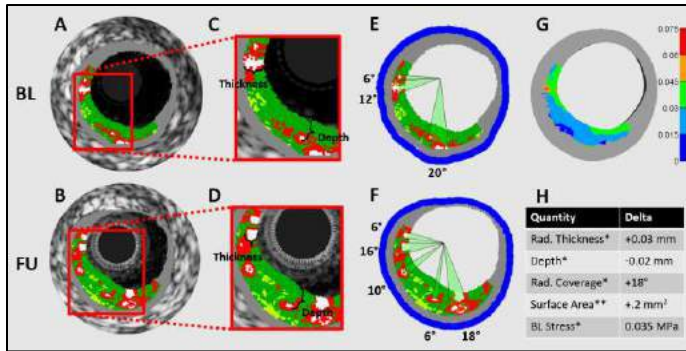

Figure 2. Image-derivable features and FEA.

A,B) Original BL and FU VH-IVUS. C,D) Plaque thickness and depth. E,F) Radial coverage. G) FEA stress. H) Calculated differences.

Image-derived features. A separate automated script analyzed every pair of BL and FU VH-IVUS images and extracted image-derivable features. These features include surface area, radial coverage, radial depth, and radial thickness of each plaque constituent [Figure 2]. The difference between BL and FU is then calculated between for use in the following analysis.

RESULTS

Preliminary results using 13 of the 16 patient datasets ($n = 842$ images) suggest that larger changes in plaque area between BL and FU occur at low-mid eff. stresses whereas smaller changes in surface area occur at mid-high eff. stresses [Figure 3A]. Similar patterns for radial coverage and radial thickness of the plaque arise as well. These patterns were not restricted to the global dataset as local changes within a single artery also exhibit a similar relationship [Figure 3B].

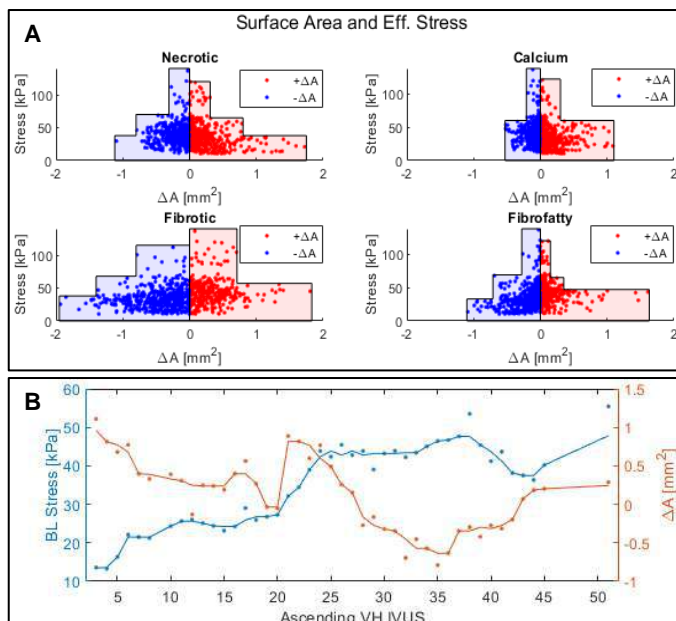

Figure 3. Mechanically mediated changes in plaque area.

A) Results for the global dataset, y-axis effective stress in kPa, x-axis change in area in mm². B) FEA results for necrotic tissue in a representative patient, x-axis VH-IVUS ascending image index, left y-axis effective stress in kPa, right y-axis changes in area in mm².

DISCUSSION

Our preliminary results corroborate the work by Samady et al. which found that low hemodynamical WSS correlated with increased plaque volume over a 6-month period [8]. It is thought that endothelial cells lining the lumen must be in a constant state of motion to maintain healthy cell-cell connections between them and minimize transport of leukocytes or LDL into the wall. Similarly, smooth muscle cells (SMCs) inside the artery wall responsible for remodeling the extracellular matrix can be negatively impacted by lower stresses. Pathological remodeling via SMCs has been replicated during in-vivo experiments. SMCs in low stretch conditions (0-10%) were found to proliferate less than those under large stretch conditions [9]. Taken together, this suggests a mechanobiological remodeling paradigm largely influenced by the mechanics felt at the cellular level. Yet, we do see some instances where it is the stress distribution rather than the magnitude that drives volume changes [Figure 4]. Further investigation is needed to quantify these relationships, but initial results indicate mechanobiological remodeling.

Figure 4. Similar volume change, different stresses. The necrotic core (red) had a similar change in volume between both pairs of BL and FU images. However, stress magnitudes were vastly different.

CHANGES IN THUMB FORCE DUE TO OSTEOARTHRITIS

INTRODUCTION

Osteoarthritis (OA) has been shown to be a debilitating musculoskeletal disease with significant degradation of the joints [1]. One of the most common locations of hand OA has been reported to be at the base of the thumb, or the carpometacarpal (CMC) joint. The CMC joint was also reported to be the most painful joint when compared to other joints of the hand [2]. Additionally, CMC OA has been shown to affect 67% of women over the age of 55 [3]. As a result, those impacted by CMC OA suffered from increased thumb pain which led to movement and strength limitations in the hand, including reduced force production. Because of the loss of hand and thumb strength, people had difficulties carrying out activities such as opening and closing containers, gripping and picking up objects, and lifting heavy items.

There are several surgical procedures to treat thumb CMC OA, however no procedure has been proven to be superior to the rest. Studies have evaluated the effectiveness of a surgery via patient questionnaires and clinical measurement devices. Clinical measurement devices, such as the dynamometer and pinch gauge, do not isolate the force produced by the thumb. Additionally, there are limited data reported on isolated thumb force generation following surgery. Relying on these clinical metrics have led to a gap in data gathered on the thumb. To determine how effective surgical treatment is for those with thumb CMC OA, we must understand not only the motion abilities, and the reduction of pain, but also the abilities to generate force post-surgery.

Thus, the purpose of this research was to determine the isolated forces generated by the thumb pre and post-surgery at two time points, 3 months and 6 months post-surgery, in those with thumb CMC OA in order to assess what strength has been restored.

METHODS

Our study included 10 female participants (average age 62.1 ± 8.9 years) (IRB# 2021-148). Of the 10 participants, a ligament

Figure 1: A) Participant performing a push at 0° of wrist supination. B) Participant performing a pull at 0° of wrist supination. C) A wooden block was mounted on the load cell with equally spaced holes where participants place the peg.

reconstruction with tendon interposition (LRTI) surgery was performed on 7 right hands and 3 left hands. Participants were of various ages: one 40-year-old, four between 50 and 59, three between 60 and 69 and two between 70 and 79. Participation in this study was voluntary. Each participant was consented, tested prior to their surgery, 3- and 6-months post-surgery. Participants sat in a chair with their back against the seat, their elbow extended, arm adducted with their hand and forearm on a custom testing device that was located on a table. The custom testing device restricted movement of the forearm and wrist allowing

individuals to focus on performing thumb force (Figure 1) and was adjustable to accommodate both right- and left-handed participants. The device included a wooden block mounted on a load cell (AMTI, Watertown, MA). The block had an array of holes spaced, approximately 12.7 millimeters apart, into 5 rows and 11 columns (Figure 1C). Force data sets were collected at 200Hz. Participants performed two trials of a thumb push and pull in 0° of wrist supination (Figure 1A and 1B, respectively). A push was described as the thumb pushing the peg “downward” or “into the ground”. A pull was described as the thumb pulling the peg in toward the index finger. Participants were instructed to execute each push and pull on the peg with their thumb positioned at a “close”, “far” and “comfortable” position. The close position was described as a position of the peg in the closest hole to the hand in which the pad of the thumb could grip the peg. The far position was described as the location of peg in the farthest hole away from the palm. And finally, the comfortable position was the most comfortable peg location selected by the participant. Each location (close, far, or comfortable) the participant was instructed to exert maximum force during each push and pull on the peg.

RESULTS

The maximum thumb pull and push forces in the comfortable position at 0° of wrist supination are presented in Figures 2 and 3., respectively. The trends shown in both figures for the comfortable position were similar to what was seen in the close and far and 90° wrist

Figure 2: Maximum pull force in the 0° wrist for CMC OA females (n=10) in the comfortable position. In green is the average maximum comfortable pull force for older healthy females.

orientation for those positions. As shown in each figure, a subset of participants each showed a positive response or non-positive response post-surgery. Nearly half of the participants reduced the amount of thumb force at 3 months post-surgery. However, some participants increased force at each time point. At 6 months post-surgery, some participants had similar or less favorable results at 6 months post-surgery, compared to pre-surgery. On each respective plot, the green line shows the average older healthy (OH) female thumb force. One participant surpassed OH female thumb pull force at 6 months post-surgery. Two participants reached or surpassed OH female thumb push force at 6 months post-surgery. Additionally, at each time point the pull force was the larger force generated as compared to push, no matter the peg location or wrist position.

DISCUSSION

In this study, force data were collected for 10 female participants both before and two time points following surgery for thumb osteoarthritis. The reason for most individuals to have this surgery is for pain reduction. Nearly all participants did experience a reduction in pain. However, little attention has been given to understanding the specific changes with force generation after the thumb surgery. Our data suggests that there is a mixed response to force generation after CMC

Figure 3: Maximum push force in the 0° wrist for CMC OA females (n=10) in the comfortable position. In green is the average maximum comfortable push force for older healthy females.

OA surgery. Ideally, each patient would reach the point of full strength, preferably to the level of a healthy adult in the same age range. Although, there were some participants who did reach the force generation level of a healthy older adult, most who improved did not improve to that magnitude, but they did increase in comparison to their pre-surgery abilities. However, others had force generation abilities that were reduced as compared to their abilities before the surgery.

It should be noted that compliance with therapy was not monitored, and the participants were only tracked to the 6-month point, so further improvement could occur beyond our measurement term.

There is a great deal more to study with regard to the biomechanics associated with thumb function particularly after surgical intervention.

AGE- AND SEX-BASED SKULL THICKNESS DISTRIBUTION FOR PREDICTING SKULL FRACTURE PATTERNS IN YOUNG INFANTS

Yousef Alsanea (1), Timothy Dixon (1), Tagrid Ruiz-Maldonado (2), Brittany Coats (1)

INTRODUCTION

Child maltreatment is the second leading cause of death in infants less than 1 one year of age [1]. Early identification is critical to the prevention of adverse outcomes, but child abuse in young infants is still highly under-detected. Skull fractures are common in both accidental and abusive head trauma and provide a unique opportunity to assess the validity of caretaker histories of infant trauma based on fracture initiation sites, fracture lengths, and level of complexity [2].

Skull thickness distribution influences skull fracture patterns [3], but the effect of age and biological sex in early development on skull thickness distribution have not been reported. The objective of this study was to develop an imaging pipeline for high-resolution, three-dimensional maps of skull thickness, and use this pipeline to compare distributions between male and females from birth (newborn) to 4 months of age. Similarity metrics were created to determine the need for sex-based anatomical templates for fracture simulation, as well as to identify appropriate age-divisions for those templates. These methods and data will lead to universal anatomical templates for skull fracture simulation, as well as form the foundation for a patient-specific modeling pipeline.

METHODS

IRB approval was obtained to review CT images of 300 healthy infant (<12 months of age) skulls from Primary Children's Hospital at the University of Utah. Serial stacks of axial and coronal images were aligned in MATLAB using DICOM image position alignment and an iterative closest point (ICP) algorithm. Cranial bone segmentation, identification of suture locations, and thickness extraction at more than 12,000 sites across the infant skull were performed using a custom python script (Fig.1).

To compare skull thicknesses at similar relative locations, despite differences in head shape and size, one subject within each age group (0-4, 5-8, 9-12 months) was selected as a template. The skull

Figure 1. Imaging pipeline for high-resolution skull thickness comparison across age and sex.

distribution in each subject was then fit to their respective template using ICP. Thickness was average across 132 discrete regions (Fig.2) representing approximately 22-39 locations in 4 cranial bones (right and left parietal, occipital, and frontal bones). 44 subjects < 4 months of age (21 female, 23 male) were selected from the dataset to evaluate changes in skull thickness distribution in early development.

The effect of age and sex was evaluated for each cranial bone using a two-way ANOVA with repeated measures, correlations of thickness with age by gender, and one-way ANOVAs that controlled for location. Moran's I and Geary's C spatial analyses were performed for each subject to identify trends in global and local skull thickness spatial clustering, respectively (Eq. 1, 2).

$$I = \frac{N \sum_i \sum_j w_{ij} (x_i - \bar{x})(x_j - \bar{x})}{W \sum_i (x_i - \bar{x})^2} \quad (1)$$

$$C = \frac{(N-1) \sum_i \sum_j w_{ij} (x_i - x_j)^2}{W \sum_i (x_i - \bar{x})^2} \quad (2)$$

The spatial weight matrix w_{ij} was calculated with an exponential function $w_{ij} = \exp(-r_{ij}/r_c)$ consisting of the Euclidean distance between two locations r_{ij} and the average distance between all locations within a cranial bone r_c .

Figure 2. Skull thickness was measured at over 12,000 locations on each skull (blue) and averaged over 132 locations (red) for comparing age and sex.

A similarity metric was developed to identify similar patterns of skull thickness distribution among the subjects. Briefly, this metric calculated and summed distances between ranked-ordered thickness locations for pairwise comparisons of all subjects. Data were normalized by the distance sums of non-ranked ordered locations. A similarity score of 0 indicates perfect similarity between regions of high and low thickness across the bone. Similarity was assessed for four groupings of data (all subjects; sex; age; sex/age combination).

RESULTS

Infant ages were either < 1.25 months of age (newborn) or 3-4 months of age (infant). Occipital and frontal bones were significantly thicker than parietal bones for both ages and sexes ($p < 0.001$, **Fig. 3**). Male occipital and frontal bones were significantly thicker than female bones at birth ($p < 0.0001$), while parietal bones were equal across sex. Increased thickness between newborns and infants was significantly more pronounced in females than males for all bones ($p < 0.001$). In fact, male skull thickness had no significant correlation of thickness with age between 0-4 months old, except for parietal bones which had a weak positive correlation ($r < 0.12$, $p < 0.001$).

Moran's I and Geary's C spatial analysis found positive correlations of skull thickness in most infants (88%), primarily on the parietal bones (**Fig. 4**). Similarity scores ranged from 1.72-3.18 across all groupings. In general, males and infants had similarity scores nearly identical to those when all data was combined, particularly for the parietal and frontal bones. However, separating by females and newborns improved similarity in skull thickness patterns by 7-8%. Further refinement by age and sex improved similarity in all groups by 3-10% in male infants and newborns and by 13-20% in female infants and newborns, respectively.

DISCUSSION

The high-resolution imaging pipeline and skull thickness comparison in this study illustrates distinct changes in skull thickness with age that are dependent on biological sex and cranial bone. Female skulls are thinner at birth, but grow rapidly and are thicker than males by 3-4 months. Areas of thicker and thinner regions of the skull are most unique in female newborns compared to other groups, and suggest that predictions of skull fracture may also be unique in this population.

The early development data from this study illustrates age- and sex-dependent changes in skull thickness distribution, and suggests the need for unique skull geometry templates between male and female

Figure 3. Skull thickness categorized by bone and age in male and female. Solid black, gray, and orange bars indicate significant differences ($p < 0.001$) for sex, age for females, and age for males respectively.

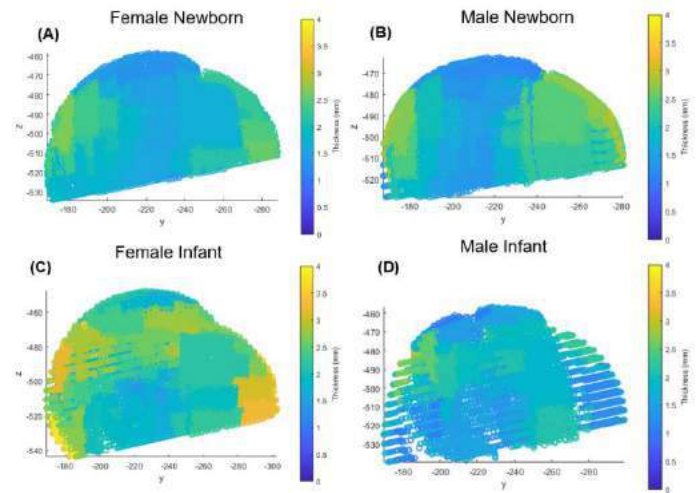

Figure 4. Contour plots of skull thickness illustrating skull thickness changes with age and sex.

newborns and young infants to accurately predict skull fracture patterns from head impact. Given large variations within the studied population, patient-specific modeling may be required. Data analysis on older infant populations is currently underway to identify if similar trends exist for infants up to 12 months of age. Once complete, these data will establish anatomical standards for simulations of head trauma in this rapidly developing age group.

DEEP LEARNING FRAMEWORK FOR STRESS STRAIN ANALYSIS OVER POINT CLOUD

Jia Lu, Nishant Sundaravaradan

Department of Mechanical Engineering, The University of Iowa, Iowa City, IA, USA

INTRODUCTION

We introduce a deep learning framework for image-driven analysis. The method is presented in the context of membrane bulge inflation test recorded by Digital Image Correlation (DIC). The DIC data provides a point-cloud representation of the surface and a one-to-one correspondence between points in different configurations. In conventional approaches, one usually extracts a deforming mesh from the point-clouds, conducts mechanical analysis on the mesh, and when needed, transfers data between the mesh and point-clouds. The transformation of geometric presentation and data transfer between geometric models entail approximations and are known sources of system error. Moreover, the workflow typically involves the use of multiple software, which is burdensome, to say the least. In the new paradigm, all analyses are conducted on a single platform, and directly over the point-cloud. This is achieved by using deep learning as the sole computation platform. In what follows, we demonstrate the new platform using an example of aneurysm tissue test.

METHODS

Figure 1 shows the DIC point-clouds of an aneurysm tissue sample at two configurations. The lower, Ω_0 , is the reference configuration. The upper, Ω , produced by the application of a transvers pressure, is the current configuration. Since point-to-point correspondence between the configurations has been registered by the DIC software, the tasks here are 1) to compute the surface strain, 2) to determine the stress field in the current configuration (the reference configuration, which was slightly pressurized, is assumed stress-free), and 3) to analyze the stress-strain behavior. We will focus on tasks 1 and 2 herein. For these tasks, the analysis consists of three steps: 1). construct an implicit continuous presentation of the surface; 2). derive a smooth mapping between the reference and the current configurations; and 3). perform stress analysis in the current configuration. All steps are accomplished in the deep learning framework. Steps 1 and 2 use neural network (NN) regression,

and step 3 employs a stress solver developed in physics informed neural network (PINN) [1].

Figure 1. Point clouds at two configurations. Blue: reference. Red: current. Length unit: mm

Step 1: Implicit continuous representation. For computing geometric features such as surface tangent, we need a continuous parameterization of the surface. To this end, the point-cloud is fitted to itself via NN regression. For the example considered here, since the geometry is dome-like, we fit the z-coordinate to a function of (x, y) , resulting in the surface form $(x, y, z(x, y))$. Geometric entities such as surface tangent can be readily computed from this form. Missing points (due to glare, for example) may also be inserted by NN prediction. The step also serves as an intrinsic smoothing process.

Step 2. Deformation mapping. The reference cloud is mapped to the current cloud by NN regression. We seek a function $\Phi: \Omega_0 \mapsto \Omega$ by minimizing the loss function $\sum (x_i - \Phi(X_i))^2$. The outcome is a smooth mapping in the NN function space. The surface deformation gradient can be obtained directly via automatic differentiation.

Step 3. Stress analysis. We leverage the property of static determinacy to find an equilibrium stress field in the current configuration. Following [2], we solve a (linear) elastic membrane problem using a fictitious elasticity model with high Young's modulus. The ensuing stress solution is expected to be a close approximation of the true stress field while the displacement solution is immaterial. The high stiffness ensures that the displacement is small and hence the deviation from the current geometry is negligible. The membrane problem is then solved in the PINN framework, which minimizes the total potential in the NN function space.

RESULTS

Continuum Model. To illustrate the utilities of the continuum parameterization, a surface tangent vector is computed at every point and the vector field is shown in Figure 2. A four-layer NN (one input layer + 2 hidden layers of 20 neurons each + one output layer) was used in this computation. The training took ~30 seconds.

Figure 2. Tangent vector field derived from NN parameterization.

Mapping. Figure 3 shows the predicted current point cloud (red) via NN regression, superposed on the original points (blue). Clearly, the point positions were recovered accurately (the mean deviation is ~0.02 mm). The same NN configuration as in step 1 was used. The computation took ~60 seconds.

Figure 2. Predicted point-cloud (red) superposed on the original cloud (blue)

Strain. Figure 4 illustrates the contour of strain norm. The strain was computed directed from the gradient field made available by NN automatic differentiation.

Stress. The surface tension (stress resultant over the wall thickness) obtained from PINN computation is shown in Figure 5. The NN used in this analysis contained three layers with 100 neurons in the hidden layer. The computation took ~4 minutes to complete. The stress distribution compares well with finite element results reported elsewhere [3].

Figure 4. Contour of the strain norm.

Figure 5. Contour of the norm of surface tension (N/mm)

DISCUSSION

We have demonstrated a deep learning framework for extracting full field strain and stress information from DIC point cloud. The neural network provides a unified paradigm (namely optimization) to address seemingly different tasks, enabling us to solve the problems in a single framework. For some individual tasks (for example stress analysis), the computational efficiency is inferior to finite element method at this moment. However, the entire workflow is much simpler and requires nearly zero user interference. The input to the analysis is a point cloud, and there is no need to introduce solid model or mesh or elaborated finite difference schemes. Continuum representations, which is indispensable for finite element type computations, is furnished naturally by NN. In principle, the techniques presented here are applicable to 3D image-based biomechanical analysis.

INTRODUCTION

Uterine rupture is an inherently biomechanical process associated with high maternal and fetal mortality [1]. A cesarean section (C-section) scar increases the risk of uterine rupture in a subsequent pregnancy due to failure of the tissue in the scar region [1]. It is well known that vertical scars along the sagittal plane in the uterus further increase the risk of uterine rupture. For this reason, vertical incisions are avoided unless needed for emergency situations and low transverse incisions are used instead. An additional complication that may lead to increased risk of uterine rupture is the presence of an isthmocele, or a defect in the uterine wall at the site of a previous C-section scar [2]. As the rate of C-sections continues to increase [1], it is critical to understand the mechanisms leading to uterine rupture with a trial of labor after C-section (TOLAC) during a subsequent pregnancy.

Although some risk factors have been identified, there is currently no reliable model to predict uterine rupture. Furthermore, to the best of our knowledge, no one has previously examined the risk of uterine rupture with C-section scars with a biomechanical approach. Finite element (FE) modeling of the uterus and the scar tissue may present a promising method to further understand and predict uterine ruptures. To work towards this goal, our objective is to first generate a mechanical model of the uterus to examine how the scar positioning (vertical versus transverse), material properties of the scar, and the presence of a defect influence uterine tissue mechanics.

METHODS

A representative model of a uterus and cervix (Fig. 1A) was

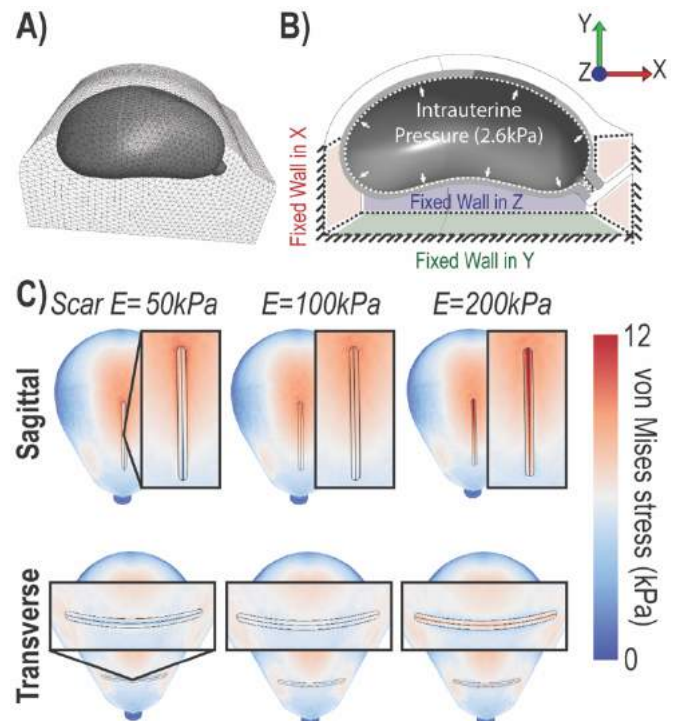

Figure 1: Geometries of the abdomen, uterus, cervix, and C-section scars were A) meshed and B) modeled in FEBio with an applied intrauterine pressure (2.6kPa), while the abdomen walls were fixed in the X, Y, Z directions. C) Heat maps of von Mises stress were generated and showed increased stress with sagittal scars compared to transverse scars with the same material properties.

generated by averaging uterine dimensions acquired from MRI images of five at-term pregnant patients and constructing the geometries in Solidworks [3,4]. Additionally, scar tissue and scar defects were also included in the Solidworks model along with a surrounding abdomen tissue. Dimensions of the scar tissue (e.g., length) and defect size (e.g., width, depth) were based on average measurements found in literature [2,5,6]. The abdomen, uterus, cervix, and scar geometries with and without defects were discretized into elements using Hypermesh (Fig. 1A). Meshed geometries were imported into FEBio and modeled as a nearly incompressible (Poisson's ratio $\nu = 0.48$) neo-Hookean elastic material. The Young's modulus (E) of the abdomen and the uterus were set to 100 kPa, while the midline of the scar region was varied (50 kPa, 100 kPa, 200 kPa). The Young's modulus of the remaining scar tissue was calculated by a linear interpolation between the midline value and the surrounding uterine tissue. The boundary conditions and a physiological intrauterine pressure (2.6 kPa) [7] were applied as shown in Fig. 1B. A finite element analysis was performed using FEBio to generate heat maps of von Mises stress.

RESULTS

When varying the stiffness of the midline of the scar region, the von Mises stress increased in the scar region with increasing scar stiffness, as expected (Fig. 1C). The magnitude of the von Mises stress was greater for all sagittal scars compared to the respective transverse scar with the same Young's modulus (Fig. 1C). Models in which the scar properties matched the surrounding tissue properties validated the boundary conditions and demonstrated the expected null-response. Literature was reviewed to determine the average dimensions and geometry of patient scar defects and a defect was incorporated into the model of the low transverse scar (Fig. 2). Preliminary results show elevated stress in the defect region of the scar compared to the low transverse scar without the defect.

DISCUSSION

The modeled stress distributions of the sagittal and transverse C-section scars were consistent with clinical observations, since the von Mises stress was higher on sagittal scars compared to transverse scars and it is well known that there is an increased risk of uterine rupture in sagittal scars compared to low transverse scars. Incorporating a defect in the model will allow us to further understand how this complication may lead to increased stress in the scar region and tissue failure.

While the results are promising, this simplified study includes several limitations. The model assumes all tissues can be represented as a neo-Hookean material and other materials, such as a fibrous material, may be more representative of the uterine and scar tissue. Additionally, we chose a Young's modulus range of 50-200 kPa, but in the future more accurate measurements of material properties of uterine tissue could be incorporated into the model. This model also did not account for spatial variation of material properties in the uterine tissue. While there was a spatial variation of material properties of the scar tissue, we assumed that the greatest change in the elastic

Figure 2: A representative isthmocele, or scar defect, geometry was determined from measurements reported in literature [2] and was included in the low-transverse scar model to understand how a scar defect alters uterine mechanics.

modulus was at the midline of the scar tissue, which may not accurately represent the spatial variation of material properties in C-sections scars. Therefore, future work is needed to characterize the material properties and spatial variation of material properties of uterine tissue and C-section scars. Lastly, the modelled geometry only represents the average dimensions of five patients. In the future, the geometry of the uterus could be varied within the bounds of patient dimensions to understand the role of uterine geometry.

Overall, the results motivate a future parametric study which not only varies the material properties of the scar, but also the geometry of the uterus (e.g., thickness of the uterine wall) and the geometry of the defect (e.g., depth). By understanding what parameters influence the strain and stress distributions in the uterine tissue, we could identify potential risk factors for uterine rupture to be considered for patient specific planning for TOLAC. In summary, the agreement of the preliminary model results with clinical observations suggests mechanical modeling of the uterus with C-section scars presents a promising method to evaluate the risk of uterine rupture.

INTRODUCTION

The presence of biomechanical crosstalk between different components of the tumor microenvironment (TME) is known; however, there is a gap in understanding these mechanobiological interactions and their role in regulating tumor progression [1]. Previous work from our laboratory has shown that endothelial cells can be mechanically stimulated to promote angiogenesis in a 3D *in vitro* model via interactions with cancer-associated fibroblasts (CAFs) [2, 3]. CAFs are stromal cells that inherently have pro-tumorigenic and pro-angiogenic properties, allowing tumor growth and subsequent progression [4]. We have shown that CAFs have higher mechanical activity than patient-matched normal breast fibroblasts (NBFs); in other words, the CAFs generate larger microstrains that induce distortions to the matrix of the TME compared to normal fibroblasts. The current project focuses on investigating the biomechanical behaviors of CAFs as regulators of cell-cell crosstalk TME, specifically in the growing vascular network.

Previous work has identified cadherins as mechanosensors that are responsible for communication between cell types. For example, competition between neural cadherin (N-Cad) and vascular endothelial cadherin (VE-Cad) is essential in regulating tumor vasculature stability [5]. Moreover, heterotypic cadherin bonding between endothelial cells and smooth muscle cells has been linked to controlling vascular growth. As smooth muscle cells also demonstrate high mechanical activity or contractility levels, we hypothesize that heterotypic N-Cad/VE-Cad bonds may form between CAFs and endothelial cells to control blood vessel growth or stability in the TME. To investigate this, our studies focused on characterizing changes in cadherin expression levels for CAFs, NBFs, and a human microvascular endothelial cell line (ATCC, HMEC-1, CRL-3243). We hypothesize that the mechanical behaviors of stromal cells directly impact the expression of cadherins.

METHODS

Human microvascular endothelial cells (HMECs), cancer-associated fibroblasts (CAFs), and normal breast fibroblasts (NBFs) were tested for protein levels of VE-Cad and N-Cad using standard Western blot procedures. Briefly, the sample lysates were collected with HALT Protease and Phosphatase Inhibitor Cocktail (Thermo Scientific, no. 78441) in RIPA buffer. Samples were run in 8% SDS-PAGE resolving gels before transfer to PDVF membranes for blocking with 5% milk in TBST. Membranes were incubated overnight at 4°C in primary antibodies for N-Cad (CST, 13116, 1/1000) or VE-Cad (Abcam, ab33168, 1/1000) diluted in TBST. Membranes were next incubated with secondary antibodies for detection with ECL (Thermo Scientific, no. 32106). The blots were imaged in a LI-COR Odyssey XF Imaging System. FIJI software was used to calculate the intensity of bands for specific cadherins relative to the intensity of β -Actin.

We utilized a previously developed *in vitro* 3D microtissue model to investigate crosstalk between the fibroblasts and HMECs [2]. We cultured HMECs, CAFs + HMECs, or NBFs + HMECs in 3D fibrin gels (10mg/mL) at a 1:1 ratio for seven days before fixing and staining the cells for analysis of N-Cad (Abcam, ab19348, 1/500) or VE-Cad (Abcam, ab33168, 1/500). Both CAFs and NBFs are tagged with GFP; DAPI was used as a counterstain to determine total cell content in each sample. An epifluorescence inverted microscope (Olympus, IX-83) was used to image the samples and provide a 100 μ m z-stack; a maximum intensity z projection was generated for each sample. FIJI software was used to calculate the average size of positive staining for specific cadherins relative to the total cell area, as shown by DAPI. All samples were run in triplicate, with results reported as average plus SEM.

RESULTS

In 2D single cultures, HMECs exhibited the highest VE-Cad expression (Figure 1a), while the NBFs exhibited the highest N-Cad ex-

pression (Figure 1b). Significantly lower levels of VE-Cad were observed in both fibroblast lines compared to HMECs. In 3D co-cultures, the samples with CAFs + HMECs displayed the highest N-Cad and VE-Cad levels visually (Figure 2a). Quantifying these images, results demonstrated that there was significantly less N-Cad and VE-Cad in HMECs alone compared to the CAFs + HMECs and NBF + HMECs samples. In addition, it was observed that the CAFs + HMECs co-culture sample had significantly higher levels of N-Cad than the NBFs + HMECs co-culture (Figure 2b).

Figure 1: Analysis of Cadherin Expression in 2D. (a.) Representative Western blot images of N-Cad and VE-Cad expression in a single culture of HMECs, CAFs, or NBFs. All samples run in triplicate. (b.) Quantification of cadherins from the Western blot images, shown as expression relative to β-actin, a loading control. Averages + SEM. N=3; * p < 0.05 vs. HMEC, ^ p < 0.05 vs. NBF.

DISCUSSION

Our results indicate that the endothelial cells (HMECs) show undetectable levels of N-Cad in 2D studies but may express N-Cad when cultured in 3D microtissues. Studies show that once the endothelial monolayer reaches maturation at confluency, the levels of N Cadherin decrease in a 2D culture [6]. The cadherin interactions in a 2D monoculture are homotypic in nature. Our results indicate that the fibroblasts express VE-Cad in 2D; while unexpected, this could be due to the origin of the CAFs and NBFs from a breast cancer patient. Recent studies have highlighted that while it was previously thought only endothelial cells express VE-Cad, vascular mimicry and aggressive tumors demonstrate aberrant VE-Cad expression [7]. We next moved to 3D microtissue models and co-cultures to better understand the cadherin interactions between the different cell types. The addition of fibroblasts to the microtissue models increased the observed levels of both N-Cad and VE-Cad. The CAFs + HMEC samples demonstrated the highest levels of both cadherin types. This could be partially due to the activated, myofibroblast-like phenotype of CAFs and that it might lead to heterotypic cadherin interactions.

Future studies will utilize shRNA to genetically inhibit mechanotransduction pathways in the CAFs before analyzing N-Cad and VE-Cad expression levels in both single and co-culture. Additionally, we will utilize a 3D microtissue model design for studies of vascular systems to investigate the expression patterns of N-Cad and VE-Cad in HMECs and fibroblasts to determine if heterotypic cadherin bonds are forming. Results from our studies will elucidate how mechanobiological crosstalk occurs between cell types to regulate the vasculature and TME.

Figure 2: Expression of Cadherins in 3D Microtissue Models. (a.) Representative images from single and co-cultures of N-Cad and VE-Cad in a 3D microtissue model. Scale bar = 200μm. (b.) Quantification of cadherin expression in stained, co-culture 3D microtissue model. Averages + SEM. N=3; *p < 0.05 vs. CAF + HMEC, ^p < 0.05 vs. NBF + HMEC.

THE MECHANICS AND MORPHODYNAMICS OF 3D MIGRATING CANCER CELLS

Bo Sun (1)

(1) Department of Physics, Oregon State University, Corvallis, OR, USA

INTRODUCTION

Cell shape is linked to cell function. The significance of cell morphodynamics, namely the temporal fluctuation of cell shape, is much less understood.

METHODS

Here we study the morphodynamics of MDA-MB-231 cells in type I collagen extracellular matrix (ECM). We systematically vary ECM physical properties by tuning collagen concentrations, alignment, and gelation temperatures. We also compare individual and collective invasion of the cells.

RESULTS

We find that morphodynamics of 3D migrating cells are externally controlled by ECM mechanics and internally modulated by Rho/ROCK-signaling. We employ machine learning to classify cell shape into four different morphological phenotypes, each corresponding to a distinct migration mode. As a result, we map cell morphodynamics at mesoscale into the temporal evolution of morphological phenotypes. We characterize the mesoscale dynamics including occurrence probability, dwell time and transition matrix at varying ECM conditions, which demonstrate the complex phenotype landscape and optimal pathways for phenotype transitions. Morphological phenotype transitions also facilitate cancer cells to navigate non-uniform ECM such as traversing the interface between matrices of two distinct microstructures.

DISCUSSION

we demonstrate that 3D migrating cancer cells exhibit rich morphodynamics that is controlled by ECM mechanics, Rho/ROCK-signaling, and regulate cell motility. Our results pave the way to the functional understanding and mechanical programming of cell morphodynamics as a route to predict and control 3D cell motility.

A COMPUTATIONAL MODEL FOR THE ROUGHNESS OF CORONARY AND CEREBRAL ARTERY STENOSIS AND TREATMENT FOR DIABETES MELLITUS DISEASE

S. Piskin (1)

INTRODUCTION

Cardiovascular diseases (CVD) are still major threats to human health since they are the leading cause of death in western countries. Atherosclerosis occurs generally in carotid and coronary arteries and is a type of CVD related to hypertension, diabetes, high levels of cholesterol, smoking, oxidative stress, and age [1]. Atherosclerosis in coronary artery disease (CAD) or carotid artery disease is treated by implementing a stent through interventional cardiology or by deploying a bypass graft through open-heart surgery. Diabetes mellitus (DM) is one of the most common comorbid conditions in patients with coronary artery disease, which is important in determining the severity of the disease, treatment strategy, and the prognosis of patients [2].

Computational hemodynamics (CH) is an in-silico methodology to plan the coronary artery bypass grafting (CABG) or predict the short term or long-term effects of the treatment. Wall shear stress (WSS) is a prominent biomarker that can be predicted by CH and is related to the patency of the graft or the stenosed artery after the revascularization operation. But it is still controversial if high, low, oscillating or any other derivative of WSS causes restenosis of the artery or closure of the CABG. There are many ongoing clinical and computational studies to find out the possible correlations. The computational hemodynamics of CABG for DM patients is not a well-studied field even though the high number of the patient cohort. Another important factor on the hemodynamics is the roughness of the surface of the artery [9] or the graft. In the healthy left anterior descending (LAD) coronary artery, surface roughness has recently been characterized [3-4]. But, the effect of roughness on the hemodynamics has not been well characterized. It may cause a substantial change in the WSS distribution. Here, we analyze and compare the DM patients' flow dynamics to healthy control using a computational model. We also aim to find out the effects of wall roughness on the WSS for the DM patient model.

METHODS

Two different in silico models have been generated and simulated using computational fluid dynamics (CFD). For simplicity and isolate the geometrical contribution into the hemodynamics, idealized coronary artery models have been designed. Figure 1 shows the geometry of the coronary artery with mild stenosis. The roughness of the wall is assigned zero (0) for the smooth artery surface and 0.001m (height) for the rough wall.

Three-dimensional (3D) continuity and steady-state Navier-Stokes (NS) equations (Equations 1 and 2, respectively) have been solved using commercially available computational fluid flow solver ANSYS Fluent (ANSYS Inc, PA, USA). The inlet boundary condition has been assigned a velocity profile and the outlet boundary has been assigned a pressure outlet. Artery geometry has a length of 30mm and a diameter of 5mm based on the typical size of the artery [5]. The wall roughness height has been assigned as $0.5 \cdot 10^{-4}$ mm and the roughness coefficient has been set as 0.5 based on the assumption of uniform roughness.

$$\nabla \cdot \mathbf{u} = 0 \quad (1)$$

$$\rho \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla p + \nabla \cdot [\mu(\nabla \mathbf{u} + (\nabla \mathbf{u})^T)] \quad (2)$$

where \mathbf{u} is the velocity vector, p the pressure, t the time, ρ and μ the density and the dynamic viscosity of the blood, respectively. Besides NS equations, the standard $k - \epsilon$ model was included to simulate the turbulence. The transport equations for the $k - \epsilon$ model are given in Equations 3 and 4.

$$\frac{\partial}{\partial t}(\rho k) + \frac{\partial}{\partial x_i}(\rho k u_i) = \frac{\partial}{\partial x_j} \left[\left(\mu + \frac{\mu_t}{\sigma_k} \right) \frac{\partial k}{\partial x_j} \right] + G_k - \rho \epsilon \quad (3)$$

$$\frac{\partial}{\partial t}(\rho\epsilon) + \frac{\partial}{\partial x_i}(\rho\epsilon u_i) = \frac{\partial}{\partial x_j} \left[\left(\mu + \frac{\mu_t}{\sigma_\epsilon} \right) \frac{\partial \epsilon}{\partial x_j} \right] + C_{1\epsilon} \frac{\epsilon}{k} G_k - C_{2\epsilon} \rho \frac{\epsilon^2}{k} \quad (4)$$

where x_i and x_j the spatial coordinates, k the turbulence kinetic energy, ϵ the rate of dissipation of turbulence kinetic energy, μ_t the turbulence viscosity, $\sigma_k (=1.0)$ and $\sigma_\epsilon (=1.3)$ the turbulent Prandtl numbers for k and ϵ , respectively, G_k the generation of turbulence kinetic energy due to the mean velocity gradients, and $C_{1\epsilon} (=1.44)$ and $C_{2\epsilon} (=1.92)$ are constants. μ_t and G_k are computed by Equations 5 and 6, respectively.

$$\mu_t = \rho C_\mu \frac{k^2}{\epsilon} \quad (5)$$

where $C_\mu (=0.09)$ is a constant, and

$$G_k = \mu_t S^2 \quad (6)$$

where S is the modulus of the mean rate-of-strain tensor, defined as $S = \sqrt{2S_{ij}S_{ij}}$. Viscosities are taken $3.5 \cdot 10^{-3}$ Pa·s and $6.8 \cdot 10^{-3}$ Pa·s [6-7] for healthy subject and diabetes mellitus patients, respectively. Densities are assigned 1060 kg/m^3 for both groups.

Figure 1: (a) Coronary artery model geometry with representative wall roughness and inlet and outlet boundary conditions, (b) Three-dimensional mesh with boundary layer at the proximity of the wall (c) Zoomed in view of the mesh around the stenosis zone.

CFD simulations have been run until the convergence of u_x , u_y , u_z , p , k and ϵ variables to an iteration error of 10^{-5} .

RESULTS

WSS distribution of the cases has been shown in Figure 2. WSS is higher at the proximity of the wall compared to the center of the artery for all cases: healthy control, DM patient and rough and smooth wall. Pressure distribution is verifies the physiology of linear pressure drop (not shown in the figure).

Table 1 presents the spatially averaged WSS (SAWSS) for all cases: healthy control, DM patient and rough and smooth wall. The wall roughness has been studied parametrically with respect to the roughness height and the corresponding SAWSS values have been presented in the corresponding table. Wall roughness value for the nominal case has been taken from the literature [3-4]. The other two heights represent hypothetical artery sickness, stent or vascular graft surfaces. They were simulated to analyze the possible treatment or medical device designs.

Figure 2: Wall shear stress distribution for the healthy case around the stenosis zone.

Table 1: Spatially averaged wall shear stress (SAWSS) values for all cases.

SAWSS	Healthy (Pa)	Diabetes Mellitus (Pa)
Smooth wall	107	175
Rough wall ($=3 \cdot 10^{-6} \text{ m}$) [3]	107	175
Rough wall ($=3 \cdot 10^{-5} \text{ m}$)	108	176
Rough wall ($=3 \cdot 10^{-4} \text{ m}$)	92	157

DISCUSSION

Diabetes mellitus patients may have substantially different blood viscosity levels compared to a healthy cohort. When they have the comorbidity with coronary artery or carotid artery stenosis, extra care is necessary for their cardiovascular disease treatments. Here, we have investigated the hemodynamics characterization of lumen or medical device roughness using an in-silico model for these patients. Preliminary results of our study show that the natural wall roughness does not cause any SAWSS change for neither DM patients nor healthy subjects (Table 1). But when the wall roughness is around $3 \cdot 10^{-4} \text{ m}$, the SAWSS decreases moderately, around 15% for healthy cases and 10% for DM patients. After deployment stents can have and cause roughness [8]. Actually, these roughness values can be possible by designing novel stents or bypass grafts. Decreasing the WSS values around the stenosis region could help to improve the outcome of interventions or surgical operations. The study is at its early stage with limited simulations. The simulations are planned to be improved using real coronary or carotid artery geometries and real surgery scenarios. But the results suggest that the WSS can be changed using surface roughness for DM patients.

INTRODUCTION

The lung is a mechanically active and highly dynamic organ, being exposed to cyclic deformations from a combination of respiration and pulsatile blood flow. The addition of the air-liquid interface makes it one of the most complex organs to probe in real-time at the subcellular level. Being continuously exposed to mechanical, biological, and immunological stresses, the lung is the site of many pathologies such as primary and metastatic cancers, pneumonia, fibrosis, and obstructive diseases. Understanding the complex and dynamic function of the lung in health and disease requires characterization of structure and function at high spatial resolution to capture molecular and cellular dynamics, and at high temporal resolutions to resolve respiration-circulation dynamics such as vascular transport and cellular trafficking.

Current imaging modalities such as MRI/CT lack the spatiotemporal resolution needed to resolve dynamic events such as alveolar deformation, capillary flow, and cellular activities. Histological analysis is commonly used to visualize a snapshot of the fixed lung tissue at subcellular resolution, however, dynamic biological and physical information relevant to respiration-circulation and cellular motility are lost. Recent intravital microscopy approaches are capable of imaging microcirculation dynamics in a limited region of the lung surface at high spatial resolution through a glass window placed over an opening in the ribcage. However, these methods do not allow normal respiratory function in the imaged region as the lung is immobilized against the glass using glue or suction thereby interfering with respiration at the region of interest. Furthermore, being limited to a small region of imaging, these approaches do not capture the lung heterogeneities (e.g., apex vs. base differences) and cannot track dynamic events outside the window of imaging.

METHODS

We developed and validated a transparent ribcage, termed “crystal ribcage” to visualize and mechanistically probe the real-time dynamics

of a functioning lung at high optical resolution. Our platform is composed of a ventilated and perfused *ex vivo* mouse lung housed in a transparent crystal ribcage (Fig. 1). The crystal ribcage is a biocompatible shell with a shape that recapitulates the native mouse ribcage to provide near-*in vivo* boundary conditions for the lung to slide against during ventilation and perfusion. We designed the crystal ribcage based on μ CT scans of the mouse lung, which was specific to the age and strain of interest. The physics, biology and immunity of the *ex vivo* ventilated, perfused, and viable whole lung is preserved at near *in vivo* physiological conditions.

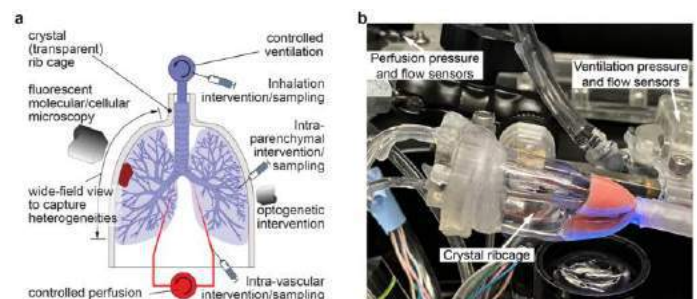

Figure 1 | Development and validation of a novel crystal ribcage and its integration into imaging platform.

RESULTS

Multiscale probing of the lung in health and disease: Utilizing the spatiotemporal resolution that this platform offers over nearly the entire surface of the lung, we, for the first time, mapped the spatial heterogeneities of alveolar deformations in healthy lungs, and quantified the alteration in alveolar deformation in multiple pulmonary pathologies such as cancer, pneumonia, and fibrosis. The large field of view provided by the crystal ribcage, combined with a novel

computational platform, allowed us to probe the lung micro-physiology in response to respiratory and circulatory pressures at multiple scales, from the whole lung down to the alveolar, capillary, and single cell scale.

We utilized LungEx to probe alveolar deformation and heterogeneities in health and key pulmonary diseases including pneumonia, fibrosis, and lung metastases with different growth patterns. We, for the first time, imaged the functional mouse lung at multiple scales starting at the whole lung level (Fig. 2a, f, k, p, u) and the lobe level (Fig. 2b, g, l, q, v), and down to the alveolar level (Fig. 2c, h, m, r, w). At all these scales, the images were acquired over a physiological range of alveolar pressures of 3, 7, 12, and 18 cmH₂O.

Next, we probed how the alveoli are remodeled by early-stage metastatic tumor. We observed much denser tumors in the case of the MMTV tumors reflected in the organ (Fig. 2f), lobe (Fig. 2g), and alveolus levels (Fig. 2h). Interestingly, in nodular growth pattern (Fig. 2i), we observed much smaller strain values (i.e., very stiff) intratumorally compared to the infiltrative tumor with similar diameters (Fig. 2n). Intriguingly, due to the “pushing” effect of the nodular tumor, alveoli remained distended even at low alveolar pressures (Fig. 2j), while the alveoli in the infiltrative tumors change diameters with pressure similar to those far from the tumor (Fig. 2o).

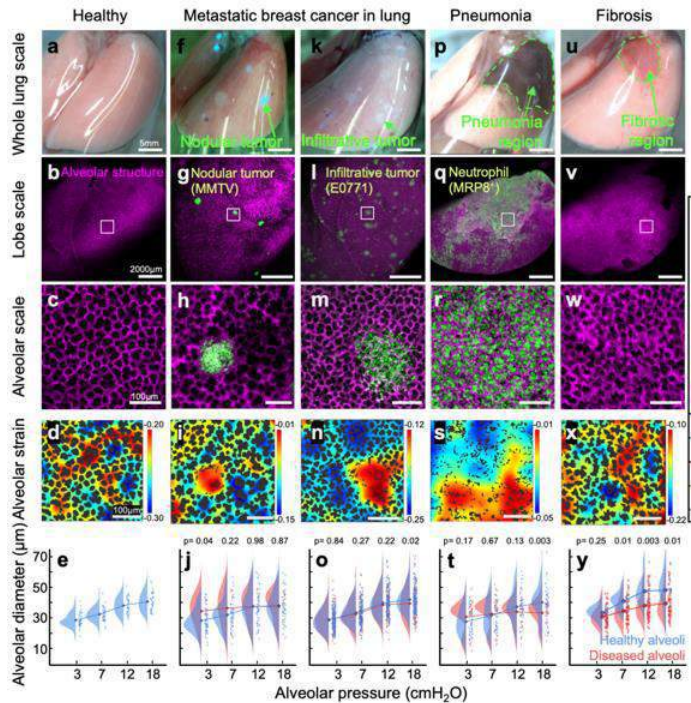

Figure 2. The crystal ribcage allows multi-scale analysis of lung micromechanics in health and disease.

Next, we probed the remodeling of single alveoli by pneumonia. We used a left lobar model of bacterial pneumonia (*Streptococcus pneumoniae* serotype 3, Sp3) induced in MRP8-mTmG reporter mice, where the MRP8+ cells (neutrophil dominant) express green fluorescent protein (GFP) in the cell membrane. The whole-lung level imaging through the crystal ribcage shows the hepatized left apex (Fig. 2p), densely packed with MRP8+ neutrophils at both the lobe (Fig. 2q) and alveolar scales (Fig. 2r). Surprisingly, the alveoli that were affected by pneumonia showed equal or even greater stiffening compared to nodular tumors (Fig. 2s,i). We also observed more heterogeneities in alveolar diameter, not only in the infected areas, but in the alveoli adjacent to them (Fig. 2t). Finally, we applied the bleomycin model of lung fibrosis

on Col1a1-Cre-mTmG reporter mice. Lung cells of this transgenic mouse are labeled tdTomato and those with an active Col1a1 promoter become GFP-labeled upon tamoxifen administration. By taking advantage of the whole lung fluorescence, we identified dense fibrotic patches in the alveolar structure imaged using tdTomato and fibroblast aggregates using GFP (col1a1-mTmG).

Figure 3. Mechanosensitivity of neutrophils to hydrostatic pressure.

Mechano-immunity of the lung: Neutrophils traffic into the lung in response to injury and infection. While neutrophil responsiveness to shear stresses and cyclic pressure has previously been reported, we show that migration of neutrophils in the lung is highly dependent on hydrostatic vascular pressure, in the absence of perfusate flow and shear stresses (Fig. 3). By real-time tracking of neutrophils at vascular pressure of 0 and 15 cmH₂O under no flow conditions and a constant alveolar pressure of 7 cmH₂O, we found that neutrophils were substantially more migratory and traveled a longer distance over 5 minutes at higher perfusate pressures (Fig. 5).

DISCUSSION

We have presented the development, validation, and several key applications of the LungEx platform for multiscale imaging of the whole, functional mouse lung in real-time. Whereas previous methods (i) do not resolve micro-scale features (such as in MRI, CT), (ii) provide no temporal resolution, lose the 3D architecture and functional air-liquid interface (such as in histology), or (iii) lack respiratory motion within a small field of view (such as in intravital microscopy), the crystal ribcage supports multiscale and high spatiotemporal resolution imaging of the whole organ with near-*in vivo* boundary conditions to capture dynamic functions of the lung simultaneously over almost the entire surface of the lung. We have applied LungEx to image a wide range of lung dynamic (dys)functions at multiple spatial scales including alveolar deformation and elasticity, capillary distensibility, cellular deformation, trafficking and migration of immune cells, and vascular transport. We demonstrated the capabilities of LungEx in health and pathologies such as nodular and infiltrative lung metastases, pneumonia, acute lung injury, and pulmonary fibrosis. Furthermore, this transformative platform offers a wide range of applications to mechanistically probe pathophysiologies relevant to the lung parenchyma such as in emphysema, adenocarcinoma, ventilation-induced lung injury, and dysfunction of blood and lymphatic vessels in aging and lung transplantation.

INFLUENCE OF MULTIDIRECTIONAL LOADING ON MENISCUS WEAR BEHAVIOR

Kate J. Benfield (1), Katherine J. Fors (2), Trevor J. Lujan (2)

(1) Biomedical Engineering Doctoral Program, Boise State University, Boise, ID, USA
(2) Department of Mechanical & Biomedical Engineering, Boise State University, Boise, ID, USA

INTRODUCTION

The menisci are fibrocartilaginous tissues that facilitate smooth articulations and attenuate 45-75% of loads across the knee joint.¹ Through overuse and mechanical wear, the menisci become prone to degeneration – a retrogressive breakdown of the fibrous network.² This degeneration affects nearly 20% of people over 50 years of age, and over 55% of people over 70 years of age.² As degeneration progresses, microstructural changes to the fiber network occur, resulting in pain, joint instability, restricted physical activity, and increased likelihood of developing knee osteoarthritis.³ Given the high prevalence of meniscal degeneration, the characterization of meniscal wear behavior is vital to understanding the pathomechanics of joint degeneration, yet no study has characterized the mechanical wear behavior of meniscus tissue.

Mechanical wear within the knee joint is a system response that is dependent on the contact conditions of interfacing surfaces. Numerous in-vitro wear studies of artificial joints have shown that unidirectional motion promotes fiber orientation and hardening along the principal fiber direction, while multidirectional motion creates an environment of continually changing shear (cross-shear), leading to accelerated wear debris.⁴⁻⁶ Similar to polyethylene components in artificial joints, meniscus tissue has a complex and highly organized fibrous network and experiences multidirectional motions during daily activities, and could therefore be susceptible to accelerated wear due to cross-shearing. The objective of this study was to characterize the wear behavior of bovine meniscus subjected to repeated multidirectional and unidirectional contact with bovine articular cartilage.

METHODS

Specimen Preparation: Cartilage plugs (n = 6) were extracted using a drill-press and custom corer from the femoral surface of one skeletally mature bovine femur. Each cartilage pin was 4 mm in diameter and composed of the cartilage layer and approximately 8 mm

of subchondral bone used for mounting (**Fig. 1A**). The medial meniscus from the same bovine specimen was harvested and packed in cellu-clay. Following our previously published methods,⁷ the meniscus was cut into 2 mm thick layers to serve as the “plate”. The most superficial layers of these strips were used for six experiments: unidirectional loading (n = 3) and multidirectional loading (n = 3). Custom-made tooling was utilized to cut each meniscal strip (25 mm x 10 mm) (**Fig. 1B**), and to flatten the natural curvature of the meniscus to allow for a uniform plate surface. Specimens were wrapped in gauze soaked in 0.9% saline solution and frozen. On the day of mechanical wear testing, each sample was thawed for 1 hour (21°C).

Figure 1: Pin-on-plate system for A) femoral cartilage pin and B) flat bovine meniscus plate. C) Two-axes of motion enable multidirectional loading (white arrows) to create cross-shear between the pin and plate in the tissue chamber.

Mechanical Wear Testing: A custom built pin-on-plate device applied unidirectional and multidirectional loading conditions by simultaneously spinning and translating the cartilage pin relative to the meniscus plate (**Fig. 1C**). For each of the six experiments, the meniscus plate was first clamped into the test chamber and immersed in 0.9% saline solution while the cartilage pin was rigidly fixed to the test apparatus via set screws. To ensure proper loading along the principal fiber direction, the meniscus plate was aligned so that the longitudinal fibers were parallel to the x-axis. Using weights, a 3.5 N vertical load was applied between the cartilage and meniscus corresponding to approximately 67% of physiological stresses during walking.⁸ For the unidirectional loading condition, the meniscus specimen oscillated linearly at a rate of 4 mm/s along the longitudinal fiber orientation (4 mm stroke). For the multidirectional tests, this exact protocol was used, except that the cartilage pin was also spinning at a rate of ~0.5 Hz, thus creating a perpendicular component to the translational motion (cross-shear) (**Fig. 1C**). For each specimen, the thickness of the meniscal tissue was measured for 10,000 cycles using a linear encoder (accuracy = 1 μm). Linear wear was recorded as the displacement of the meniscal tissue over the duration of testing. Following testing, each specimen was imaged using a light microscope (Leica DM750) to visualize the worn meniscus surface. The effect of loading condition on linear wear was assessed using an independent t-test in SPSS ($p < 0.05$).

RESULTS

The multidirectional loading condition showed greater meniscal tissue displacement within the wear region-of-interest than unidirectional loading (**Fig. 2A-B**). Steady-state wear was achieved for multidirectional ($R^2 = 0.94$) and unidirectional ($R^2 = 0.92$) loading after an initial 1000 cycles (run-in). The menisci had average steady-state wear rates of $0.016 \mu\text{m}/10^3\text{-cycles}$ and $0.012 \mu\text{m}/10^3\text{-cycles}$ for multidirectional and unidirectional loading, respectively (**Fig. 2C**). Overall, the application of multidirectional loading increased the linear wear of meniscus by 30% relative to unidirectional loading (**Fig. 2C**), a significant increase ($p = 0.013$).

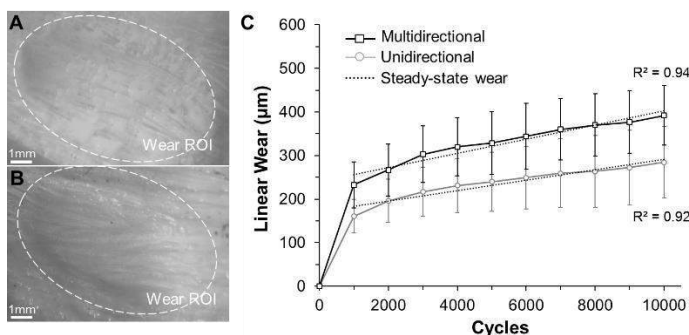

Figure 2: Wear behavior of bovine meniscus subjected to A) unidirectional and B) multidirectional contact conditions. C) Linear wear is greater for multidirectional motion relative to unidirectional x-axis motion ($p = 0.013$).

DISCUSSION

Given the high prevalence of meniscal degeneration, characterizing meniscal wear behavior is vital to understanding disease pathomechanics. While prior studies have evaluated the coefficient of friction in meniscus tissues ($0.09 - 0.25$)⁹, and the mass wear rate of bovine knee articular cartilage ($52 \pm 0.24 \mu\text{g}/\text{m}^3$)¹⁰, no study to our knowledge has quantified the wear behavior of meniscal tissue. This study characterized bovine meniscus wear behavior under varying contact conditions using a pin-on-plate test system. To our knowledge,

this is the first study to evaluate the influence of multidirectional loading on mechanical wear within meniscus tissue, or any soft tissue.

Our results show that the application of multidirectional loading significantly increases the steady-state wear rate of bovine meniscus tissue by nearly 30% (**Fig. 2C**). These results follow a similar trend to those observed during wear testing of polyethylene components in artificial joints. Marrs et al., determined that multidirectional motion led to greater wear versus unidirectional motion in polyethylene,¹¹ however their wear rates were nearly 3x greater than the wear rates observed in the present study. Additionally, our results can be compared to a prior cartilage-on-cartilage study. Northwood et al., applied 30,000 cycles of unidirectional and multidirectional motion between a bovine articular cartilage pin and cartilage plate and found a 60% increase in surface roughness for the multidirectional case.¹² This is consistent to our results as increased surface roughness may potentially lead to more material wear debris being removed from the surface. Furthermore, we observed that the worn meniscal surfaces of the unidirectional cases appeared to have more pronounced fiber alignment and hardening within the wear region of interest (**Fig. 2A**) than the reoriented fibers of the multidirectional case (**Fig. 2B**). This indicates that the cross-shear phenomena, observed in polyethylene⁵, may also exist in meniscal tissue. Consequently, daily activities associated with cross-shear may be detrimental to the structural integrity of meniscus tissue, thus potentially leading to greater risk of degeneration. For example, stair climbing creates multidirectional joint motions, and is associated with nearly two times greater risk of meniscal degeneration.¹³

A principal limitation of this study is that the measured wear may be caused by material wear, creep, or a combination of the two. This challenge can be overcome through the use of a load-soak control (axial loading only) to determine the linear displacement due to creep and swelling.¹⁴ Additionally, plate specimens were independent of meniscus region (anterior, central, posterior) which could have influenced mechanical wear behavior. Future experiments are planned to apply varying loading magnitudes to 100,000 cycles within different meniscus regions to better understand the regional wear behavior under multidirectional and unidirectional contact conditions.

In summary, we have shown that meniscal wear is dependent on contact motion, which suggests that activities associated with cross-shearing could increase the risk of tissue degeneration. This study provides a basis for measuring meniscus wear and important joint system responses that are essential to developing mechanistic theories that describe and predict the pathomechanics of meniscus degeneration.

DEVELOPMENT AND VALIDATION OF A SMART SCREWDRIVER (SSD) FOR SPINE SURGERY

INTRODUCTION

Spinal fusion is prescribed to treat spinal deformity and instability resulting from a variety of indications, such as spine fracture, degenerative disks, severe scoliosis, or stenosis [1]. As technologies in spinal surgeries have advanced, so have recommendations for spinal fusion, resulting in an increased frequency of fusion surgery [1],[2].

A critical demand for all fusions is implant fixation, which relies primarily on anchors that connect to bone. Trabecular bone screws, such as pedicle screws, are the most common anchors used in fusion surgeries. Achieving optimal screw fixation is crucial, especially in osteopenic or osteoporotic patients. Failure of screw fixation such as screw migration, loosening, or pullout can lead to severe complications such as fusion non-union, unstable spine segments, or even neurological injury that increases the likelihood of revision surgery. According to data from 2002 to 2009, mechanical complications of implanted devices was the most common primary diagnosis for all revision fusions [3].

Though many factors affect screw fixation strength, peak insertion torque is known to be a key determinant [4]. Over-torquing can cause the screw to strip in trabecular bone, while low insertion torque implies a missed opportunity for greater fixation strength and higher risk of complications following surgery. Currently, surgeons rely on intuition and feel to determine when a screw has been appropriately tightened, but optimal torque is a quantitative property that is not reliably discerned by the surgeon's hand and varies based on bone quality, trajectory, and screw design. A comprehensive study found surgeons stripped screws more frequently than biomechanical researchers with no surgical experience (48% vs 18%), and for researchers and surgeons with high stripping rates, an augmented screwdriver that indicated when optimal torque had been reached reduced stripping rates [5].

We have characterized three phases of cancellous bone screw insertion (**Fig. 1**). The initial goal of this project is to develop a device to conduct extensive experimentation studying the correlation between torque value in phase 1, torque slope in phase 2, and percentage of total

torque in phase 3 with varied bone quality and screw size using both foam and cadaveric bones. This data will be used to develop an algorithm which can predict peak torque based on initial phase 3 torque, therefore determining optimal torque to achieve strong screw insertion.

Figure 1: Characterization of screw insertion mechanics and relation between insertion torque and screw strength.

Because of the inconsistency in successful screw fixation, and evidence suggesting that real-time quantitative indicators of optimal fixation improve surgeon performance, there is a need for a tool that can be used in a surgical setting to assist with determination of optimal fixation. Therefore, the ultimate goal of this work is to develop an intelligent, instrumented screwdriver which measures insertional torque and can provide algorithmic predictions of bone strength and implant failure.

METHODS

Device Design

A custom benchtop device was designed and constructed to insert screws into foam bones or vertebral bodies with controlled parameters, while collecting data characterizing the insertion torque profile (**Fig. 2**).

Figure 2: Smart Screwdriver Device (SSD).

The device consists of an electropneumatic regulator connected to a low friction pressure cylinder, which provides a constant, axial force when the device is in operation. A load cell (Transducer Techniques, Model: MLP-100, 100lbs) connected to the pressure cylinder measures and reports force. The end-effector of the device is rotated using a motor, and a torque transducer (Interface Force Measurement Solutions, Model: T2-10-A3A, 10Nm) measures insertion torque as the screw is driven into samples. A custom LabVIEW program allows the user to specify insertion distance, rotation speed, and axial force.

Data Collection

Data was collected on foam bones intended to mimic both osteoporotic and healthy bone (Synbone PCF 12.5 and PCF 20 Cell, respectively) using a 40mm pedicle screw. Screws were inserted with an axial force of 15N at a speed of 5rpm until the surrounding foam bone stripped, or the head of the screw was sunk into the foam bone. Insertion parameters were selected based on values measured from an instrumented screwdriver and load cell as a spine surgeon drove screws into similar foam blocks.

Foam bone samples were tapped and pre-drilled using appropriately sized clinical tools and clamped such that the pre-tapped hole was directly in line with the path of the screw as attached to the end-effector of the device (Fig. 2). Initial testing and validation of the device sought to ensure that reasonable torque profiles were acquired and could be used to detect differences between foam bone densities.

RESULTS

The healthy bone surrogate stripped at a higher peak torque than the osteoporotic bone surrogate (2.1 Nm and 0.76 Nm, respectively), which stripped prior to entering phase 3 of the expected torque profile (Fig. 3). Torque per 90° screw rotation was also assessed (example, Fig. 4), which shows torque increases across individual turns and isolates turns in which bone was stripped.

Figure 3: Torque insertion profile of a 40mm pedicle screw for PCF 12.5 Cell and PCF 20 Cell foam bones (Synbone).

Figure 4: Torque per 90° screw rotation. Colors indicate insertion depth (mm). Torque increases steadily until the final turn, where the sharp drop-off in mid-rotation indicates stripping.

DISCUSSION

There are many variables affecting screw fixation strength and failure, one of which is the person inserting the screw. One recent study compared screw tightness and stripping between surgeons and biomechanical researchers and demonstrated that the surgeons stripped screws at a higher rate [5]. This may indicate that mechanical training is a factor in optimal screw fixation. Successful development of an SSD that has been well-trained by machine learning and AI could help eliminate human error.

Initial data collections using the SSD are promising. Torque profiles vary between foam bones of different densities, and higher values are required to strip “healthy” bone than “osteoporotic” bone, consistent with clinical trends. Bone stripping can be isolated to a single screw rotation.

Additional data will be collected on varying foam bones and pedicle screws to increase sample power and develop algorithmic predictions of stripping torque. Once collection on foam bones is complete, data will be collected using vertebrae from cadaveric specimens. Finally, engineering design will move to development of a handheld device that could feasibly be used in a surgical setting, as opposed to a benchtop device.

INTRODUCTION

The mechanical behavior of soft collagenous tissues is largely influenced by the reinforcing collagen fiber microstructure. The anisotropic collagen microstructure can remodel in response to changes in mechanical loading, which can dramatically alter the mechanical properties of the tissues and the mechanical environment of the resident cells. It is important to study the remodeling mechanisms of collagen tissues to understand the pathophysiology of various connective tissue diseases. We hypothesize that the collagen structure actively changes in response to mechanical stimuli through concurrent processes of collagen deposition and degradation and that the rates of these processes are altered by collagen mechanochemistry, mechanosensitive collagen production, and cellular contraction. In prior studies, we developed micromechanical models of collagen tissues to investigate the role of collagen mechanochemistry and mechanosensitive collagen production in remodeling the collagen fiber structure and tissue growth.[1,2] We found that stress inhibition of enzymatic degradation and stimulation of collagen production can explain many phenomena, including remodeling the anisotropic collagen structure along the directions of the maximum principal stress and the development of stress homeostasis.

The goal of this study is to investigate the effect of mechanical loading on the active behavior of the cells. Our approach uses a model 3D microtissue system, self-assembled on a magnetically actuated two-pillar system (μ TUG), to investigate these cell-collagen interactions and effects of mechanical loading.[4] The micropillar support allows for measurement of the active cellular contraction, while the magnetic tweezer allows for mechanical testing of the microtissue under a controlled stress rate. Digital image analysis is applied to measure the local two-dimensional (2D) strain field.

To analyze the mechanical measurements for mechanical properties of the collagen structure and active behavior of the cells, we developed a micromechanical model for the mechanical behavior of the microtissue. The micromechanical model includes the elastic behavior

of the anisotropic collagen structure and the anisotropic active behavior of the cells. To describe mechanosensitive cellular contraction, we assume concurrent polymerization/depolymerization of actin filaments, where the polymerization rate increases with the fiber stress.[3]

In this paper, we will briefly summarize the model and describe an initial model validation by comparing to μ TUG experiments measuring the stress-strain behavior of the microtissue to load-unload tests.

METHODS

Mechanical characterization: To validate our model we considered previous studies of Liu et al. [4] of microtissues composed of bovine pulmonary artery smooth muscle cells (SMCs) in model collagen/fibrinogen matrix. In this prior study, microwell array devices (μ TUGs) were fabricated from poly(dimethylsiloxane) (PDMS) via replica molding. One of the two micropillars in each well was affixed with a 100 μ m nickel sphere for actuation by magnetic tweezers. Microtissues were seeded in the μ TUG arrays from SMC-collagen/fibrinogen mixtures at a density of \sim 300 cells per microwell. Over the course of 24-48 hours microtissues self-assembled on the pillars. During tissue formation, the cells contracted and compacted the extracellular matrix (ECM) causing the pillars to deflect. The deflection of the pillars was measured via phase-contrast imaging [4] and used to calculate the baseline active stress $\sigma_0 = 5.1$ kPa.

Uniaxial quasi-static load-unload tests were performed on individual microtissues by actuating the magnetic pillars via magnetic tweezers. The tissues were stretched using a magnetic force of 25-35 μ N over 120 s and then unloaded to nominally zero stress at the same rate. The passive mechanical behavior of the ECM was directly measured with the same stretching protocol on tissues treated with Triton X-100 for 10 min, to lyse the cells.[4]

Micromechanical constitutive model of microtissue: We conceptualize the microtissue as an anisotropic network of wavy collagen fibrils arranged in an isotropic matrix that represents the

nonfibrous extracellular matrix materials and passive mechanical behavior of the cells. The wavy collagen fibers are modeled as planar sinusoidal elastica, with initial crimp angle $\Theta(\mathbf{X})$, subjected to a horizontal force, which causes the fibers to unbend and stretch axially. The axial stretch, $\lambda_f(\mathbf{X})$, and deformed crimp angle $\theta(\mathbf{X})$ can be determined as described by Comninou and Yannas [5]. The strain energy density of the fiber is given by, [1]

$$U_f = \int_0^1 \left[\underbrace{\frac{E\beta D^2}{2} (\theta(\bar{X}_1) - \theta(\bar{X}_1))^2}_{U_{bend}} + \underbrace{\left[\frac{E}{2} (\lambda_f(\bar{X}_1) - 1)^2 \right]}_{U_{axial}} d\bar{X}_1, \quad (1)$$

Where E is the fiber axial modulus, β is the bending stiffness of the fiber cross-section, and D is the collagen diameter. The contractile cells exert a force on the collagen fibrils in their environment. The active stress of an actin filament is described by a Hill-Type law given in [2],

$$\sigma_{sf}(\theta) = \sigma_{\max} f(\lambda_\theta) g(\dot{\lambda}_\theta), \quad (2)$$

where σ_{\max} is the isometric contraction of an actin filament and $f(\lambda_\theta)$ and $g(\dot{\lambda}_\theta)$ describe the strain sensitivity and rate sensitivity of the contractile stress. We assume the cellular component of the tissue can be described by an anisotropic network of stress fibers that undergo concurrent polymerization and depolymerization in response to stress. Furthermore, we assume that the rate of polymerization increases with the fiber stress. This process is incorporated into the model as a kinetic equation for the fiber volume fraction. [3]

$$\frac{d\phi_{sf}(\theta)}{dt} = (k_0^f + k_1^f \sigma_{sf}(\theta, \lambda_\theta, \dot{\lambda}_\theta)) \phi_{am} - k_d \phi_{sf}(\theta) \quad (3)$$

Finally, we assume that active stress of the cells and passive stress of the extracellular matrix add to give the tissue stress response,

$$\sigma = \frac{1}{\pi} \phi_{sf} \int_{-\pi/2}^{\pi/2} \sigma_{sf}(\theta) \rho_{sf}(\theta) \mathbf{a} \otimes \mathbf{a} d\theta + \frac{1}{\pi} \phi_{cf} \int_{-\pi/2}^{\pi/2} \frac{\partial U_f}{\partial \lambda_\theta} \frac{1}{\lambda_\theta} \rho_{cf}(\theta) \mathbf{F} \otimes \mathbf{F} d\theta + \phi_m (\mu \mathbf{B} - p \mathbf{I}), \quad (4)$$

where ϕ_{sf} , ϕ_{cf} , and ϕ_m are volume fractions, ρ_{sf} and ρ_{cf} are angular distributions of fibers, \mathbf{a} is the deformed orientation of the fibers, σ_{sf} is the active stress generated by the stress fiber. We applied the model to simulate the uniaxial tensile tests of the microtissues (Fig. 1C-D).

RESULTS

We fit the scaled isometric contraction $\phi_{sf} \sigma_{\max} = 0.2$ kPa to the baseline stress of the microtissue and use the parameters of $f(\lambda_\theta)$ and $g(\dot{\lambda}_\theta)$ determined in a prior study.[3] We used $\beta = 0.02$ and initial crimp angle $\Theta_0 = 29^\circ$ determined in a prior study [1] and fit the axial modulus $E = 1.2$ MPa (Fig.1C). These results are used to validate the model response in Fig. 1D. This preliminary result shows that the model can recapitulate the loading curve for the untreated tissue. The model accurately predicted the modulus at small strain but overestimated the peak stress. In contrast, the model produced a poor fit for the Triton treated cells. Experiments showed that the Triton treated tissues also exhibited a small baseline stress $\sigma_0 = 1.6$ kPa caused by tissue compaction, which we neglected. The small baseline stress may have straightened the collagen fibers, such that subsequent stretch produced a linear stress-strain response. Fig. 1E shows the model prediction of the reorientation of stress fibers towards the loading direction.

DISCUSSION

This study proposed a model for the investigation of the interaction of mechanosensitive stress fiber evolution and the non-linear properties of the ECM in 3D microtissues. The current model demonstrates how physically derived parameters can describe the mechanical response of

the microtissues. The model has some limitations. First, the model neglected the effects of tissue compaction and the viscoelastic behavior of the collagen structure. Consequently, the model cannot reproduce the hysteresis of the unloading response. The viscoelastic response of the collagen needs to be coupled with the contractile dynamics of the cells to investigate the shielding by the cells of the viscoelastic effects.

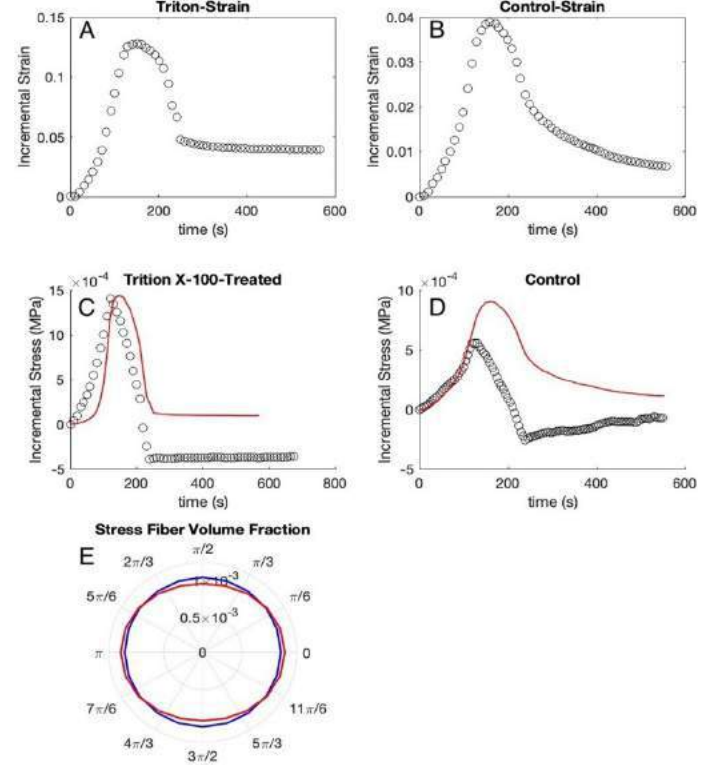

Figure 1: (A-B) Measured strain of Triton-treated and untreated tissue. (C) Model fit of the stress response of Triton-treated tissue. (D) Model prediction of the stress response of the untreated tissue. (E) Loading caused the initially isotropic stress fibers (blue) to align in the loading direction (red). Data in A-D from [4].

We also assumed an initial isotropic distribution of the collagen and stress fibers. However, confocal imaging of the matured tissues before loading revealed that the collagen and stress fibers exhibited a dominant axial orientation. To account for tissue maturation, we will incorporate the anisotropic collagen and actin fiber structure and the cell-mediated tissue compaction of the matured tissue.

In future studies, we apply a viscoelastic extension of the model to investigate the effect of strain rate on cell response. Furthermore, we will extend the model to include a fiber-level description of collagen remodeling and the effects of strain inhibition of collagen degradation and strain stimulation of collagen production.

RETROPUBIC TROCAR TEMPORAL CHARACTERISTICS BETWEEN EXPERT AND NOVICE SURGEONS

Md A. Arif (1), Austin Bachar (2), Gregory W. King (1), Gary, Sutkin (2), Antonis P. Stylianou (1)

(1) School of Science and Engineering, University of Missouri – Kansas City, Kansas City, MO, USA

(2) School of Medicine, University of Missouri – Kansas City, Kansas City, MO, USA

INTRODUCTION

The Retropubic Midurethral sling (MUS) procedure is the most common surgical treatment for stress urinary incontinence. During the procedure, a sharp trocar is used to place the sling beneath the urethra. The trocar is blindly navigated through the vaginal canal, cephalad to the pubic symphysis and finally exiting the body above the pubic bone. This path is adjacent to the urethra and bladder and near the iliac blood vessels and the bowel. Surgeons must rely on haptic feedback from the trocar as it makes contact with the surface of the suprapubic bone. Failure to guide the trocar correctly can lead to several complications including bladder and urethral perforations (4.9%), bowel perforation (0.1%) and injuries to major blood vessels (2.0%). Error rates among novice surgeons are higher in comparison to experts [1-2].

Successful trocar passages depend on correct navigation of the trocar through the retropubic space using a series of discreet steps. The discreet steps of the procedure can be defined as: Stage 1: trocar tip from incision to pubic bone contact, stage 2: trocar tip from first contact to the most cephalad point of the pubic bone, stage 3: trocar tip from most cephalad point to the most ventral point of the pubic bone, stage 4: trocar tip from the most ventral point of the pubic bone to the exit point. Novice surgeons are instructed to advance the trocar in an anterior/cephalad direction until the trocar makes contact with the pubic bone, then aim for the exit point right above the pubic symphysis and about 2 cm lateral to the body midline while continuously maintaining contact with the pubic bone.

The objective of this study was to investigate trocar temporal and spatial characteristics during simulated MUS procedures between expert and novice surgeons.

METHODS

Three expert surgeons with experience performing and teaching at least 100 retropubic MUS procedures and three novice surgeons with no experience performing the procedure participated in this study.

Simulated MUS procedures were performed on a surgery simulator described previously [3]. Briefly, three simulation models were created by segmenting the pelvic bones and organs, and 3d printing the pelvic bone structure from MRI of three patients with urinary stress incontinence. The open space in the simulator was filled with thermoballistic gel to provide the haptic feedback associated with trocar passage through soft tissue. The biofidelity of the simulator was investigated previously [3].

Participants used a Gynecare TVT trocar with the mesh tape removed connected to a Gynecare TVT introducer (Ethicon Inc, Somerville, NJ). The introducer was fitted with a 3d printed rigid body that included seven 8 mm reflective motion capture markers. Reflective markers were also mounted on the simulation model and all markers were tracked with 12 motion capture cameras connected to the OptiTrack Flex 13 motion capture system. The marker trajectories were sampled at 120 Hz through the Motive software (NaturalPoint Inc, Corvallis, OR). Each participant performed 15 trocar passes. The order of simulation models used and the order of patient's side passage was randomized.

Multibody kinematics models were created in ADAMS (MSC Software Corp, Santa Ana, CA). These models included the 3d geometries of the surgery simulators and the trocar. Major blood vessels and the bladder geometries were segmented from the MRI and overlaid in the multibody model by aligning the pelvic geometry using least squares fit. Landmark oriented planes corresponding to the end of stages 2,3, and 4 were also added to the model (Figure 1). Motion capture data from the experimental trials on the simulators was used as an input to drive the kinematic analysis. For each trial, the outputs of the kinematic analysis were the trocar tip location, the time intervals for each of the four stages, contact and penetration of the trocar into the bladder or the major blood vessels. Passage of the trocar posterior to the pubic symphysis was also noted.

Linear mixed models were used to analyze the data. Significance was set at $p < 0.05$. All statistical analysis was done in SAS 9.4 (SAS Institute Inc, Cary, NC).

Figure 1: Multibody used for kinematic analysis. Includes the surgery simulator, trochar, and landmark planes.

RESULTS

Experts completed 27 error free passes and 18 passes where the trochar penetrated the bladder (40%). While novices completed 18 error free passages, 4 passes where the trochar penetrates the bladder and 23 passes where the trochar passed anterior to the pubic symphysis resulting in an overall error rate of 60%. Trocar tip trajectories were significantly different between error free passes and bladder error passes in the anterior-posterior and caudal-cephalad directions for both left and right trocar passages. These trajectory difference existed when comparing the total trocar trajectories (whole procedure) and when comparing only in stage 3 (which is the stage when bladder penetration can happen). Incidence of anterior trocar passage error was significantly higher in novice surgeons for both left and right passes. Anterior error passes had significantly altered trocar tip trajectories in all directions.

A mixed model was used to decompose total trocar path variation and the results indicate that 14% of the variation was attributed to experts while 45% was attributed to novice surgeons.

Temporal characteristics were analyzed by stages and shown in figure 2. Since anterior trocar error passages do not have stages 2,3, and 4, those trials were excluded from this analysis. There was no significant difference in stage 1 duration between error free posterior passages and anterior error passages.

DISCUSSION

Results indicate that monitoring the kinematics of the trochar handle can provide insight into the types of errors that can occur during the blind passage of the trochar in MUS procedures. In particular, during stage 3, the cephalad excursion of the trochar was smaller in bladder error trials compared to error free trials.

Bladder error for the expert surgeons was 40% which is slightly higher with previous studies looking at error ratios from the OR. Bladder error for the novice surgeons was 20% but this rate may not be indicative of the true error because anterior pass error trials are not

included in this calculation. Novices had 23 anterior pass error trials out of 45 trials performed. The overall error (bladder plus anterior) for the

Figure 2: Trocar temporal characteristics by stage.

novices was 60%. This is the first time that anterior error passages were observed in the MUS procedure. This is attributed to the fact that most previous studies looked at surgery outcomes post-surgery. Since anterior passages are in fact a complete failure in terms of MUS placement, they would have been addressed in the OR by repeating the trocar pass until a posterior placement is achieved. In our study, participants were allowed to perform the procedure without an attending surgeon correcting and guiding their passes therefore we were able to observe this error. In our study, inexperienced surgeons seemed to have a hard time navigating the trocar cephalad to the pubic bone after initial contact with the pelvis.

Path trajectory variation was higher for the novices indicating that they are not able to follow a consistent trocar path between trials. Overall differences between experts and novices indicate that experience is a major factor in successfully placing the sling without complications such as bladder perforation.

This is the first study that incorporated motion capture to track the trocar instrument during the MUS procedure. Monitoring the temporal and kinematic characteristics of the trocar provides insight into the types of errors that can occur and can also provide insight into proper education of young surgeons. Methods used in this study can also be implemented for monitoring sling placement in the OR thus reducing preventable surgical errors. The surgical simulator and real time trocar motion monitoring can also be used in an educational setting so that young surgeons can acquire the necessary skills for performing the MUS procedure.

INTRODUCTION

Elastin is a key component of elastic fibers which endow many important tissues and organs, from arteries and veins, to skin and heart, with strength and elasticity. Due to its intrinsic long life and low turnover rate, damage in elastin induced by pathophysiological conditions, such as hypercalcemia and hyperglycemia, accumulates during biological aging and in aging-associated diseases, such as diabetes mellitus and atherosclerosis. Prior studies have shown that calcification induced by hypercalcemia deteriorates the function of aortic tissues. Glycation of elastin is triggered by hyperglycemia and associated with elastic tissue damage and loss of mechanical functions via the accumulation of advanced glycation end products. Yet, molecular mechanisms associated with these processes are still poorly understood. To evaluate the effects on elastin's structural conformations and elasticity by hypercalcemia and hyperglycemia at the molecular scale, which is yet unknown, we perform classical atomistic and steered molecular dynamics simulations on tropoelastin, the soluble precursor of elastin, under different conditions, based on our previously established all-atom model. We characterize the interaction sites of glucose and calcium and associated structural conformational changes. Additionally, we find that elevated levels of calcium ions and glucose hinder the extensibility of tropoelastin by rearranging structural domains and altering hydrogen bonding patterns, respectively. Overall, our investigation helps to reveal the behavior of tropoelastin and the biomechanics of elastin biomaterials in these physiological environments.

METHODS

The starting structure of tropoelastin was chosen from our previous work based on human tropoelastin isoform 2 [1], where the molecule has been well equilibrated by REMD simulations. Atomistic classical MD simulation of wild type (WT) tropoelastin was performed using the Gromacs simulation package, for a total running time of 1000 ns.

Simulations of tropoelastin in calcium, glucose and mixed solution were studied. Topology and force field parameters were assigned from the CHARMM36m protein parameter set for elastin and from the CHARMM36 sugar parameter set for α -D-glucose and calcium. Domains 10-19 of tropoelastin were spliced from the same starting structure of the whole molecule to perform steered MD simulations, as these domains are chiefly involved in elastin's elasticity. The α -carbon of the last residue in domain 19 was fixed, and the α -carbon of the first residue in domain 10 was pulled at a velocity of 50 m/s and a force constant of 1000 kJ mol⁻¹ nm⁻² along the axis parallel to the length of the molecule. To investigate the specific role that calcium ions and glucose play in altering mechanical properties of tropoelastin and the correlation between such variations and calcium/glucose concentrations, we introduced calcium ions with a concentration range of 100 mM, 750 mM, 1000 mM, 1500 mM to 2000 mM, to represent hypercalcemia, and glucose with a concentration range of 246 mM, 493 mM, 738 mM, 985 mM to 1969 mM, to represent hyperglycemia, with tropoelastin only as the control. We set up three replicates for each condition. All modeling used in-house and Gromacs scripts.

RESULTS

Compaction of elastin's structure and depletion of hydration waters results in a higher modulus of elasticity in calcium solution. In the mechanical pulling simulation, we find a significant increase in elastic modulus (Fig 1). With more calcium ions present, it becomes increasingly harder to pull the molecule at the same strain. Notably, the phase-wise deformation patterns become more pronounced in the presence of higher calcium concentrations, as seen in the corresponding snapshots presented. Such distinct deformation patterns point to calcium-induced stiffness. To examine the role of each domain in this phase-wise deformation pattern, we analyze dissociation profiles of protein-protein hydrogen bonds formed within each domain. Interestingly, compared with the dissociation profiles of hydrogen

bonds of the control, the presence of calcium ions encourages the formation of a larger number of more stable hydrogen bonds formed by each domain, especially in domains 10, 11, 12, 14, pointing to roles for calcium ions in stabilizing hydrogen bonds formed within the protein for increasing global molecular stiffness.

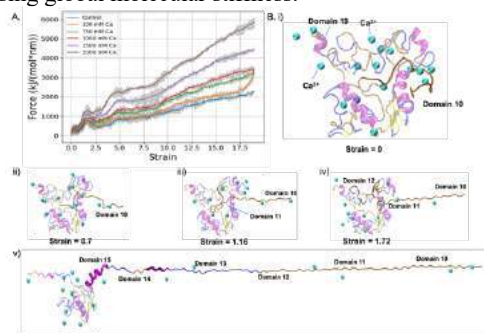

Fig 1. Calcium effects on tropoelastin mechanics. (A) Force vs strain curves in the presence of various concentrations of calcium. (B) Snapshots of tensile tests at various strains, (i-v).

Replacement of hydration water and viscosity conferred by glucose yields altered mechanical properties. We examine the number hydration waters within a shell radius of 2.2 Å and 3.2 Å, in the presence of glucose and in the control. The former shows a reduced number of hydration waters that can be attributed to competing hydrogen bonding between protein and glucose replacing interactions with water. This bonding behavior also influences the mechanical properties of tropoelastin (Fig 2). With a higher concentration of glucose, the elastic modulus increases. The phase-wise deformation patterns observed in tropoelastin with 1969 mM glucose are more discernible compared to the control. We believe such distinct deformation patterns to be the consequence of hydrogen bonding between glucose and tropoelastin. To examine the role each domain plays in this phase-wise deformation pattern, we also analyze dissociation profiles of hydrogen bonds formed within the protein by each domain. Our findings suggest the supporting roles of domains 10-14 in resisting deformation; the earlier dissociation pattern compared to control and tropoelastin with 1000 mM calcium ions, however, suggests the increased elastic modulus and overall stiffness are not likely due to increased intramolecular bonding, but instead, is associated with intermolecular hydrogen bonding between glucose and protein.

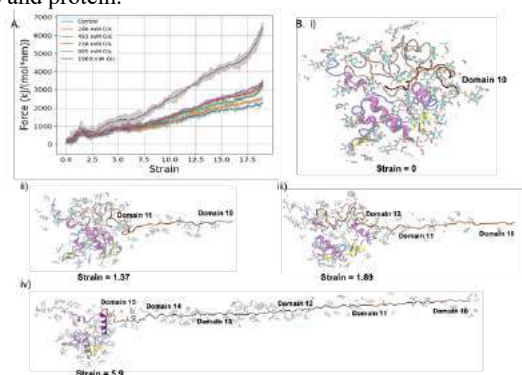

Fig 2. Glucose effects on tropoelastin mechanics. (A) Force vs strain curves in the presence of various concentrations of glucose. (B) Snapshots of tensile tests at (i) Strain = 0, (ii) Strain = 1.37, (iii) Strain = 1.89, (iv) Strain = 5.9, tropoelastin + 1969 mM glucose.

The addition of calcium in the presence of glucose induces linear alterations in mechanical profiles. Due to the heterogeneous conformations identified in response to calcium and glucose coupling

effects, different intramolecular contact maps for various conditions are found (two shown, Fig 3A). As the hydration water number in both nearest hydration shells shows a nearly linear decrement as the calcium concentration increases (data not shown), we would expect there to be a clear linear change in mechanical profiles. However, when glucose concentration dominates, the addition of calcium only shows significant difference between tropoelastin with 738 mM glucose + 100 mM calcium and tropoelastin with 738 mM glucose + 200 mM calcium, and a slight difference between tropoelastin with 738 mM glucose + 200 mM calcium and tropoelastin with 738 mM glucose + 400 mM calcium (Fig 3B). It is possible that changes due to the relatively small increase in calcium concentration are not discernible in steered MD simulations, and glucose may block calcium from interacting with the protein, as observed in the case of MD simulation of tropoelastin with 738 mM glucose + 400 mM calcium.

Fig 3. Calcium and glucose coupling effects on tropoelastin structure and mechanics at glucose concentration 738 mM. (A) Residue-wise contact maps showing intramolecular interactions in 738 mM glucose and (i) 100 mM calcium or (ii) 200 mM calcium. (B) Mechanical profiles of control and various calcium/glucose concentrations.

DISCUSSION

The introduction of different combinations of glucose and calcium to tropoelastin yields nonlinear variations in protein conformations, since these solvents invoke divergent changes to the molecule's structural rearrangement, namely, structural collapse by calcium, and structural dissociation by glucose. Interestingly, we find that when glucose concentration dominates, protein dynamics do not exhibit a correlation over a range of calcium concentrations, possibly due to a higher number of conformational degrees of freedom that arise from the molecular flexibility promoted by glucose binding.

From a macroscopic perspective, our findings provide insights into diseases of elastin of genetic origin. For instance, elastin gene deletions in Williams Syndrome result in reduced expression of functional elastin and an altered deposition of elastin in skin. Given reports of occasional childhood hypercalcemia in Williams Syndrome, there are, nevertheless, contradictory observations of the phenotype of accompanied arterial stiffness. Our findings may point to a general recovery through reversible calcium binding, and support a general model where other calcium-binding molecules are needed to achieve persistent vascular calcium binding. It may also be that elastin attracts calcium through persistent binding, and that this persistence is locked in by resident calcium-binding proteins such as fibrillin-1. Overall, these studies have implications for uncontrolled, persistent hypercalcemia and hyperglycemia, where we hypothesize changes in biomechanics and adverse physiological consequences due to stiffening on a larger scale, still to be probed, particularly in the vasculature where functional elasticity is needed.

INTRODUCTION

Previous studies in the literature have linked geometric features of the carotid bifurcation to the prevalence of hemodynamic disturbances resulting in vessel wall thickening and atherosclerosis [1,2]. A common approach to finding a mechanistic explanation of the effect of geometry on flow is based on computational fluid dynamics (CFD) simulation. Patient-specific CFD requires two key pieces of information: geometric boundary conditions and flow boundary conditions which include input flow and outlet pressure [3]. Geometric boundary conditions are generally defined through a laborious process including segmentation and meshing. Flow boundary conditions can be derived from phase-contrast magnetic resonance imaging. The solution of the CFD problem typically involves long processing time and high computational power. To date, these factors have limited the use of CFD in clinical decision-making.

Due to the complex dependency between geometry and flow in the carotid bifurcation, there is a need in the field for mechanistic studies on larger datasets to better identify geometrical risk factors. *Therefore, the aim of this work is to conduct a CFD study on a large set of realistic, synthetically generated carotid bifurcation geometries based on previously published geometric features such as the bifurcation angle, common carotid (CCA) radius, internal carotid artery (ICA) bulb area expansion, tortuosity, and inlet flow condition.* We choose wall shear stress (WSS) as a measure of disturbed blood flow [1], and we analyzed the relationship between WSS in the carotid bifurcation and various geometric features.

The gold standard WSS values are derived from three-dimensional, three-directional, ECG gated, time-resolved, phase-contrast magnetic resonance imaging (4D Flow MRI). 4D flow MRI will be used as qualitative validation for the data generation and simulation method [4].

METHODS

A total of 250 synthetic carotid bifurcations were generated and CFD simulations were conducted. The geometries included two main populations, healthy and diseased models with varying degree of stenosis in the ICA representing atherosclerosis. One healthy volunteer (27-year-old female) underwent an MRI scan for validation. Pre- and post-processing was conducted in python and ParaView.

Geometric Data Generation: each bifurcation geometry is represented by bifurcating vessel centerlines; each centerline point is associated with the radius of an inscribed sphere centered in the point. The envelope of the inscribed spheres was computed as a triangulated mesh and used as geometric boundary conditions for CFD simulations. A literature search was conducted to extract realistic geometric features to generate the synthetic carotid bifurcation (Table 1) [1,2].

Table 1: Parameters with corresponding ranges used to generate synthetic carotid artery:

Parameter	Ranges Used
CCA diameter	4.3 - 7.7 mm
ICA bulb: CCA Diameter Ratio	1.2 - 2.5
Bifurcation angle	31.2° - 97.6°
ICA angle	1.8° - 62.7°
ICA tortuosity	0.006 - 0.521

ICA: CCA Diameter Ratio	0.52 - 1.04
ECA: CCA Diameter Ratio	0.50 - 1.10
ECA: ICA	0.63 - 1.39
Inlet mean Velocity	20 - 40 cm/s
Stenosis	25% - 80%

For each generated geometry, flow boundary conditions were assigned as mean inlet flow and flow split at the carotid bifurcation, these were also varied as in **Table 1**.

Fluid Simulation: We adopted a fast, graphics processing unit- (GPU-) accelerated CFD solver using the lattice Boltzmann method (LBM) and previously validated [5]. This supports automatic selection of optimal spatial and temporal resolutions for accuracy and stability. Additionally, an average value of the velocity and WSS was calculated at every cross-section and associated to the corresponding centerline point. The main region of interest in this work was the expansion region in the bulbar segment of the ICA.

Solution Validation: To validate our method, we generated a carotid bifurcation based on a healthy volunteer that underwent an MRI scan including black blood vessel wall scan and 4D flow MRI scan. The black blood scan was used to extract geometric features for synthetic geometry generation while the 4D flow MRI scan was analyzed using EnSight to compare the velocity profile to the CFD solution.

RESULTS

An example of synthetic carotid bifurcation is seen in **Figure 1** (left). The computed flow field has a good qualitative agreement with the flow field derived from the healthy volunteer scan, with very similar velocity profiles across multiple cross-sections in the carotid geometry.

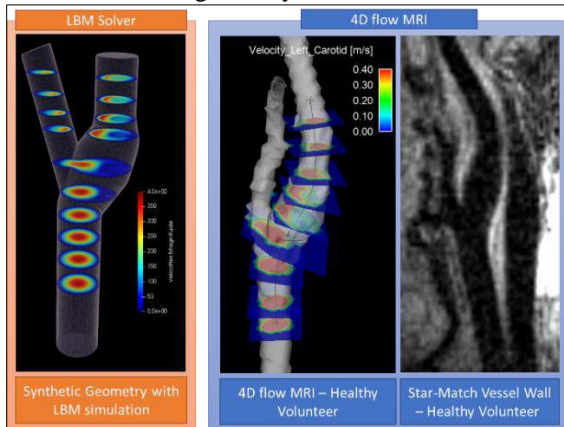

Figure 1. An example of a synthetic carotid bifurcation based on measurements from Vessel Wall Black blood MRI with LBM simulation (orange background) compared to a healthy volunteer 4D flow MRI scan with multiple cross-sections displayed in EnSight.

Analysis of the geometric features and WSS measurements on the full database of synthetic geometries is shown in **Figure 2**. WSS is highly dependable on geometric features including radius, flow, cross-sectional area and bifurcation angle. Normal geometries can be clearly separated from abnormal geometries.

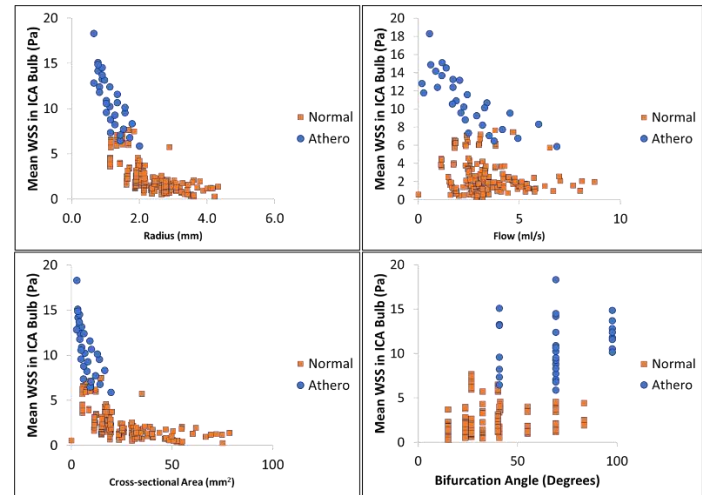

Figure 2. The effect of radius, inlet mean flow, cross-sectional area, and bifurcation angle on the mean WSS in the ICA bulbar segment in normal and stenosed geometries.

DISCUSSION

In this work, we were able to generate synthetic geometries of carotid bifurcation to assess the effect of different geometric features on flow disturbance. Few limitations of this method are that all simulations were done for steady flow conditions rather than pulsatile. Additionally, the averaging of the WSS around the cross-section contour does not allow studying localized flow disturbance. The longer-term goal of this work is to generate richer data sets including more variation in geometry and flow conditions, as well as more detailed descriptors of local flow patterns. A regression model will then be defined using machine learning techniques to elucidate the complex effect on local flow features of geometric measurements of the carotid bifurcation. The model will allow the assessment of disturbed flow in patient-specific anatomical models of the bifurcation, without the need for time consuming CFD analysis.

The concepts and information presented in this paper are based on research results that are not commercially available. Future commercial availability cannot be guaranteed.

INTRODUCTION

The simulation of many complex, biological problems has been addressed using existing commercial finite element software packages (e.g., AnsysTM, ABAQUSTM, and NIKE3DTM) or open-source solvers like FEBio (University of Utah). However, many common biomechanics problems cannot be addressed or cause significant investments of time due to human-in-the-loop parameter tuning, especially in the presence of contact forces. These problems generally include some combination of very large deformations, deformations that occur quickly, contact between multiple deformable bodies, irregular geometries, and/or extremely soft and/or highly heterogeneous materials in terms of stiffness. End-users often have to make compromises related to the physics of the problem, the geometry, or the mesh to achieve a solution. Fortunately, the recent development of novel, smooth contact models and the corresponding interior point solvers address many of these compromises.

PolyFEM, a C++ FE library implementing Incremental Potential Contact (IPC), is one such solver. Implementing IPC into the solver allows for robust and accurate time-stepping and guarantees intersection- and inversion-free solutions to simulations that are undergoing large deformations and large time steps. We aimed to compare the usability of PolyFEM and compare it to the well-established biomechanics FE approaches (FEBio 3.0) using problems with published solutions to evaluate its utility in challenging scenarios common in biomechanics.

METHODS and RESULTS

We compared each of the solvers in four head-to-head comparison tests, 1) the FEBio test suite, 2) the FEBio validation paper [1], 3) three material high-energy contact, 4) simulation of hip and jaw movements. Each set of simulations is designed to compare the capabilities of the two solvers to determine their strengths and limitations.

First Benchmark. The test suite is a set of examples that outline the features of FEBio, including static, dynamic, and contact simulations. A group of 18 problems was selected from the test suite and simulated using both solvers. The selected simulations are a mix of static (with and without contact) and dynamic problems. Depending on the type of simulation, displacement, stress, and simulation time were collected and compared. Of the 18 selected simulations, 9 were static and involve contact. The other 9 were dynamic. We noticed that both FEBio and PolyFEM produce similar results, but PolyFEM, in general, takes more time to simulate. For example, consider the simulation *co07* (Figure 1). This simulation was of a curved plane being pushed into and then dragged across a block. Both the materials are modeled as Neo-Hookean (curved plane: $E = 10$ kPa, $\nu = 0.0$, $\rho = 1.0$; block: $E = 1.0$ Pa, $\nu = 0.45$, $\rho = 1.0$). No friction is involved. Figure 1 shows the initial and final configuration of the simulation. The computation time for FEBio is 12.1 seconds, while PolyFEM takes 585.2 seconds. We observe similar results in most other tests. Note that the FEBio TestSuite is carefully tuned to work best for FEBio; PolyFEM works without any manual tuning of the simulation. Including this tuning, time may make the overall runtimes more similar.

Figure 1: Simulation result of *co07* from FEBio TestSuite. A) configuration at $t = 0$ and B) final configuration.

Second Benchmark. Our second set of comparisons was based on the validation paper released by FEBio, which compares the results of FEBio to analytical results, and results generated with ABAQUSTM and NIKE3DTM [1]. This paper outlines ten simulations and compares the results between

the three solvers. In the “upsetting of an elastic billet” simulation from this work, a 1 mm x 1 mm x 0.1 mm elastic billet (meshed with 40x40x1 hexahedral elements) is compressed to 60% of its initial height between two rigid surfaces. A limitation of PolyFEM is that there was no way to use rigid bodies therefore these rigid surfaces were simulated as extremely stiff deformable bodies. This example was chosen as it is a good example of contact-driven deformation with an easily interpretable outcome measure. Using a quarter symmetry assumption, only one-quarter of the elastic billet is simulated. The billet is modeled as a Mooney–Rivlin material ($C_1 = 1$ MPa, $C_2 = 10$ MPa, $K = 10$ GPa), Figure 2A. The outcome measure of this simulation is the maximum lateral displacement of the elastic billet.

Figure 2: Figure showing the displacement of the elastic billet caused by the compression of the two rigid surfaces. A) Elastic billet at the beginning of the simulation, B) elastic billet fully compressed, C) Plot comparing the lateral displacement of the billet due to compression.

We were able to replicate seven of the ten simulations from the validation paper published by FEBio, the only exclusions were the simulations that are not possible in PolyFEM based on the current feature set [1]. In the example case, the solvers agreed on the lateral displacement of the top of the billet to the thousandths of a millimeter (0.781 mm, Figure 2) The simulation was significantly faster when conducted in FEBio when compared to PolyFEM (3 v. 56 seconds).

Third Benchmark. The third comparison test was developed to emphasize the difference in contact algorithms and human-in-loop optimization differences between the solvers. These differences are apparent when considering contact between two very soft materials. First, we generated three geometries using Houdini (v19.5.388). A dodecahedron (planet) and a rectangular prism consisting of two different materials, a relatively soft material (jello), which was encased by a relatively rigid outer material (mold). All three materials are modeled as neo-hookean materials (planet: $E = 100$ kPa, $\nu = 0.4$, $\rho = 5000$ kg m⁻³; jello: $E = 500$ kPa, $\nu = 0.4$, $\rho = 1000$ kg m⁻³; mold: $E = 100$ GPa, $\nu = 0.4$, $\rho = 1000$ kg m⁻³). The bottom face of the mold was fixed in all three directions. The planet was dropped onto the top face of the jello accelerated by gravity.

Figure 3: Frames from simulation of the high energy collision between two very soft materials (Planet = Red, Jello = Black, Mold = Gray). A) Approximate time in the simulation where FEBio failed. B) Point in the simulation where the planet has deformed the most.

The simulation of the planet falling onto the jello emphasized the capabilities of the contact algorithm used by PolyFEM. FEBio was unable to finish this simulation and failed due to an inverted element around the time of initial contact (Figure 3A).

Fourth Benchmark. Next, we assessed the performance of PolyFEM when using patient-specific models of the human body. We used the hip

and jaw FE models from the LibHip and Open-Full-Jaw repositories [2, 3]. The anatomical structures are assumed homogeneous and modeled using Neo-Hookean material (hip bone: $E = 17$ GPa, $\nu = 0.30$; hip cartilage: $E = 12$ MPa, $\nu = 0.45$; teeth: $E = 2$ GPa, $\nu = 0.3$; periodontal ligament: $E = 68.9$ MPa, $\nu = 0.45$; jaw bone: $E = 1.5$ GPa, $\nu = 0.30$). We set up pseudo-stance and biting scenarios for the hip and jaw models, respectively [2, 3]. As PolyFEM’s contact algorithm checks for potential contact between each object at every timestep there is no need for manual tagging of contact interfaces. Some simulations from this test were unable to be replicated by FEBio. Specifically, in the case of the biting simulation, FEBio fails to converge due to an inverted element in the extremely soft ligamentous tissue. Otherwise the simulations were nearly identical between PolyFEM and FEBio. Additionally, we benefit from the adaptive P -refinement option in PolyFEM and assign *Tet10* elements to the soft tissues to increase the simulations’ accuracy.

Figure 4: The von Mises stress distribution in the human hip (A) and jaw (B) in response to pseudo-stand and biting scenarios.

DISCUSSION

This study demonstrates that PolyFEM produces results matching those from FEBio for previously published simulations based on solid, hyperelastic materials. This provides important verification of the solutions provided by PolyFEM. Further, this study demonstrates that PolyFEM offers solutions to problems that are challenging for other solvers involving contact. Finally, this study demonstrates the utility of PolyFEM in solving patient-specific models in biomechanics. Thus, this alternative solver is very suitable for solving many problems in biomechanics where geometric nonlinearities are common.

It is important to note that at this stage of development, PolyFEM lacks many of the features available for other solvers. These include a user interface (PolyFEM uses a JSON setup file and Paraview for post-processing), a wide array of materials, shell and rod elements, a rigid body solver, tied-contact, a multi-physics platform, and optimization for parallel performance. However, it has a high potential for biomechanical simulation due to its higher automation and robustness. In addition, one limitation of using a barrier potential for contact is that the simulation cannot have interpenetrating surfaces in its initial configuration. This will need to be considered when creating meshes from segmented medical images. The upside of this limitation is the higher robustness and the guarantee that there will be no penetrations in all timesteps.

While PolyFEM is early in its development, it currently provides verified solutions for hyperelastic materials that are consistent with FEBio, and it is capable of simulating challenging problems in biomechanics where other solvers fail. It is also open-source and publicly available. Future work will aim to implement many of the aforementioned features to provide more options for the biomechanics community to implement it as another tool in their workflows.

DEVELOPMENT OF A SYSTEM FOR MEASURING AORTIC VALVE DEFORMATION USING DIGITAL IMAGE CORRELATION

Alexander W Hooke¹, Christopher Noble², David Morse², Melissa Young², Amir Lerman²

(1) Biomechanics Core, Mayo Clinic, Rochester, MN, USA

(2) Department of Cardiovascular Medicine, Mayo Clinic, Rochester, MN, USA

INTRODUCTION

The demand for transcatheter aortic valve replacement (TAVR) aortic valve replacement continues to outpace that of standard surgical intervention.[1] While TAVR valves were originally intended only for treatment of elderly patients or those deemed too high risk for open heart surgery, their utilization has shifted to include lower risk and younger patients, increasing the call for improved TAVR durability.

As valve materials, geometry, and designs are studied to heed this call, the ability to thoroughly quantify the strain and stress on valves' leaflets is crucial to both understand the currently available commercial valves' performance and develop next generation of bioprosthetic heart valves. The combination of its non-invasive nature and its high temporal and spatial resolutions make three-dimensional digital image correlation (DIC) an excellent candidate to measure valves' functional mechanics. Similar measurements of aortic replacement valves have been performed by Abbasi et al. [2] and Stanova et al. [3], with promising results. The objective of this project was to expand on their techniques, improve compatibility with a larger number of valve types/models, improve the resolution of DIC measurements, and create an overall robust DIC system to support bioprosthetic valve research.

METHODS

Hardware & Software

A test set up was created consisting of a custom-fabricated optically clear acrylic tank, 2 peristaltic pumps, 2 pressure transducers, and an interchangeable set of chamber dividers that enabled the valve to be mounted at different orientations relative to the camera. A pair of GOM Aramis 12M SRX cameras (Carl Zeiss GOM Metrology GmbH, Braunschweig, Germany), mounted with a stereo angle of 20°, with Titanar 75 mm lenses were mounted atop a custom test rack and held rigid to the tank after calibration with a standoff distance of 620mm, resulting in an image scale of 28.9 pixel/mm (Figure 1). All DIC

analyses were performed using the Aramis Pro 2018 software (Carl Zeiss GOM Metrology GmbH, Braunschweig, Germany).

Valves

An assortment of TAVR valves were tested including: the Edwards Sapien 9300TF, the Medtronic Core Evolut, and the Medtronic EvProPlus as well as custom, in-house fabricated valves made from fixed porcine pericardium. These valves were tested before and after undergoing 200 million cycles of simulated wear using a TA Durapulse 4-station heart valve test instrument. Two retrieved, ex vivo TAVR valves were also tested.

Patterning

Patterning of the valves required consideration and compromise of several factors including: their state of wetness, the adherence of the pattern to the material, ability to withstand endurance testing, inaccessibility of some valve surfaces due to their geometry, and permanence of staining prohibiting patterning corrections. The selected balance of these factors resulted in a patterning technique of aerosolized India ink to create contrast on the tissue's white surface for the

Figure 1: Test set up with camera mount on left atop test rack and acrylic chamber on right equipped with angled mount.

Figure 2: Custom-built TAVR valve A) unpatterned and B) patterned with aerosolized India Ink with typical feature size.

commercially available valves and aerosolized methylene blue stain for the ex vivo. For the in-house fabricated valves, patterning was done on sheets of the pericardium material prior to their assembly into valves, yielding a more complete pattern coverage over all valve surfaces. These techniques resulted in a minimum attainable feature diameter size of 0.24-0.41mm (7-12 pixels), seen in Figure 2.

Calibration

The system was calibrated using a vendor-supplied calibration panel (model CP20/55x44, Carl Zeiss GOM Metrology GmbH, Braunschweig, Germany) with the panel in the water-filled tank during acquisition of all calibration images. The resulting calibration consisted of a measuring volume of 80mm wide x 60mm high x 40mm deep with a calibration deviation of 0.1 pixels (3 μ m).

Noise Floor

An unloaded valve remains open in its resting state and when loaded by peristaltic pump there is an oscillation in the valve's load and displacement. These conditions made an accurate determination of the system's noise floor challenging. To achieve a noise floor measurement, a vent was opened on the aortic side of the valve, resulting in the valve shutting under the static and steady atmospheric pressure. This loading was recorded to determine the in-plane and out-of-plane noise floor.

Testing

The two chambers were filled with distilled water. Valves were mounted in a silicone ring, creating a seal around their perimeter, then press fit into a polycarbonate tube separating the two chambers. Each valve was tested using the chamber's flat mount, enabling measurement on the broad, belly surface of all leaflets and the areas approaching the perimeter annulus, as well as the chamber's angled mount, enabling measurement of individual leaflet's central surface near the central

leaflet intersection. The mounting tube's fixture included a rotary bearing, allowing rotational adjustment of the region of the valve seen by the cameras such that each leaflet could be visible when using the angle mount. Load was applied to the valves via peristaltic pumps, decreasing the pressure behind the valve through altering the pump flowrate. Images, aortic pressure, and ventricular pressure were recorded at 64Hz. For most valves and conditions, pressure differentials of 60mmHg, 80mmHg, and 120mmHg were produced across the valve via control of the pumps.

Analysis Parameters

A subset size of 30 pixels and step size of 15 pixels was used for all deformation analyses. The primary outcome measures included principal technical strain and displacement with a reference value taken at the minimum pressure under which the valve would be closed.

RESULTS & DISCUSSION

The system results in a virtual strain gauge (VSG) size of 1.0mm with a noise floor estimate of 0.02mm in-plane and 0.07mm out of plane. The deformation of the commercial TAVR valves tested showed mean displacements on the leaflet bellies of 0.7-1.1mm compared to 0.3-0.8mm in the Abbasi study. [2]

The presented system can continue to be improved. While the current patterning technique is largely successful, speckle resistance to fade under wear, adherence, and the minimum feature size can all still be improved. Additionally, a more robust valve orientation adjustment method would enable more surface of the leaflets to be measured and both the pressure measurement and pump control can be improved to yield more precise control over the load applied to the valves.

Future studies using these techniques will include the analysis of a phantom sample for uncertainty evaluation, a pre- and post- wear analysis on a set of custom TAVR valves, and validation of valve finite element modeling.

EFFECTS OF WILDLAND FIRE SMOKE EXPOSURE ON AIRFLOW AND PARTICLE DEPOSITION IN THE MOUSE RESPIRATORY TRACT

Matthew J. Eden (1), Jacqueline Matz (1), Chiara Bellini (1), Jessica M. Oakes (1)

(1) Department of Bioengineering, Northeastern University, Boston, MA, USA

INTRODUCTION

The occupational health hazards associated with being a wildland fire fighter (WLFF) remain largely unknown, in spite of growing evidence that wildland fire smoke (WFS) inhalation may affect the function of both pulmonary and extrapulmonary organs. Epidemiological data is challenging to acquire in the WLFF population due to the sporadic nature of wildland fire events, varying length of employment, and because WLFFs are constantly mobile. To compliment limited epidemiological data, animal models are valuable tools for ascertaining the health effects of repeated WFS exposure.

We recently developed a mouse model to investigate the cardiopulmonary health implications following repeated WFS exposure¹. To design our exposure protocol, we leveraged 1-D dosimetry modeling to equate the smoke particle mass deposited on the lungs of our mouse model to that of a WLFF with a mid-length career, normalized by their respective lung surface areas. Following exposure, we experimentally assessed alterations in pulmonary health through functional and structural measurements. Herein, we integrate experimental measurements into a high-fidelity computational fluid-particle dynamics (CFPD) framework to understand how WFS induced changes in pulmonary function impacts airflow and particle transport in the mouse upper airways.

METHODS

Recording of breathing waveforms. Smoldering Douglas fir smoke (DFS) at a mass concentration of 22 mg/m³ was generated with a custom-built apparatus, consisting of a quartz-tube furnace mounted onto a linear actuator^{2,3}. Whole-body barometric plethysmography was used to monitor breathing patterns in male *Apoe*^{-/-} mice when exposed to either filtered air (e.g., normal breathing) or DFS (N = 5). Following 15 minutes of exposure, breathing waveforms were collected to extract respiratory rate (RR) and tidal volume (TV). Their minute volume (MV) was then calculated as: $MV = RR * TV$.

Mouse Airway Geometry Construction. A male *Apoe*^{-/-} mouse was anaesthetized and whole-body imaged using a μ CT scanner (SkyScan 1276, Bruker BioSpin Co.). The open-source software SimVascular⁴ was then used to manually segment and create the mouse airway geometry, shown in Figure 1.

Figure 1: Male *Apoe*^{-/-} mouse airway model

Airflow Simulation and Particle Tracking. Airflow in the mouse airway geometry was modeled using the incompressible Navier-Stokes equations and numerically solved with SimVascular's finite element solver svFSI. A steady Dirichlet boundary condition was applied to the nostrils, at the average MV measured during either normal breathing or DFS exposure. A constant zero pressure boundary condition was applied at all outlets since the bronchial tree extended to approximately the same generation in each lobe.

An in-house Lagrangian particle tracking solver was used to model the transport and deposition of spherical smoke particles in the mouse respiratory tract⁵. A particle's position was updated using a reduced form of the Maxey-Riley equation, which accounts for viscous drag, Brownian diffusion, and gravitational sedimentation. We simulated particle sizes of 100, 150, and 200 nm, since the majority of DFS

particle mass falls within this range¹. We assumed particles were noninteracting and do not impact the flow field.

Table 1: Exposed respiration conditions, * $p<0.05$

	RR (breaths/min)	TV (mL/breath)	MV (mL/min)
Air	404 ± 8	0.30 ± 0.02	122 ± 8
DFS	83 ± 10*	0.34 ± 0.05	27 ± 4*

RESULTS

Mice exposed to DFS experienced a significant decline in MV when compared to air-exposed mice ($p<0.05$), which was driven by a stark reduction in RR (Table 1). This resulted in a 4.5x decrease in volumetric flow rate in the DFS exposed model, compared to normal breathing. The flow fields are similar between the left and right nasal passages (Figure 2, A1-A2 & B1-B2). Distal of the nostrils, most of the mass flux is concentrated at the floor of the nasal cavity, with little mass flux in the olfactory region (B1-B2). Consequently, we anticipate few particles being transported to this region. A small jet of high fluid velocity is observed at the glottis due to its smaller cross-sectional area (C1-C2). The flow split between the right and left lung is 73 and 27%, respectively, for both DFS and normal breathing (D1-D2).

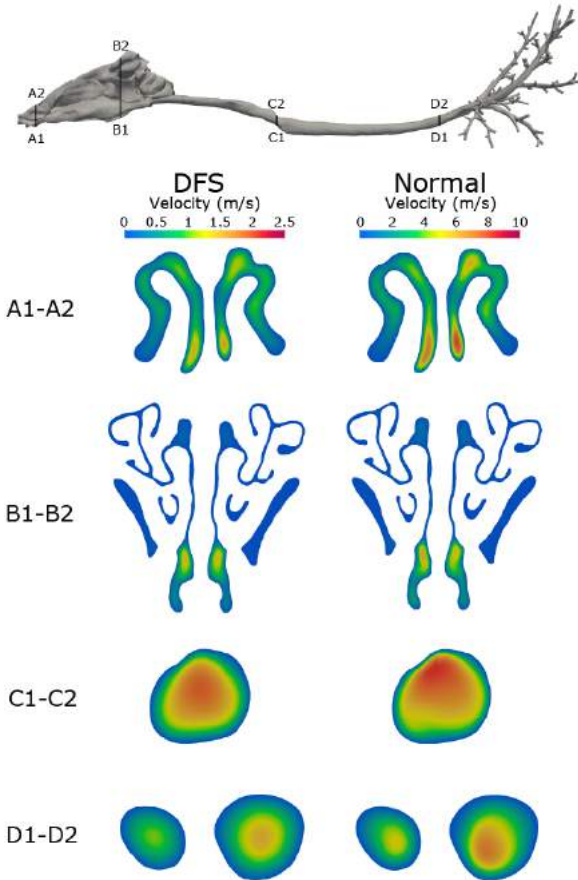

Figure 2: Cross-section velocity profiles from CFD results

Particle deposition in the size range considered in this study is notably dependent on breathing conditions, with normal breathing mice on average exhibiting a deposition percentage 146% greater than the DFS group (Figure 3). Deposition in the nasopharyngeal region is effectively constant over the particle sizes considered for the DFS exposed group, however, there is a notable decrease in deposition in the upper respiratory tract (URT) for 200 nm particles, compared to the

other two sizes. In the normal breathing group deposition is relatively constant across the 150 and 200 nm particle sizes, while there is a substantial decrease in deposition in the URT between 100 and 150 nm.

Figure 3: Particle deposition fraction at varying sizes

DISCUSSION

To date, the non-accidental occupational health risks posed to WLFFs remain poorly understood. Mouse models serve as an effective surrogate for studying the health consequences following repeated WFS exposure. Regional deposition of smoke particulates impacts how toxins are cleared, retained, or translocated from the lung, thereby affecting their overall toxicity. Thus, the deposition patterns of inhaled particulates are important to consider when interpreting the health consequences following exposure. In this study, we leveraged plethysmography and particle size measurements to computationally investigate how DFS exposure impacts airflow and particle transport in the mouse respiratory system.

Consistent with previous studies, we found that exposure to biomass smoke causes a significant decrease in the mouse minute volume⁷. This reflex may be triggered by sensory irritants found in DFS. We found that deposition patterns in the mouse respiratory tract are dependent on the ventilation rate, in agreement with Kolanjiyil et al. (2019)⁸. Therefore, breathing measurements are critical for accurately calculating particle deposition, particularly when the treatment may alter respiration. Lastly, our CFPD results show that regional deposition percentages can be sensitive to particle size. This is likely due to size-dependent contributions from the mechanisms by which particles deposit in the lungs, mainly sedimentation, impaction, and diffusion.

In conclusion, we developed a mouse airway model to enable high-fidelity CFPD simulations. We found regional and cumulative deposition of smoke particulates to be dependent on the particle size and breathing conditions. Future work will focus on implementing physiologically-inspired boundary conditions to investigate the effects of WFS-induced remodeling on airflow and particle deposition.

INTRODUCTION

Carries and trauma compromise pulpal regeneration demanding an endodontic intervention to restore overall tooth health. Current endodontic interventions of replacing damaged pulp with synthetic filling such as calcium hydroxide paste (CHP) and mineral trioxide aggregate (MTA) *via* root canal therapy have proven successful against early bacterial protection and dentin bridge formation. However, bacterial leakage overtime into healing pulp, poor cohesive strength, cost, and longer setting time highlight the need for a novel dental restorative offering improved patient outcomes [1,2]. Preserving the biosensing ability of tooth through vital pulp therapy have proven successful in younger population, and a cell homing strategy can recruit endogenous dental pulp stem cells (DPSCs) residing in the pulp tissue to the damaged site in need of repair. Exosomes, bioactive vesicles constantly shed by cells can serve as both biomarker and drug with detailed profiling of its content for reversing disease pathophysiology [3,4]. We hypothesized that exosomes would stimulate dental pulp regeneration by promoting DPSC recruitment and subsequent angiogenic differentiation. The aim of this study was to characterize DPSCs-derived exosomes (DPSC-Exos) and evaluate the effect of DPSC-Exos on *in-vitro* cell homing, proliferation and angiogenic differentiation for pulpal regeneration. We further examined the profile of exosomal microRNA (miRNA) for validating exosome effects.

METHODS

Characterization of DPSCs and DPSC-Exos: Incisor pulps from two New Zealand White rabbit cadavers were harvested to isolate DPSCs and establish its lineage-specific differentiable ability; angiogenesis and odontogenesis. Exosomes were isolated under growth media condition. The characterization of exosomes was confirmed by Exo-Check™ exosome antibody array (System Biosciences) which included 8 positive markers (CD63, epithelial cell adhesion molecule (EpCAM), annexin A5 (ANXA5), tumor susceptibility gene 101 (TSG101), flotillin-1 (FLOT1), intercellular adhesion molecule 1 (ICAM), programmed cell death 6 interacting protein (ALIX), and CD81), a negative control (cis-golgi matrix protein (GM130)), 2 positive controls (+ ctrl) and blank. Exosome morphology was imaged using scanning electron microscopy (SEM), and cellular exosome uptake was evaluated

by a PKH67 uptake assay (Sigma-Aldrich) according to the manufacturer's instructions. The size distribution and concentration of DPSC-Exos were analyzed by nanoparticle tracking analysis (NTA).

***In-vitro* effects of DPSCs-Exos:** Initial cytotoxicity screening was performed to select optimal concentration of exosomes with varying concentration of exosomes (low (Exo-L): 5×10^7 /ml, medium (Exo-M): 5×10^8 /ml, high (Exo-H): 5×10^9 /ml) prior to cell proliferation assay using CellTiter 96® Aqueous One Solution (Promega). Transwell® plates with an 8 µm pore (Corning) was used for a migration assay, and the number of migrated cells was stained with Calcein AM (Thermo Fisher Scientific) after removing non-migrated cells. RNAs were isolated from DPSCs treated with DPSC-Exos for real-time polymerase chain reaction (RT-PCR) with probes of key angiogenic markers including vascular endothelial growth factor A (VEGFA), Fms-related tyrosine kinase 1 (FLT1), and platelet and endothelial cell adhesion molecule 1 (PECAM1).

miRNA profiling via Next-Generation Sequencing (NGS): To quantitate known small RNAs and to identify novel miRNAs, we used the Nextflow-based workflow nf-core/smrnaseq (version v1.1.0, <https://github.com/nf-core/smrnaseq>) as a small-RNA sequencing analysis pipeline. To determine differential expression, a model incorporating all the experimental factors was created, and Wald tests were used to compute statistical metrics. To identify novel miRNAs, sequence read files (fastq) from samples in the same group were first concatenated together then ran through the same nf-core/smrnaseq workflow with the miRDeep2 software used for novel miRNA identification. The results from miRDeep2 were filtered to include only potential novel miRNAs.

RESULTS

Characterization of DPSCs and DPSC-Exos: Multi-differentiation potential of DPSCs was validated by both endothelial tube formation and alizarin red staining. DPSCs formed capillary-like formation (Fig. 1A) and apparent calcium deposit (Fig. 1B) in angiogenic and odontogenic induction medium, respectively. Isolated DPSC-Exos were confirmed by exosome markers with ANXA5, TSG101, FLOT1, ICAM, ALIX, and CD81 (Fig. 1C). Exosomes had morphologically a spheroid shape with approximately 100 nm-diameter (Fig. 1D and F)

and $11.6 \times 10^{10}/\text{ml}$ concentration (Fig. 1F). PKH67-stained exosomes were effectively taken up by DPSCs cultured under exosome-depleted media condition (Fig. 1E).

In-vitro effects of DPSCs-Exos: Cytotoxicity test revealed that the cells were less damaged in concentrations of $5 \times 10^7/\text{ml}$ and $5 \times 10^8/\text{ml}$ in comparison with higher concentration ($5 \times 10^9/\text{ml}$) (Fig. 2A). Cell proliferation assay with preselected exosomal concentrations ($5 \times 10^7/\text{ml}$ and $5 \times 10^8/\text{ml}$) demonstrated an anabolic effect of DPSC-Exos in $5 \times 10^8/\text{ml}$ (Exo-M) (Fig. 2B). In the migration assay, the number of migrated cells was dramatically increased in exosome-treated groups, especially $5 \times 10^8/\text{ml}$ (Exo-M) (Fig. 2C and D). In addition, DPSCs treated with DPSCs-Exos showed significant increases in the mRNA levels of angiogenic markers, VEGFA, FLT1, and PECAM1 when cultured with angiogenic induction medium (Fig. 2E).

miRNA profiling: A total of 474 mature and 254 hairpin miRNAs were discovered (Table 1). Interestingly, *ocu-miR-146a-3p*, *ocu-miR-199a-3p*, *ocu-miR-122-5p*, *ocu-miR-221-3p*, *ocu-miR-143-3p*, *ocu-miR-24-3p*, and *ocu-miR-21-5p* were detected over 100,000 total reads. *miR-146a-5p* and *miR-122-5p* function as negative regulation of inflammatory response [5] and positive stimulation of cell proliferation [6], respectively. Regulation of nitric oxide pathway and extracellular signal-regulated kinase (ERK) / mitogen-activated protein kinase (MAPK) signal pathways by *miR-199a-3p* and *miR-21-5p* can involve in promoting angiogenesis [7,8]. Additionally, 88 novel miRNAs were identified (data not shown).

DISCUSSION

The objective of this study was to demonstrate the potential of DPSCs-Exos on pulpal regeneration. Exosome treatment significantly improved cell migration/homing, proliferation and angiogenic differentiation *in-vitro*. Through NGS, the profiled miRNAs can be functionally categorized to confirm its efficacy in dental pulp regeneration. For *in-vivo* efficacy of DPSC-Exos, we plan to use a partial pulpotomy animal model, which can mimic clinical conditions in human (Figure 3). In conclusion, our exosome-based cell homing and angiogenic differentiation strategy has a significant therapeutic potential for dental pulp regeneration.

IMPACT FORCES OF DIVISION 1 COLLEGIATE OFFENSIVE AND DEFENSIVE AMERICAN FOOTBALL PLAYERS USING PRACTICE SLED

Sloan Kanat (1), Ryan Harth (1), William Burghardt, PhD (2), Tamara Reid Bush, PhD (1)

(1) Department of Mechanical Engineering, Michigan State University, East Lansing, MI, USA

INTRODUCTION

The NCAA reports a steady increase in the number of collegiate American football players from 40,000 in 1981 to over 70,000 players in 2013 [1]. As the number of players increases in the sport, so has the number of injuries. A study analyzing collegiate football players through 2002-2020 reported .89 injuries per year which correlates to 1.17 per 100,000 participants obtaining a sports-related structural injury [2]. Additionally, the study found that the majority of players injured were on defense or offense at the time of injury, as opposed to being on special teams [2].

Repeated head trauma, even minor traumas that may not be recognized as a moderate or severe traumatic brain injury (TBI), can lead to chronic traumatic encephalopathy (CTE). CTE is brain degeneration that occurs after repeated head trauma. CTE symptoms can be latently onset making it harder to diagnose until later in life. One study found 87% of a sampled population of ex-football players (n=202 players) had evidence of CTE [2]. CTE can lead to mood disorders in younger populations and cognitive impairment in older populations [3]. With the sport of football growing every year, the risk of more individuals experiencing CTE also increases.

Previous research has focused on measurement of direct head and helmet impacts. Although an important measure, direct helmet impacts do not provide the ability to look at the force transference when the impact occurs elsewhere on the body, for example to the torso. Since it is clear that the potential for head injury exists with tackle football, it is equally important to quantify and understand the magnitude of forces that occur to the body with a “hit”, particularly with regard to a torso hit. Using this information, hit technique can be analyzed for both efficiency and safety.

The goals of this study were to quantify the impact force of a football hit from different stance points (2, 3, and 4 point stances). This data will help to bridge the gap between direct head impact and transference impacts to other regions of the body.

METHODS

This study investigated 15 Michigan State University male football players and obtained the forces they exerted on a practice sled (IRB Approval #00007331). Players had an average age of 19.29 years with a standard deviation of 1.43 years and were exclusively offensive and defensive linemen. A Bertec force plate was mounted on a practice sled and a blocking pad was secured on top of the system. The measurement system was hit by the player and then was pushed up the rails as the player advanced forward. Force data perpendicular to the sled (Z direction) were collected at a sample rate of 1000 Hz during a simulated hit (Fig. 1). Anthropometric measurements of each player were also recorded.

Figure 1. Mounting of the force plate with green blocking pad secured. Z-direction was labeled to show the direction of recorded force.

The players began the hit in one of three different stances: 2-point, 3-point, and 4-point (Fig. 2); the stance selection was randomized. Each player completed two trials in each of the stances.

The hit against the force plate was broken up into three sections. The impact was defined as the largest recorded force immediately after contact with the force plate was made. After the initial contact, the players continued to push the sled until it reached the end of the track. Two parameters were developed to analyze these data 1) average drive force and 2) a drop-off force. The force recorded from the time the sled began to move until the end of the track was averaged to obtain the drive

force. The drop-off force occurred between the impact and the beginning of the drive force. The measured force decreased rapidly after the initial impact and before the drive force began.

Figure 2. Demonstration of a player in A) a 2-point stance, B) a 3-point stance, C) a 4-point stance

RESULTS

Figure 3. Characteristic example of force generated by a player performing a hit on the sled.

Figure 3 demonstrates the impact force, or the peak force immediately after contact with the force plate was made. It also demonstrates the start and end of the drive force. After the initial impact force, the drop-off force was calculated for each player (Fig. 4). This drop-off force signifies a decrease in the applied force against the force plate before the player begins to drive the sled forward.

Figure 4. Demonstration of the drop-off values. The graph on the left shows a player with a much smaller drop off value than the player in the graph on the right.

As seen in Figure 5, when examining a set of five players who were in the same height (300-305cm) and weight ranges (87.5-89.8kg) two of the five players had a maximum impact force below the average and the other three were above the average.

The stance in which the maximum impact force occurs varies between players (Fig.6). The percentages (33% in 2-point, 27% in 3-point, 40% in 4-point stance) show the number of players that achieved the maximum impact in the corresponding stances.

Figure 5. Maximum impact force values for 5 players with similar height and weight. The red line indicates the average impact force across players.

Figure 6. Maximum impact force in each stance.

DISCUSSION

This study quantified the forces exerted by football players during a hit on a practice sled across different tackle stances.

The impact values represent the maximum value delivered by the football player. These would also represent the force that the player was applying to their opponent and can be used for consideration in force transmission as it relates to head trauma. This research provides a better understanding of the force profile that is seen when an “initial hit” is being applied to the players during the initial drive between offensive and defensive players.

In terms of the stance, for some players, the stance affected the impact force applied to the sled, whereas others, the stance has little influence on the force generated. Our data also indicates that estimating the force generated by a player just by their height or weight is problematic. In our sampling of players with similar height and weights, there was a differential force of ~700N in the maximum impact force.

While there was substantial research regarding impacts directly to players helmets, there is limited data regarding the force exerted at the initial impact of a body hit after the whistle is blown to start a play. The data presented here demonstrates the ability to gather force data and analyze it from multiple aspects of a tackle, including impact force, drive force and drop-off force.

Future work for this study will look at the mechanics of the transference of forces from a hit to the chest up through the neck and to the head. It will also look at differences in teenage versus adult impacts to determine the influence of the weight of the player and the muscle distribution to the transference of forces to the head during impact.

GROWTH AND REMODELING IN SPARSE AND SEMI-SPARSE TISSUES: BRIDGING THE GAP BETWEEN THE CONSTRAINED MIXTURE MODEL AND ESHELBY'S INCLUSION

Ryan R. Mahutga (1), Elizabeth D. Shih (1), Patrick W. Alford (1)

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

INTRODUCTION

The field of computational growth and remodeling (G&R), and computational mechanobiology has largely been driven by constrained mixture models [1]. These models work well for many tissues, particularly those with dense, homogeneous microstructures [2,3]. However, tissue compositions vary widely between organs, and in disease. For example, the anterior cruciate ligament (ACL) has a much lower density of cells than the aorta. While the aorta does tend to have dense, organized cellular substructures, it is quite common to see apoptosis and reductions in cellularity in diseases like aneurysm.

The foundation of many models of growth and remodeling is tensional homeostasis. Tensional homeostasis assumes that cells attempt to modify themselves and their environment to return to a homeostatic state of stress. In tissues with low or reduced cellularity, stresses can be concentrated near cells, which could change the remodeling process. In this work, we propose a model based on strain concentration factors allowing us to bridge between the constrained mixture assumption and Eshelby's inclusion [4,5]. This allows us to model growth and remodeling in cell-sparse tissues like the ACL, and through the time-course of disease like aneurysm.

METHODS

Tissue Material Behavior: For this model we assume tissues are made up of an incompressible mixture of constituents including an extracellular ground matrix given by

$$W^g = C_1(I_1 - 3) \quad (1A)$$

where W^g is the strain energy density, C_1 is the neo-Hookean material parameter, and I_1 is the first strain invariant of the right Cauchy-Green tensor, an extracellular collagen fiber component given by

$$W^c = k_1 \left[\exp \left(\alpha \left(\lambda^2 + \frac{2}{\lambda} - 3 \right) \right) - 1 \right] \quad (1B)$$

where W^c is the collagen strain energy density, k_1 is the collagen fiber modulus, and α is the collagen fiber nonlinearity, and a cellular component having both active and passive properties given by

$$W^m = C_a \left[\left(\frac{\lambda}{\lambda_a} \right)^2 - 1 \right] + k_2 \left[\exp \left(\beta \left(\lambda^2 + \frac{2}{\lambda} - 3 \right) \right) - 1 \right] \quad (1C)$$

where W^m is the cellular strain energy density, C_a is the active contraction parameter, λ_a is the minimum active contraction stress, k_2 is the cellular fiber modulus, and β is the cellular fiber nonlinearity.

The total stress within the tissue is given in terms of the mass fractions and the strain concentration factors in 1D as

$$\sigma_{11} = S^{cell} \varphi^m \sigma_{11}^m + S^{ecm} (\varphi^c \sigma_{11}^c + \varphi^g \sigma_{11}^g) \quad (2A)$$

Where σ_{11} is the total averaged stress, S^{cell} is the 1D cellular strain concentration factor, $\varphi^h = m^h / \sum_h m^h$ is the mass fractions of each constituent, h, subject to $\sum_h \varphi^h = \varphi^m + \varphi^c + \varphi^g = 1$, σ_{11}^h is the constituent stress as calculated from the remotely applied boundary conditions (i.e. calculated like the constrained mixture model), and S^{ecm} is the extracellular matrix strain factor calculated to make the total strain factor stress equivalent to the constrained mixture stress.

Based on previous work in our lab, a good functional form for the 1D strain concentration factor is based on an exponential weighting of the mass fraction with the Eshelby strain factor

$$S^m = \exp(-\kappa \varphi^m) [S^{Eshelby} - 1] + 1 \quad (2B)$$

Where $S^{Eshelby}$ is the Eshelby strain factor, which is a function of cell aspect ratio (diameter to length) and cell stiffness relative to the extracellular matrix stiffness [5].

Growth and Remodeling: Growth and remodeling is applied similarly to conventional constrained mixture models with the addition of a strain factor. In our model, collagen turns over and cells and the ground matrix do not. The evolution of collagen mass is

$$m^c(t) = m^c(0)Q(t) + \int_0^t \dot{m}^c(t, T) dt \quad (3A)$$

where $m^c(0)Q(t)$ is the survival of the initial mass at time t, $\dot{m}^c(t, T)$ is the change in mass of collagen (which is deposited at time T and exists at the current time t). The change in collagen mass is broken down as an exponential decay and an addition related to the cellular stress level

$$\dot{m}^c(t) = \begin{cases} -k^d m^c(t) + \dot{m}^\alpha & \text{if } \sigma^m(t) \leq \sigma_\infty^m \\ \dot{m}^\alpha + \dot{M}(\sigma^m(t) - \sigma_\infty^m) & \text{else} \end{cases} \quad (3B)$$

where k^d is the decay time constant for masses existing prior to time t , \dot{m}^α is the basal deposition rate for mass deposited at time t , \dot{M} is the cell stress dependent deposition rate, and σ_∞^m is the target cell stress. Collagen is further assumed to be deposited at a pre-defined stretch so the mass additions are made at length $L^c(t) = L(t)/\lambda_{dep}$. Because of the inclusion of deposition stretch, the masses are tracked individually, the differential equations are solved using forward Euler, and integrals evaluated using a simple Riemann sum.

1D Examples: To demonstrate this new G&R framework, we apply two simple 1D cases: 1. a bar at fixed length and 2. a bar under controlled stress. One could think of these cases loosely representing growth and remodeling of cell sparse tissues during 1. the period following tendon or ligament reconstruction or grafting and 2. normal growth of the tendon or ligament with the body during development.

RESULTS

Remodeling of a 1D Bar at Fixed Length: During remodeling of a bar at a fixed applied length, we see an instantaneous spike in stress following the application of stretch (after the Basal remodeling phase), which is recovered, as one might expect. All constituents experience a spike in stress, which is recovered with the remodeling of collagen (Fig. 1). As the cell strain factor increases (Fig. 1A), we get more collagen remodeling, which results in lower ECM stresses overall (Fig. 1B). When we decrease the magnitude of stretch, we see a dip in the stresses for all constituents, and we still see lower overall stresses on the ECM in cases of increasing strain factor.

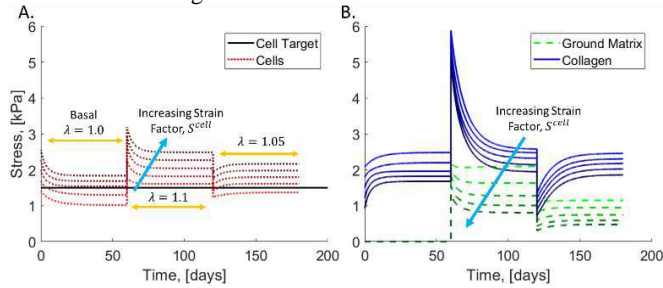

Figure 1. A. Cellular stresses and **B.** extracellular matrix stresses during stretch-controlled remodeling using different strain factors.

During the stretch phase, we further see increases in collagen mass fraction which accompanies decreases in ground matrix and cell densities (Fig. 2A). The result of this decrease in cellular mass fraction is an increase in strain factor (Fig. 2B). Further, the higher the initial strain factor, the more collagen is added, the lower the cell mass fraction, which results in larger increases in the remodeling strain factor creating a positive feedback loop. When, the stretch is reduced, we see decreases in collagen content, which correspond to increases in ground matrix and cell content, and leads to lower cell strain factors.

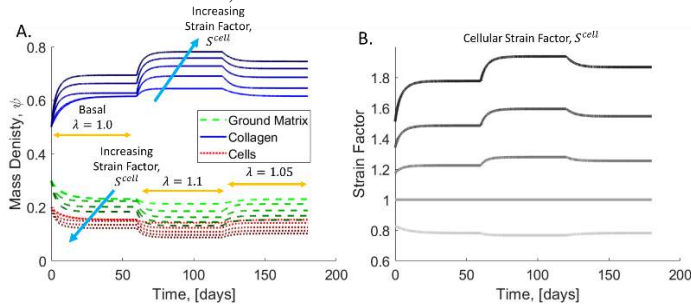

Figure 2. A. Mass fraction evolution of constituents during remodeling and **B.** Evolution of the cellular strain factor during remodeling.

Remodeling of a 1D Bar under Controlled Force: Under an increase in applied stress (following the Basal phase), the cell stress increases along with the ground matrix, while the collagen remodels to lower stress (Fig. 3). When the stress is decreased, the cell stress and ground matrix stress slowly decrease, while the collagen stress increases. Similarly to the controlled stretch, an increase in cellular strain factor resulted in higher cell stress which results in lower ECM stress (Fig. 3).

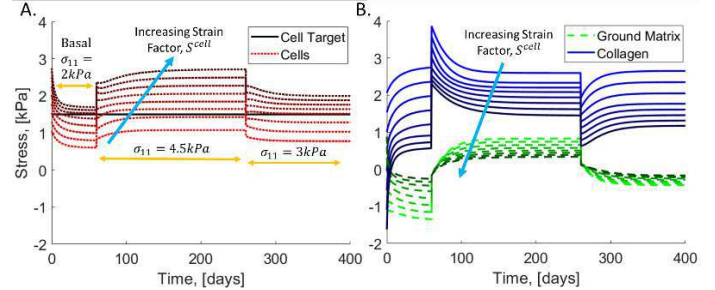

Figure 3. A. Cellular stresses and **B.** extracellular matrix stresses during stress-controlled remodeling using different strain factors.

The bar grows with increased stress and shrinks with reduced stress, as one might expect (Fig. 4A). In addition, higher strain factor results in more growth with higher stress, and more contraction with lower stress (Fig. 4A). When the stress is increased, the collagen density increases while the ground matrix and cell content decreases (Fig. 4B). When the stress is decreased, the collagen content decreases while the ground matrix and cell content increase (Fig. 4B).

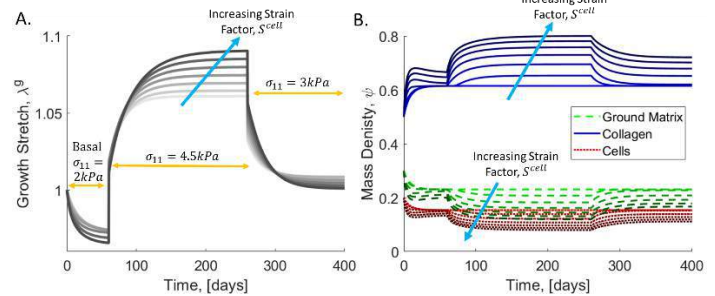

Figure 4. A. Growth under sustained stress, and **B.** mass fraction evolution of constituents during remodeling

DISCUSSION

Growth and remodeling in cell-sparse tissues is a significant challenge with current computational tools [1,2,3]. To try to understand how cell sparsity might influence G&R, we have created a new framework based around the definition of strain factors allowing us to span from the single inclusion of Eshelby to the fully parallel assumptions of the constrained mixture model. Our model shows that as tissues become more sparse, the cellular stresses increase leading to increased collagen deposition, which results in lower overall ECM stress. The increase in collagen content drives down the cell content which increases the strain factor. Thus, this creates a positive feedback loop where the addition of more matrix results in higher strain concentration on cells, which results in more remodeling.

INTRODUCTION

The life-threatening medical condition known as acute ischemic stroke (AIS) occurs when a blood clot lodges in the cerebral vasculature and restricts blood flow to the brain. A number of previous studies have been performed to examine cerebral hemodynamics [1-7], primarily focusing on measuring regional blood flow. The severity of AIS is largely determined by the location and the extent to which emboli become trapped in the cerebral vasculature. Elucidating the underlying causes and therapy of AIS requires quantifying blood flow, pressure, and embolus migration in the cerebrovascular, which are extremely challenging to measure in AIS patients. The goal of our research is to develop and validate a computer model for predicting the hemodynamics and the migration and lodging of emboli in complex anatomical models of the cerebrovasculature.

METHODS

As reported by Bhardwaj et al. [8], a representative anatomical model of the aorta and cerebral vasculature is used in this study (Fig. 1). The model was designed by United Biologics (Irvine, CA, USA) based on patient medical image data from several sources (e.g., the NIH Visible Human Project, patient-specific CT data). The *in vitro* model is made of silicone with an elasticity that is representative of human arteries. A corresponding computational model of the *in vitro* model is created by reconstructing high-resolution 3D micro computed tomography (μ -CT) scans (Fig. 2). Using the 3D reconstructed model, computational fluid dynamics (CFD) simulations are performed using the open-source computational continuum mechanics library, OpenFOAM.

The working fluid in the experimental flow loop that is being modeled is a solution of water (60% by weight) and glycerol (40% by weight) that has a density and dynamic viscosity similar to blood [9] (1.09 g/mL and 3.98 cP, respectively). The inlet flow was ensured to be fully developed by connecting an additional tube of 900 mm in length to the model inlet. By adjusting clamps on the outlet tubing downstream of the pressure and flow rate measurement sites, the regional flow distribution to the different arteries was tuned to match available data in the literature [10-11]. This resulted in a regional flow distribution

in which 73.2% of the fluid flowed through the descending aorta and 26.8% was distributed to the other arteries branching from the aortic arch. The *in vitro* stroke condition was achieved by clamping right middle cerebral artery (RMCA), right posterior artery (RPCA) and right access port using forceps.

Figure 1: Circulatory flow loop illustrating (a) the experimental setup for normal physiological conditions and (b) the locations of cerebral artery clamps that are used to mimic a stroke condition. The flow rate and pressure are measured during steady flow at the numbered cerebrovascular outlets. Here, LSA and RSA are left and right subclavian arteries, LECA and RECA are the left and right external carotid arteries, LMCA and RMCA are the left and right middle cerebral arteries, and the LAA and RAA are left and right anterior arteries.

Figure 2 depicts the CFD models for the normal and stroke conditions (clamping RMCA, RPCA and right access port). The boundary conditions were chosen to correspond to the *in vitro* experiments. To obtain fully developed flow entering the inlet to the ascending aorta at a flow rate of 5.17 L/min, a steady, uniform inlet velocity was applied to the extended inlet. On the walls, which were assumed to be rigid, a no-slip velocity boundary condition was imposed. At the inlet, a zero-gradient pressure condition was used, and fixed static pressure boundary conditions were specified for all outlets. The outlet pressure values were determined by

iteratively performing simulations to match the measured flow rate in each outlet in the experiments to within $\pm 10\%$.

Figure 2: (a) 3D reconstructed computational model of the corresponding *in vitro* cerebrovascular model for normal physiological conditions with (b) a cut plane in the aortic arch to illustrate the mesh, and (c) the CFD model for the stroke condition.

RESULTS

Table 1 summarizes the volumetric flow rate (L/min) and pressure (mmHg) data recorded at the various arterial outlets in the experiments. The superior arteries originating from the aortic arch receive 26.8% of the overall flow rate entering the model and 73.2% of the fluid flows through the descending aorta. For the stroke condition, when there is no flow from outlet 4, the change in arterial pressure and volumetric flow rate were also measured.

Table 1: Flow rate (L/min) and mean arterial pressure (mmHg) obtained from *in vitro* experiments in normal and stroke conditions at the inlet and outlets.

Location	Flow Rate (L/min)		Pressure (mmHg)		% Diff	
	Normal	Stroke	Normal	Stroke	Flow Rate	Pressure
Inlet	5.16	5.15	84.91	84.15	-0.19	-0.90
1	0.197	0.206	83.84	83.24	4.57	-0.72
2	0.199	0.212	82.56	81.21	6.53	-1.64
3	0.154	0.161	83.93	82.52	4.55	-1.68
4	0.143	0	82.11	-	-	-
5	0.147	0.149	83.43	80.34	1.36	-3.70
6	0.157	0.159	83.51	79.23	1.27	-5.13
7	0.189	0.188	83.9	80.78	-0.53	-3.72
8	0.185	0.185	83.83	79.24	0.00	-5.48
9	0.331	0.322	80.31	78.44	-2.72	-2.33

The experimental measurements reveal that the pressure at all of the outlets reduces for the stroke condition. As seen in Table 1, the flow rate through the right artery outlets, as well as outlets 5 and 6, increases to compensate for the blocked flow caused by the stroke. Figure 3 depicts the pressure and velocity distribution for the stroke condition from CFD. A comparison of pressure and volumetric flow rate between the normal and stroke conditions reveals that the mean pressure at all of the outlets reduces in the stroke condition, as observed in the experiments.

Figure 3: (a) Mean pressure contours and (b) profiles of mean velocity at various sections in the anatomical cerebral vascular model from CFD for the stroke condition.

DISCUSSION

In order to investigate flow and embolus migration and lodging in the brain, this work aims to create a realistic *in vitro* experimental model and a corresponding computational model of the cerebral vasculature. To validate the accuracy of the flow predictions, pressure and flow rate measurements were acquired and corresponding CFD simulations were performed. Overall, the CFD simulations compare reasonably well with the experiments. The aortic arch flow pattern in the current study is similar to that reported by Numata et al. [12]. The transient flow field found in the aortic arch in our work has also been reported in other studies [13-16]. Future work will investigate the migration and lodging of emboli in this cerebrovascular model.

QUANTIFYING THE EFFECT OF FEMORAL COMPONENT INTERNAL ROTATION ON LIGAMENT FORCES FOR TOTAL KNEE ARTHROPLASTY WITH VARUS TIBIAL

Jonathan Glenday, Jonathan Vigdorchik, Peter Sculco, Cynthia Kahlenberg, David Mayman, Eytan Debbi, Joseph Lipman, Timothy Wright, Fernando Quevedo Gonzalez

Hospital for Special Surgery, NY, NY, USA

INTRODUCTION

One of the main goals of total knee arthroplasty is to achieve a well-balanced knee that will provide appropriate kinematics, stability, and longevity [1]. Modern TKA techniques, like kinematic alignment, avoid soft tissue manipulations and achieve balance of the knee through appropriate component placement that replicates the native knee anatomy [2]. After component placement, surgeons evaluate knee balance by applying varus and valgus stresses to the knee, typically in full extension and in 90° of flexion, to determine the constraints provided by the different ligaments. While biomechanical research typically focuses on the effect of varus/valgus component alignment in the frontal (i.e., coronal) plane on joint mechanics and balance [3], little attention has been paid to component alignment in other planes. As such, while the axial (internal/external) rotation of the femoral component can directly impact knee balance in flexion, its effect on the soft tissue forces, particularly in the context of alignments which replicate the native coronal orientation, remains unclear. Furthermore, the connection between this intraoperative knee balance assessment and knee function during daily activities also remains unclear. Therefore, we asked two questions: (1) what is the effect of internally rotating the femoral component to match the tibial coronal alignment in flexion on the intraoperative ligament forces? (2) How do these intraoperative ligament forces relate to functional ligament forces during gait?

METHODS

We adapted a generic multibody dynamic musculoskeletal model of the lower limb [4], developed in OpenSim [5] to calculate subject-specific ligament forces and tibiofemoral kinematics and kinetics (Fig. 1). The model included 44 Hill-type muscle-tendon units spanning the leg. The affected knee of the generic model was replaced by a six degrees-of-freedom (DOF) tibiofemoral joint and a 6 DOF patellofemoral joint, using the Joint and Articular Mechanics (JAM) toolbox (<https://simtk.org/projects/opensim-jam>) [3]. This formulation uses 12 non-linear spring bundles to represent the principal knee ligaments, patellar tendon, posterior capsule, and iliotibial band. This formulation models the ligaments as non-linear, tension-only springs, with a slack region where the ligament could stretch without generating force and a linear region, where the ligament force was proportional to its change in length. In addition, the JAM formulation uses an elastic foundation model to determine the joint contact forces in the knee.

We adapted the generic model by introducing the subject-specific anatomy and motion capture markers from the third Grand Challenge Competition to Predict In Vivo Knee Loads [6]. This dataset included pre- and postoperative CT-scans and motion analysis data of five gait trials from a 63-year-old female with an instrumented TKA.

Next, in the coronal (frontal) plane, we virtually implanted the tibial component in 5° varus and the femoral component in 5° valgus to represent an extreme deviation of the components from the mechanical axes of the bone whilst maintaining a neutral hip-knee-angle alignment. For the axial rotation of the femoral component, we considered two scenarios: (1) the component oriented parallel to the epicondylar axis (2) the component internally rotated by 5° to match the varus alignment of the tibial component.

For the JAM toolbox's elastic foundation model, we discretized the articular surfaces of the femoral component and tibial insert using

triangular elements with an edge length of 1 mm, which was reported to be adequate for musculoskeletal simulations [7]. The femoral component was assumed rigid, and the tibial insert was modeled as linear elastic ultra-high molecular weight polyethylene (UHMWPE) with an elastic modulus of 463 MPa and a Poisson's ratio of 0.46. Similar to prior studies [3], we reduced the stiffness of the tibial insert by a factor of 10 to improve simulation convergence.

We considered a single definition of the ligament properties across based on the default knee position. Ligament stiffness was obtained from literature and the slack length of each bundle was calculated using the resting length at 0° of knee flexion and the corresponding reference strains [3].

For both varus alignments, we reproduced the intraoperative varus/valgus assessment by performing passive forward dynamic simulations at 0° (full extension) and 90° of knee flexion with an applied tibial compression of 50 N and 10 Nm of varus torque and valgus torque. Subsequently, we used the Concurrent Optimization of Muscle Activation and Kinematics algorithm [3] to simulate the five gait trials provided in the dataset. For both the varus/valgus assessments and the gait simulations, our primary outcome measure was the force of the medial and lateral collateral ligaments (MCL and LCL, respectively) and the posterior cruciate ligament (PCL).

Figure 1: Overview of the musculoskeletal simulations used to predict TKA joint mechanics.

RESULTS

During the simulated intraoperative varus/valgus assessments (Fig. 2), femoral component internal rotation decreased the MCL force at 90° flexion (0 N vs. 102 N for the valgus assessment). Conversely, femoral component internal rotation resulted in negligible change of the LCL force at full extension and a small decrease at full extension at 90° flexion (6 N vs. 1 N for the varus assessment). Femoral component rotation also resulted in a large increase of the PCL force, which was greater at 90° flexion than full extension (278 N vs 630 N across both assessments).

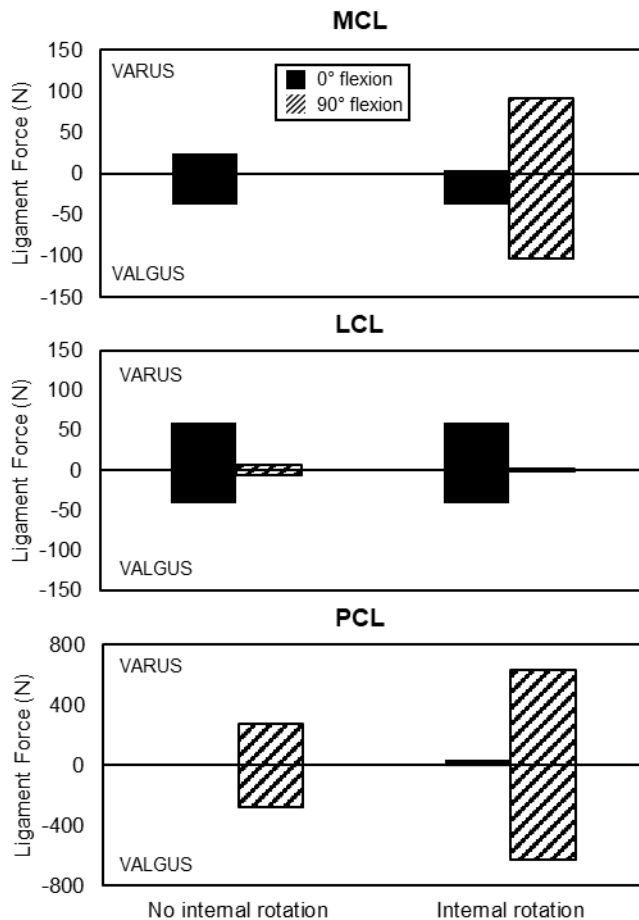

Figure 2: Bar graphs of the MCL (top), LCL (middle), and PCL (bottom) forces for the varus/valgus assessments performed at 0° and 90° of flexion for the varus alignment without (left) and with matching (right) femoral component internal rotation. Ligament force is reported as a positive value for the varus assessment and as a negative value for the valgus assessment.

During gait, femoral component internal rotation increased the MCL force, especially at late stance, when the knee flexion was at its greatest (Fig. 3, top). Femoral component internal rotation resulted in a small decrease in LCL force throughout stance (Fig. 3, middle). Conversely, femoral component internal rotation resulted in a large increase in PCL force throughout stance (Fig. 3, bottom). These changes in ligament forces during gait due to the femoral component internal rotation followed the trends observed during the simulated intraoperative assessments.

Figure 3: MCL (top), LCL (middle) and PCL (bottom) forces during the stance of a gait trial.

DISCUSSION

Using the predictions from our musculoskeletal simulations, we observed that the effect of femoral component position on the functional ligament forces during gait were consistent with the changes observed during the simulated intraoperative varus/valgus assessments. In this way, the MCL force increased during late stance when the femoral component was internally rotated, which was consistent with the increase in ligament force that occurred at 90° flexion of the varus/valgus assessments. Similarly, the increase in PCL force observed for the varus/valgus assessment at 90° flexion was reflected by larger PCL forces throughout stance, while the small reduction in LCL forces during simulated intraoperative assessments led to a small reduction in the LCL forces during gait. These changes could have implications for knee kinematics and stability. Future studies should aim to investigate how these coronal and axial plane deviations of the implant alignment can affect the fixation mechanics at the bone-implant interface.

EXTRACELLULAR MATRIX COMPOSITION AND VISCOELASTICITY ARE LONGITUDINALLY HETEROGENEOUS IN TENDON

Hannah M. Larson (1), Olivia J. Ward (1), Sarah Calve (1)

(1) Paul M. Rady Department of Mechanical Engineering, University of Colorado, Boulder, CO, USA

INTRODUCTION

Tendons perform a critical function in the body by connecting and transmitting forces from muscle to bone. The extracellular matrix (ECM), composed of a three-dimensional network of macromolecules, provides tendons with the mechanical structure necessary to bear loads and assists in cellular communication and biochemical regulation. The material structure of tendon ECM can be viewed as a fiber-reinforced composite comprised of load bearing *fibers* of type I collagen and elastin embedded in a *matrix* of ECM constituents including proteoglycans (PGs) and glycosaminoglycans (GAGs), with an interface where fibers and *matrix* bond. Canonically, in composites, the *matrix* is responsible for binding the material and transmitting stresses between load bearing fibers.

The hierarchical structure of collagen, from the molecular scale to fibril, fiber, and fascicle scales, drives the characteristic stress-strain response of tendon. However, the mechanism of load transfer between and within hierarchical levels is unknown [1]. Previous studies aimed at characterizing the multiscale mechanics of collagen are limited by the removal of fibrils and fibers from physiological boundary conditions at insertion sites and/or without the surrounding *matrix*. Furthermore, the role of *matrix* ECM in mature tendon mechanics is not clearly defined, though PGs have been shown to impact fiber recruitment [2]. Much of the previous work that aimed to define the effect of *matrix* ECM was limited by the use of enzymes, which can cause off-target effects due to lack of substrate specificity.

The objective of this study was to define how collagen fiber mechanics are altered by the surrounding ECM composition. Specifically, we investigated the distribution of PGs and GAGs longitudinally across tendon. Further, we examined how ECM heterogeneity along the length of the tendon impacts collagen fiber deformation. Investigating the effect of relative ECM composition on the collagen mechanical response will contribute to the knowledge of

how fibers share loads in tendon, illuminating how and when individual fibrils stretch and recover from applied forces.

METHODS

The extensor capri radialis longus tendon, a forelimb positional tendon, was harvested with muscle and bone insertions preserved from adult C57Bl/6 mice and kept hydrated in PBS throughout experiments.

Mechanical testing was performed using a Femtotoools micromanipulator system (FT-RS1002) and microforce sensor probe (FT-S100000) attached to our lab's custom designed floating-platform mounting system [3]. Tendon samples (N=2) were held at insertion sites and displaced at 1%/s to a set force of 80,000 μ N at the beginning of the linear stress-strain regime (previously found to be 15% of average failure force), then held for 10 minutes to allow the force to equilibrate. Samples were imaged using an Olympus FVMPE-RS twin laser multiphoton system and a 25 \times (NA = 1.05) FV30-AC25W truResolution water-immersible objective at a digital zoom of 3. Collagen was visualized using second harmonic generation (SHG) (Figure 1A-1A'). Five *x*-positions equidistant along the length of the tendon were selected to probe the fiber mechanical response. At each *x*-position a fiber, below the surface of the tendon, was selected and two region of interest (ROI) lines were placed perpendicular across the fiber 20 μ m apart (Figure 1A'). A sequence was then performed to 1) take an initial image of the tendon (Figure 1A); 2) ablate each ROI line, effectively cutting the fiber without disturbing surrounding tissue; and 3) image the strain recovery of the ablated fiber segment from 100 ms after ablation to 300 s after ablation. To ensure no effect on the order in which *x*-positions were ablated, each sample was tested in opposite order (proximal to distal, or distal to proximal). Image sequences were processed using FIJI to calculate average fiber segment length immediately after ablation (L1) and after 300 s (L2) to compare with the ROI length (L0). These values were used to calculate the change in length after load is removed, or strain recovery (Equation 1).

$$\epsilon_{\text{recovery}} = \frac{L_{\text{final}} - L_{\text{initial}}}{L_{\text{initial}}} \quad (1)$$

To view the distribution of *matrix* ECM throughout the tendon, tendon samples (N=3) were fixed in 4% PFA and immunohistochemically stained. Hyaluronic acid (HA), a non-sulfated GAG, was stained using hyaluronic acid binding protein (HABP) with AF555 conjugated streptavidin and a subset of PGs containing sialic acid and *N*-acetylglucosaminyl residues were stained using AF647 wheat germ agglutinin (WGA). Samples were imaged using a STELLARIS 5 confocal microscope (Leica) and an Apochromatic 10× (NA = 0.40) water-immersible objective with a digital zoom of 0.75. Image stacks of the full tendon length and depth were acquired and processed using FIJI (NIH) to view as a maximum z-projection.

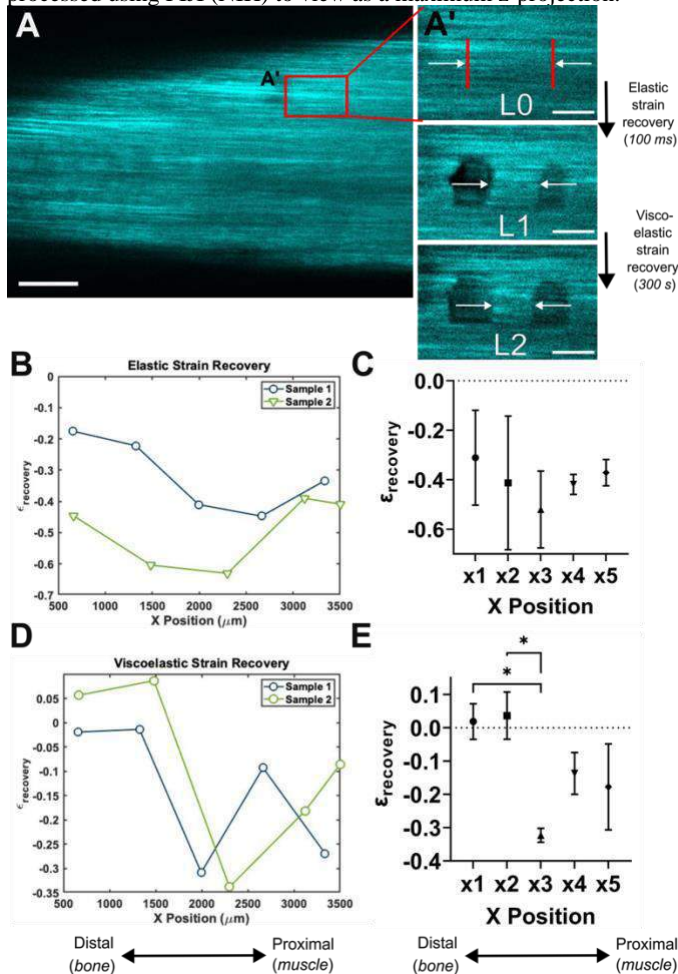

Figure 1: Mechanical perturbation of collagen fibers *in situ*. A) Representative SHG image within tendon subsurface (scalebar = 25 μm). A') Zoom inset of ROI lines defining 20 μm fiber segment (L0), fiber segment length after 100 ms (L1), and fiber segment length after 300 s (L2) (scalebar = 10 μm). B) Individual data points for elastic strain recovery with *x*-position. C) Mean +/- SD for elastic strain recovery. D) Individual data points for viscoelastic strain recovery with *x*-position. E) Mean +/- SD for viscoelastic strain recovery.

RESULTS

The elastic, or instantaneous, strain recovery varied with *x*-position along the length of the tendon, irrespective of the order in which

positions were ablated (Figure 1B). Broadly, *x*-positions near insertion ends appeared to experience less strain recovery than central positions; however these differences were not significant. (Figure 1C). The viscoelastic, or time-dependent, strain recovery also varied with *x*-position (Figure 1D). In both samples, the two *x*-positions closest to the distal bone insertion experienced no strain recovery in the 300 s of imaging after ablation, whereas the three *x*-positions nearest the proximal muscle insertion did experience viscoelastic strain recovery in this period. Similarly, the central point on the tendon (*x*3) experienced significantly more viscoelastic strain recovery than the two distal positions near the bone, as determined by a one-way ANOVA with significance of *p*<0.05 (Figure 1E).

Immunohistochemical staining intensity also varied along the length of the tendon. HABP fluorescence was greatest at the distal bone insertion side of the tendon through the center, indicating greater amounts of HA in those regions (Figure 2A). WGA fluorescence was also greatest at the distal end of the tendon, indicating higher concentrations of PGs in that region compared to lower staining intensity in the proximal side of the tendon (Figure 2B).

Figure 2: Representative confocal images of immunohistochemical staining. A) Hyaluronic acid binding protein (green). B) Wheat germ agglutinin (red). Both scalebars = 250 μm.

DISCUSSION

In this work, we demonstrated that both collagen fiber strain recovery and the distribution of PGs and GAGs were heterogeneous along the length of tendon. Near the bone insertion, tendons exhibited greater amounts of PGs and GAGs than on the muscle insertion end, as shown by immunofluorescence. In *x*-positions that had high amounts of HABP and WGA fluorescence, no viscoelastic recovery was seen in ablated collagen fibers. This result suggests that PGs and GAGs support interfibrillar sliding, thereby reducing the amount of time it takes for a fiber under strain to recover to initial length. We found that elastic strain recovery was greatest in the central tendon region, which may result from differences in macroscopic strain across the tendon. This study leveraged the regional differences in ECM distribution found in tendon to investigate the effect of varied ECM composition on load transfer from the bulk tissue to collagen fiber. Further, laser ablation offered the unique ability to probe fiber mechanics *in situ* and observe mechanical behavior within physiological boundary conditions. Additional studies will further these findings by comparing regional fiber-scale strain recovery with macroscopic strain across the tendon, as well as using mouse models that vary in PG and GAG composition in tendon. Overall, these findings indicate a potential role of PGs and GAGs in regulating stretch and viscoelasticity at the fiber scale.

A CONSTITUTIVE MODEL THAT INCORPORATES A MICROSTRUCTURAL MECHANISM OF HOMOGENIZING TRANSMURAL STRESS DISTRIBUTIONS IN ARTERIES

Taisiya Sigaeva (1), Yanhang Zhang (2)

(1) Department of Systems Design Engineering, University of Waterloo, Waterloo, Ontario, Canada.

(2) Department of Mechanical Engineering and Department of Biomedical Engineering, Boston University, Boston, Massachusetts, USA.

INTRODUCTION

Designed by nature to be strong, flexible, and resilient, arteries are constantly adapting to changing environments and seeking to maintain stable and balanced mechanobiological states across different length scales [1]. At the tissue level, it is believed that cells relentlessly work to alter vascular microarchitecture and thus ensure mechanical homeostasis, or the state at which mechanical stresses are kept constant at some target value across the arterial wall [2]. Despite the vital role of homeostasis in vascular functions, the exact microstructural mechanisms enabling it are still unknown.

The primary load-bearing microstructural components commonly identified for arterial walls are: 1) an isotropic ground substance, 2) elastic fibers which enable artery recoiling and respond to mechanical loads linearly, and 3) wavy collagen fibers that resist deformations in a stiff and nonlinear manner when straightened. In material models, collagen fibers are usually considered to enable an anisotropic and nonlinear response of the arterial wall, while the contributions of elastic fibers and a ground substance are simply combined to be represented by the isotropic neo-Hookean solid (e.g., [3]). However, only a fraction of collagen fibers are known to engage during a normal cardiac cycle [4], while most of the load is carried by elastic lamellae (EL), a structure represented by concentric layers of wavy sheets made of elastic fibers (Fig. 1a) [5]. Importantly, in addition to the load-bearing function, the function of maintaining homeostasis through vascular adaptations is also attributed to EL [5].

The recent study [6] used microscopy to observe how concentric layers of EL unfold and deform during inflation and extension of the artery (Fig. 1a). One important finding was that EL layers closer to the inner wall of the artery are wavier than EL layers further away from it. Because the inner regions of the artery experience more deformations due to blood pressure, such structural heterogeneity essentially relieve these regions from excessive stresses and can be directly linked to homeostasis. There are no existing models of EL capable of capturing such behaviour, and, in this study, we propose a novel model for this structure using the concepts of worm-like-chain elasticity [7]. We then utilize this model to demonstrate how EL structural heterogeneity can homogenize transmural stress distributions.

METHODS

Worm-like chain-fiber model: Wavy EL layers consist of elastic fibers; for simplicity, it is assumed that global EL waviness matches the elastic fibers waviness. Each elastic fiber is represented by a worm-like chain (WLC) of length L_c with end-to-end distance x (Fig. 1b). Because elastic fibers are extensible, the ratio x/L_c describes both unfolding and stretching, or simply the chain deformation. The chain force F required to unfold/stretch such fibers from the referential state x_0/L_c is shown in Fig. 1c and found from the relationship [7]

$$F = \frac{kT}{L_p} \left[\frac{x}{L_c} + \frac{1}{4 \left(1 - \frac{x}{L_c} - \frac{F}{K_0} \right)^2} - \frac{1}{4} - \frac{F}{K_0} \right]. \quad (1)$$

Here k and T are the Boltzmann constant and the absolute temperature, while L_p and K_0 are unknown constants which define, respectively, the toe region and the linear behaviour of elastic fiber-chains upon straightening. Notably if we assume $K_0 \rightarrow \infty$, we will obtain an inextensible version of the WLC model with the chain deformation x/L_c used for unfolding only and with $F \rightarrow \infty$ as $x \rightarrow L_c$. This version of the model will be used to model collagen fibers as it was successfully done before [8].

Loaded artery kinematics: A loaded artery is modelled as a two-layered non-linearly elastic cylindrical annulus undergoing internal inflation and axial extension described by the following deformation field [3]:

$$r = r(R), \quad \theta = \Theta, \quad z = \lambda_z Z. \quad (2)$$

Here λ_z is the axial stretch, coordinates $\{r, \theta, z\}$ and $\{R, \Theta, Z\}$ are used to describe the deformed and reference configurations, respectively. The incompressibility condition allows for the solution of $r = r(R)$ explicitly and to express the deformation gradient \mathbf{F} . Further, the principal invariants can be derived as $I_1 = \text{tr} \mathbf{C}$ and $I_{4,j} = \mathbf{M}_j \otimes \mathbf{M}_j : \mathbf{C}$, where $\mathbf{C} = \mathbf{F}^T \mathbf{F}$ and \mathbf{M}_j describe a unit vector along a fiber family j . To link the kinematics of individual fiber-chains defined via (1) with the bulk kinematics for a fiber family j , the following relation is used:

$$(x/L_c)_j = (x_0/L_c)_j \sqrt{I_{4,j}}. \quad (3)$$

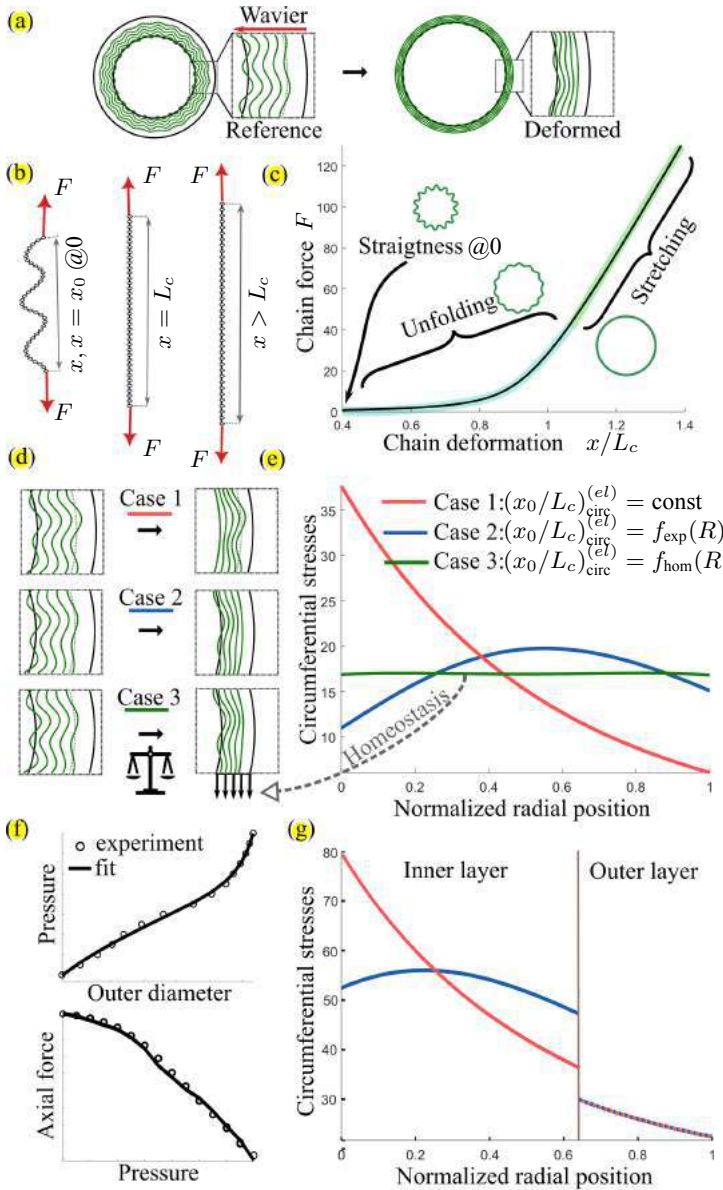

Figure 1: (a) Deformations of EL layers in arteries [6]; (b) WLC model of an EL's elastic fiber and (c) chain force-deformation curve; (d-e) isolated EL transmural circumferential stresses for three cases of structural heterogeneity $(x_0/L_c)^{(el)}_{\text{circ}}$; (f) model fit to the actual experimental data [6] and (g) the resulting transmural stress distributions.

Loaded artery material: It is assumed that the arterial wall consists of the ground substance (gs), circumferential and axial fiber families of elastic fibers (el) representing EL in the inner layer and four fiber families of collagen fibers (clg) in the outer layer. The strain energy density function is then given by

$$\Psi = \Psi^{(gs)} + \Psi^{(el)} + \Psi^{(clg)} \quad (4)$$

with the neo-Hookean term $\Psi^{(gs)} = \mu(I_1 - 3)/2$ and the terms for elastic and collagen fiber families $\Psi^{(el)}$ and $\Psi^{(clg)}$ expressed via chain forces (1) along an individual fiber family j as $\Psi_j = (\gamma \int F(x) dx + \Psi_{rep})_j$. Here μ is the shear modulus, γ is the fiber density and Ψ_{rep} is a repulsive energy term to ensure no stresses in the reference configuration [8].

Solution and Fitting: With (4), the constitutive law is derived as

$$\sigma = -p\mathbf{I} + \mathbf{F} \left[2 \frac{\partial \Psi}{\partial \mathbf{C}} \right] \mathbf{F}^T, \quad (5)$$

where p is the Lagrange multiplier and \mathbf{I} is the identity tensor. When used with the equilibrium equations $\nabla \cdot \sigma = 0$ and boundary/interface conditions, the internal pressure and axial force can be expressed as functions of the geometry and unknown material constants (4). Then, the model can be fitted to the experimental data from [6], from which the unknown material constants can be determined [3]. Importantly, (4) allows to directly

incorporate the structural heterogeneity observed in EL [6] (Fig. 1a) via the initial elastic fiber straightness $(x_0/L_c)^{(el)}_{\text{circ}} = f(R)$, defined as a function of the radial position.

RESULTS

Circumferential EL term: First, we investigate the behaviour of the term from (4) associated ONLY with the EL's circumferential elastic fiber family. Reduced circumferential stress distributions are plotted in Fig. 1e for three cases with everything the same but the structural heterogeneity $(x_0/L_c)^{(el)}_{\text{circ}} = f(R)$. Case 1 represents the homogeneous distribution of fiber waviness across the wall $(x_0/L_c)^{(el)}_{\text{circ}} = \text{const}$ (Fig. 1d). For this case, high stresses are observed on the inner surface of the artery and lower stresses on the outer surface, with a significant gradient across the wall (Fig. 1e). Cases 2 and 3 are somewhat similar heterogeneous cases $(x_0/L_c)^{(el)}_{\text{circ}} = f(R)$ (Fig. 1d) that both immediately demonstrate the reduced gradient in the stress distributions due to non-uniform EL waviness (Fig. 1e). The difference is that Case 2 is experiment-based $(x_0/L_c)^{(el)}_{\text{circ}} = f_{\text{exp}}(R)$ [6], while the heterogeneity distribution $(x_0/L_c)^{(el)}_{\text{circ}} = f_{\text{hom}}(R)$ for Case 3 is optimized to produce nearly constant circumferential stresses representing the homeostatic state (Fig. 1e). Now, with the new understanding of how the circumferential EL fiber family behaves outside of the model (4), it can be studied how it interacts with the other load-bearing microstructural components. For simplicity, only Cases 1 and 2 are retained.

Experimental data fitting: The two-layer model of the artery that includes contributions from all identified load-bearing microstructural components (4) was successfully fitted to the experimental data from [6]. The fitting was very similar for the homogeneous Case 1 and the experiment-based heterogeneous Case 2 (Fig. 1f). In contrast, at the physiological deformation state, the corresponding transmural stress distributions in the inner layer (where EL layers are defined) were quite different (Fig. 1g.) As in Fig. 1e, there is a significant stress gradient for the homogeneous EL structure $(x_0/L_c)^{(el)}_{\text{circ}} = \text{const}$, while the heterogeneous EL structure $(x_0/L_c)^{(el)}_{\text{circ}} = f_{\text{exp}}(R)$ results in more uniform stresses.

DISCUSSION

This work proposes a novel approach to include EL layers into the material description of the artery using the extensible worm-like-chain model. It allows to directly include the microscopically observed structural heterogeneity of EL layers $(x_0/L_c)^{(el)}_{\text{circ}}$ and robustly fit the experimental data [6]. Similarly to residual stresses [3], EL structural heterogeneity homogenizes the transmural stress distributions. However, it has a more evident connection to the arterial microstructure and is also capable of producing a homeostatic stress state (Fig. 1e, Case 3). Hence, the proposed model has a potential to improve our understanding of vascular pathways to maintaining homeostasis and it clearly demonstrates the importance of accounting for EL and its structural heterogeneity in constitutive modelling of arteries.

INTRODUCTION

For individuals with transtibial limb loss, the ankle roll-over shape (ARS) model describes the rocker-like movement of the prosthetic foot-ankle complex during stance. It is typically calculated as the transformation of the center of pressure (COP) into a shank-based coordinate system, which creates an arc that forms the ARS. Believed to be a critical mechanism for efficient walking, an ideal ARS reduces step to step transition work [1] and enables the exchange of kinetic and potential energy as described by the Inverted Pendulum Walking Model [2]. Asymmetries are common with prosthetic gait. Models have shown that the vertical center of mass (COM) excursion can be attributed almost entirely to step length and ARS rocker radius [2]. Using the ARS model, we can gain insight into how categories of prosthetic feet influence prosthetic gait symmetry. A prosthetic foot should be designed to achieve the appropriate ARS, while prosthetic alignment positions the resulting arc with the ideal orientation [3]. We hypothesize that the traditional method of calculating ARS is dependent on prosthetic alignment and is an inaccurate method to determine ARS for individuals with transtibial limb loss. Ultimately, this can negatively impact foot design and alignment guidance. The purpose of this study was to calculate ARS parameters using a modified Socket Coordinate System (CS) that controls for prosthetic alignment as to further optimize the design and alignment of prosthetic feet.

METHODS

ARS is determined by transforming the center of pressure data in stance to a planar coordinate system. The resultant trajectory is then fit using a quadratic circular regression, resulting in a circular fit that follows Equations 1 and 2.

$$R = \sqrt{(COP_x - x_0)^2 + (COP_y - y_0)^2} \quad (1)$$

$$\theta = \tan^{-1} \left(\frac{COP_y - y_0}{COP_x - x_0} \right) \quad (2)$$

R defines the arc radius, while the arc center is given by x_0 and y_0 (Eq 1). These parameters are then normalized by the participant's height. θ defines the angle between the arc center and the COP progression along the arc. θ_0 and θ_e define the initial and end points of the arc. The traditional ARS analysis uses the Shank CS (Fig 1A), calculated by the following steps.

Figure 1: A) Shank and B) Socket CS Visualization

- 1) Calculate the functional knee axis.
- 2) Project the midpoint between the medial and lateral knee markers onto the functional knee axis: this is the CS origin.
- 3) Find midpoint between the medial and lateral ankle markers.
- 4) The Y axis is determined by the line from the distal ankle center point to the proximal knee center.
- 5) The X axis is determined by the plane of best fit between the two joint centers and the lateral ankle and knee markers.
- 6) $\hat{X} \times \hat{Y}$ defines the Z Axis

The modified CS, the Socket CS, uses only socket markers in its calculation (Fig 1B), detailed below.

- 1) Calculate the functional knee axis – defining the Z axis.
- 2) Project the midpoint between the medial and lateral knee markers onto the functional knee axis: this is the CS origin.

- 3) A marker placed on the tibial tuberosity is projected to the height of the knee center landmark to create a virtual landmark. The line between these two landmarks defines the X Axis.
- 4) $\hat{Z} \times \hat{X}$ defines the Y Axis.

The comparison between the Shank and Socket CS was performed for 24 participants, on three different categories of prosthetic feet: Energy Storing and Returning (ESR), Articulating (ART) ESR, and powered (PWR) ESR. Each participant was fit with each type of foot in a randomized order and given separate, 1-week acclimation periods. Following each acclimation period, participants underwent a biomechanical gait evaluation. Motion and force data were collected using an optical motion capture system (Qualisys, Goteborg, Sweden) and force platform system (AMTI, Watertown, MA). Additionally, ten individuals without limb-loss (controls) completed the same biomechanical assessment. The data was then processed using Visual 3D (C-Motion Inc.) and a custom MATLAB (The MathWorks Inc.) script. Independent T-tests were then used to determine significant differences ($p < 0.05$) in three key analyses (A1-A3): A1 and A2 assessed the differences between feet and between experimental and control groups in the Shank CS and the Socket CS, respectively; A3 compared the ARS parameters of the feet between the Shank and Socket CS.

RESULTS

Figure 2 is a visual representation of the average ARS for each foot and controls in both the Shank and Socket CS. Visual differences between the ARS for experimental and control groups were present in all three feet in the Shank CS. However, when removing the influence of alignment using the Socket CS, the ARS of the three feet aligned to the controls. This is confirmed in Figure 3, where the five ARS parameters are shown. Tables 1-3 highlight the significant differences in all key analyses.

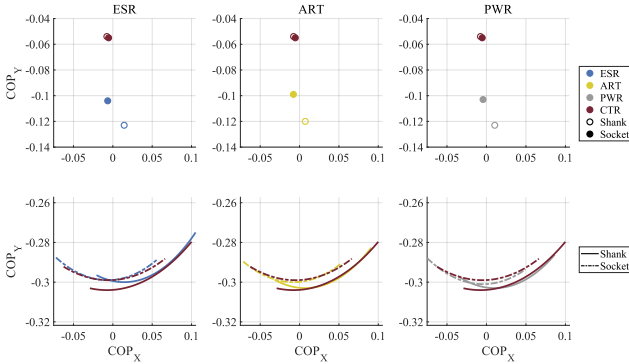

Figure 2: Shank and Socket CS ARS Comparison

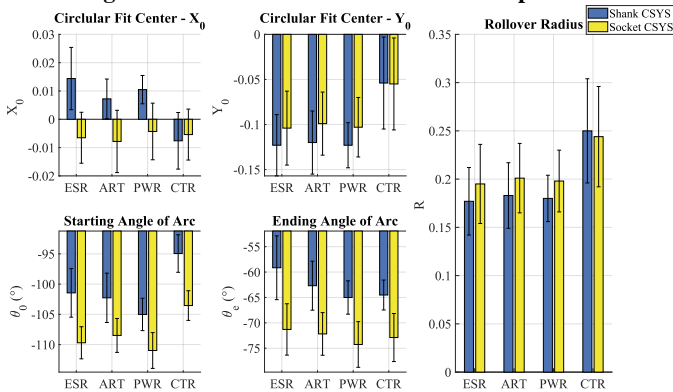

Figure 3: Shank and Socket CS ARS Parameters Comparison

Table 1: Shank CS P-Values (A1)

Parameters	ESR-ART	ESR-PWR	ART-PWR	ESR-CTR	ART-CTR	PWR-CTR
X Center	0.01	0.12	0.07	0.00	0.00	0.00
Y Center	0.75	0.97	0.74	0.00	0.00	0.00
Radius	0.58	0.77	0.72	0.00	0.00	0.00
Start Angle	0.50	0.00	0.01	0.00	0.00	0.00
End Angle	0.04	0.00	0.06	0.02	0.27	0.69

Table 2: Socket CS P-Values (A2)

Parameters	ESR-ART	ESR-PWR	ART-PWR	ESR-CTR	ART-CTR	PWR-CTR
X Center	0.66	0.43	0.25	0.74	0.53	0.77
Y Center	0.67	0.89	0.74	0.01	0.01	0.00
Radius	0.63	0.84	0.75	0.01	0.01	0.00
Start Angle	0.14	0.13	0.01	0.00	0.00	0.00
End Angle	0.52	0.04	0.11	0.40	0.67	0.44

Table 3: Shank and Socket CS Comparison P-Values (A3)

Parameters	ESR	ART	PWR	CTR
X Center	0.00	0.00	0.00	0.61
Y Center	0.10	0.06	0.03	0.97
Radius	0.11	0.09	0.04	0.81
Start Angle	0.00	0.00	0.00	0.00
End Angle	0.00	0.00	0.00	0.00

The alignment differences were largely found in x_0 and θ_e in the Shank CS analysis (Table 1), whereas the Socket CS normalized these values to the controls (Table 2). Also, there were several differences in x_0 , θ_0 , and θ_e between feet in the Shank CS analysis (Table 1), but only two differences in θ_0 and θ_e between ART & PWR and ESR & PWR respectively (Table 2). In Table 3, comparing ARS parameters from the Shank and Socket CS analyses, θ_e and θ_0 were found to be significantly different for all groups between CSs. x_0 also varied between CSs for all three feet. The control group's x_0 held constant. The PWR was the only group to see a significant difference in y_0 and R .

DISCUSSION

Using the Shank CS reference frame, key differences in ARS parameters were found. However, those variances were not found in the alignment neutral Socket CS, suggesting that prosthetic alignment was the driving force behind the ARS shape, not the foot type. Additionally, when the Shank and Socket CS analyses were performed on control participants, the only differences found were in starting and ending angles (θ_0 and θ_e). This difference was caused by the rotation of the Socket CS compared to the Shank CS and is consistent across all groups. Otherwise, the ARS parameters of the control group were constant between CSs, demonstrating that differences found in the experimental group were due to alignment effects, not by a change in CS. Radius (R) and Arc Center Height (y_0) were only found to change between CSs in the PWR group. It is hypothesized that the PWR device is aligned to optimize powered push-off rather than ARS. While the ESR and ART feet are aligned for low energy step to step transitions, the PWR foot is aligned to take advantage of the powered push-off, an effect not captured in the ARS analysis. The PWR's difference from ESR and ART in θ_e and θ_0 , respectively, also hints at this alignment adjustment. Future analyses can compare the changes in alignment priority (powered push-off vs. ARS) and the effects on step-to-step transition work. This would be useful in determining the trade off in changing the rollover radius compared to maximizing power output in late stance.

INTRODUCTION

Mitral regurgitation (MR) is a highly prevalent cardiac disease affecting approximately 2% of the United States population. MR is typically categorized into two broad groups each covering a wide range of etiologies. Degenerative MR (DMR) is caused by primary myxomatous degeneration of the mitral valve (MV) tissue. In contrast, functional MR (FMR) is an insufficiency of an otherwise normal MV secondary to ischemic or non-ischemic cardiomyopathy and the associated left ventricular dilatation. MR of either type is also a major prognostic factor of mortality, with even mild MR increasing the risk of mortality by 17% in patients with ischemia but no MR [1]. Furthermore, MR remains severely undertreated despite its deadly outcomes, even in patients with low comorbidity, suggesting a critical need for treatment planning optimization [2].

Transcatheter edge-to-edge repair (TEER) techniques are significantly safer options for MV repair compared to traditional surgical approaches and have thus broadened the eligible patient cohort for MR treatment. However, the long-term durability and efficacy of TEER has been unpredictable especially when compared to surgical undersized ring annuloplasty or guideline-directed medical therapy, with major randomized controlled trials reporting diametrically opposite outcomes. These inconsistencies have largely been attributed to the vast heterogeneity of the MR patient population and have generated prolific inquiry into image-based predictive markers of TEER success [3]. However, the clinical utility of these markers has not been demonstrated in practice. Therefore, there remains an urgent, unmet clinical need for *quantitative, patient-specific* treatment optimization techniques that account for the highly variable patient population and combinatorial nature of TEER.

Advances in real-time 3D echocardiography (rt-3DE) have enabled the acquisition of high-resolution MV images over the entire cardiac cycle using standard-of-care imaging techniques. Thus, we have developed a patient-specific MV simulation pipeline *based strictly on*

preoperative, standard-of-care imaging to predict post-repair MV functional behavior.

METHODS

First, we developed a finite-element model of the full, patient-specific MV apparatus. Since the MV chordae tendinae (MVCT) are not visible on rt-3DE, we quantified the left ventricular MVCT origins and MVCT insertions on the MV leaflet from 5 CT-imaged excised human hearts. From this data, we determined a normalized MVCT insertion map which guided the distribution of MVCT on the leaflets for each patient (Fig. 1B). Next, we obtained rt-3DE images of the MV from 10 patients who underwent TEER with MitraClip (Abbott Inc.). Half the patients presented with mixed or DMR, and half with FMR. For each patient, we segmented the end-diastolic (ED) and end-systolic (ES) leaflet geometries from preoperative rt-3DE images and meshed both states using triangular shell elements. Additionally, we segmented all identifiable MVCT origins from rt-3DE images and tracked them from the ED to ES states. To produce the final MV apparatus model, we used the insertion distribution map to place 160 MVCT on the patient-

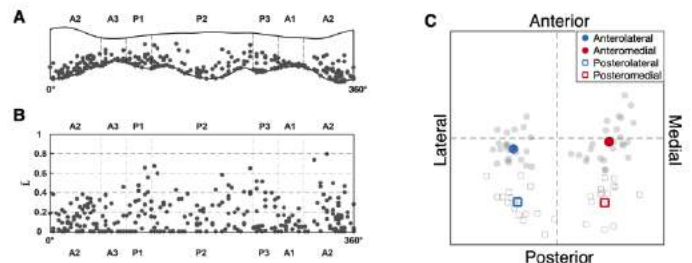

Figure 1: (A) All MVCT insertion points on an averaged MV leaflet geometry (B) MVCT insertion density map on a normalized MV leaflet grid (C) MVCT origin positions relative to normalized MV annular centerlines.

specific ED leaflet geometry and connected each insertion to its nearest segmented MVCT origin using truss elements (Fig. 2).

Figure 2: Full patient-specific MV apparatus, with unbranched MVCT and boundary conditions.

In order to model MV closure, we set ED to ES annular and MVCT origin displacements as Dirichlet boundary conditions, assigned an established structural model for the human MV leaflet and an Ogden model for human MVCT, and applied a ventricular pressurization in Abaqus 6.14 [4,5]. Given that patient-specific material properties are impossible to obtain from rt-3DE imaging, we calibrated the model by adjusting MV leaflet and MVCT prestrains such that the l^2 -norm between the simulated and segmented preoperative ES geometries was minimized. First, we iteratively updated the MVCT prestrain until the mean change in l^2 -norm was less than 5%. Next, we divided the MV leaflets into three zones (MVCT insertion zone, anterior clear zone, posterior clear zone), and iteratively updated the prestrain in each zone using fininsearch in MATLAB to the same convergence criterion. We utilized this fully calibrated MV model to simulate MV repair scenarios by implementing 3D MitraClip models onto the MV leaflets (Fig. 3).

Figure 3: Predictive TEER simulation progression with full patient-specific MV apparatus.

RESULTS

Our anatomical analysis of the excised human hearts quantitatively demonstrated that most MVCT insertions are located near the free edge of the MV leaflets (Fig. 1A), and that the majority of MVCT origins are shifted towards the posterior side of the LV wall (Fig. 1C). In all postoperative simulations, the mismatch between the predicted and segmented ES geometries was less than 1 mm. Furthermore, the predicted MV leaflet strain fields showed close correspondence in both the circumferential and radial directions and captured local variation in deformation across the MV leaflets (Fig. 4). Additionally, we analyzed the circumferential and radial MV leaflet strains for all 10 patients and noted considerable heterogeneity in preoperative deformation in both material directions, with no obvious patterns when grouped by etiology (Fig. 5). There is also substantial variation in MV annular orifice area, though the FMR MVs tend to be slightly larger, likely due to the underlying mechanism of LV dilatation ($10.09 \pm 3.17 \text{ cm}^2$ DMR, $13.58 \pm 3.45 \text{ cm}^2$ FMR, $p > 0.05$).

DISCUSSION

Given the complexity and inadequacy of current stratification methods for patient selection in MR treatment, there is a clear need for quantitative, patient-specific methods of predicting MV repair outcomes preoperatively using readily available clinical data. In this

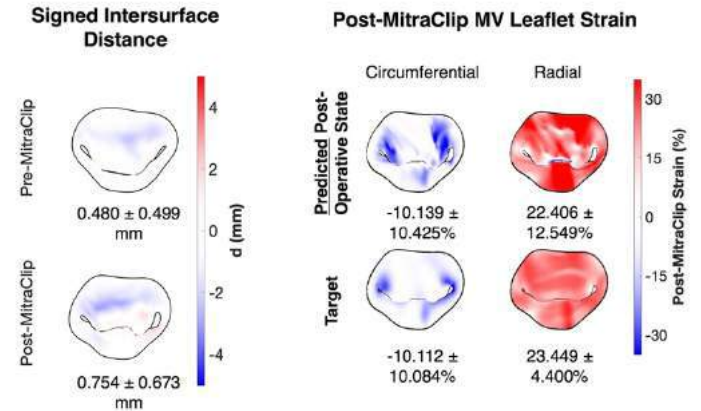

Figure 4: Preoperative calibration and postoperative prediction results for a representative TEER case, showing close correspondence between the target and predicted geometries and deformation fields.

study, we have developed an anatomically faithful, patient-specific full MV apparatus model and a *predictive MV repair simulation pipeline based solely on preoperative standard-of-care imaging*. We have demonstrated the capacity of this pipeline to predict postoperative MV geometry and deformation with close agreement to segmented data. Additionally, we observed large variation in preoperative deformation in our patient cohort, highlighting both the fundamental challenge that underscores MR treatment planning and the importance of a patient-specific approach for optimization of TEER outcomes.

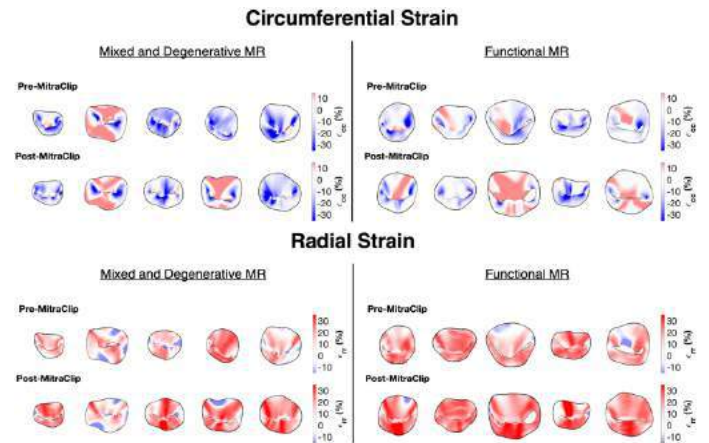

Figure 5: Circumferential and radial strain fields before and after TEER for the full patient cohort. There is wide variation in deformation amongst the patients, even those with the same type of MR, underscoring the need for patient-specific treatment planning.

INTRODUCTION

The physics of flow of blood through the cardiovascular system constitute a strongly coupled fluid-structure interaction, and consequently many aspects of the functional and dysfunctional physiology may be determined by the relationship between the deformation of the vessels and the pressure and flow generated by the heart. Numerous numerical methods and computational models of fluid-structure interactions (FSI) in blood vessels have been reported. The most general approaches solve the full fluid and solid mechanics within an anatomically detailed and realistic geometric model of some portion of the vascular system; however, solving these for dynamic problems in 3D domains is computationally demanding, thus a 1D approach based on several simplifying assumptions has seen wide application for simulation of large networks of blood vessels.

While previous works have compared 1D and 3D simulations to our knowledge this has been limited to cases where the arterial wall is modelled as a linear elastic material, yet in 3D solid mechanics advanced hyperelastic material models including multiple fiber components have been shown to be much better suited to describe the behavior of the arterial wall tissue [1]. Some works have developed 1D versions of such models [2, 3], but to our knowledge no comparison of such 1D models with comparable 3D-FSI simulations has been reported. We have developed new 1D implementations of several hyperelastic materials and present here a comparison of several 1D models and 3D models of an idealized cylindrical arterial geometry.

METHODS

In 1D arterial pulse wave propagation models, the tube law or compliance model relates the radius at a given point in the artery to the blood pressure at the same point. The most widely employed tube law is based on assuming linear elasticity and a thin walled cylinder [4]. However, due to the relatively large deformations and nonlinear stress-strain relationship of the arteries, nonlinear hyperelastic models are generally applied in studying the solid mechanics of arterial tissue [1]. We consider 3 hyperelastic constitutive laws defined by a strain energy function Ψ in terms of the Left Deformation Tensor \mathbf{C} or the Green Strain tensor \mathbf{E} . The first strain energy density approximates linear elasticity and is referred to as the Isotropic Elastic Model

$$\Psi = \frac{1}{2} \lambda (\text{tr } \mathbf{E})^2 + \mu \mathbf{E} : \mathbf{E}. \quad (1)$$

where $\lambda = \frac{\nu E}{(1+\nu)(1-2\nu)}$, $\mu = \frac{E}{2(1+\nu)}$ are Lamé parameters in terms of the Young's modulus E and Poisson ratio ν . The second is a NeoHookean material

$$\Psi = \frac{\mu}{2} (I_1 - 3) - \mu \ln J + \frac{\lambda}{2} (\ln J)^2 \quad (2)$$

where $I_1 = \text{tr}(\mathbf{C})$ and $J^2 = |\mathbf{C}|$.

Finally, the Holzapfel-Gasser-Ogden material is one of the most accurate models for characterising the deformation of arterial wall tissue

$$\begin{aligned} \Psi = & \frac{c}{2} (I_1 - 3) - c \ln J + \frac{k_1}{2k_2} \sum_{\alpha} (\exp(k_2 \langle E_{\alpha} \rangle^2) - 1) \\ & + \frac{K_0}{2} \left(\frac{J^2 - 1}{2} - \ln J \right) \end{aligned} \quad (3)$$

with $E_{\alpha} = \kappa (I_1 - 3) + (1 - 3\kappa) (I_{4\alpha} - 1)$ and $I_{4\alpha} = \mathbf{a}_0 \mathbf{C} \mathbf{a}_0$ with \mathbf{a}_0 specifying the fiber direction and κ fiber dispersion. The parameter c represents the stiffness of tissue matrix while the parameters k_1 and k_2 determine the contribution of the fibers, and K_0 is the bulk modulus.

We follow the approach of Mehta et al. [5] to implement a tube law based on each of these strain energy functions. This is a quasi-static approximation and assumes that the principal directions of stress are aligned with the local cylindrical coordinate system of the vessel and that axial deformation is constant throughout the cross section. Then the equilibrium equations are

$$\frac{\partial}{\partial R} \frac{\partial \Psi}{\partial \lambda_R} + \frac{1}{R} \left(\frac{\partial \Psi}{\partial \lambda_R} - \frac{\partial \Psi}{\partial \lambda_{\Theta}} \right) = 0 \quad (4)$$

which may be evaluated to find a second order differential equation for $r(R)$ by substituting $\lambda_R R = r$ and $\lambda_{\Theta} = \frac{r}{R}$. Together with the internal (p_i) and external pressure (p_e) a boundary value problem may be formulated with boundary conditions $\frac{\partial \Psi}{\partial \lambda_R} (R = R_{i,e}) = \lambda_{\Theta} P_{i,e}$. We solve this numerically using the `solve_bvp` routine from `scipy` [6].

We compare the solution produced by this 1D approach with the solution produced by FEBio [7, 8] for equivalent 3D models using the same hyperelastic constitutive laws. The idealized artery was modelled as cylinder. The wall was meshed with 32 angular sections, 8 layers and 32 longitudinal sections. The inner radius was 2.654 mm and the thickness was 0.3 mm. No deformation was allowed at the ends of the cylinder. The fluid domain was meshed using a hexahedral butterfly mesh with square elements extending to 70% of the internal radius and 5 transitional layers to the boundary. A parabolic inflow profile was imposed, and pressure

was imposed at the outlet. Backflow and tangential stabilization was also employed at the outlet. For the isotropic elastic and Neo-hookean materials $E = 0.7\text{MPa}$ and $\nu = 0.49$ were used. The Holzapfel-Gasser-Ogden material parameters were $c = 0.3\text{MPa}$, $k_1 = 20.9\text{kPa}$, $k_2 = 56.5$ and $K_0 = 1.5e7$. The fiber direction was assumed to be 30 degrees relative to the axial direction. The density of the wall and fluid was set to 1000kg/m^3 for all cases. For the fluid simulations, a Newtonian fluid with shear viscosity of $0.001\text{Pa} \cdot \text{s}$ and bulk viscosity of 0.01 was employed.

RESULTS

The deformation of the inner and outer wall at the midpoint of the cylinder is shown in Figures 1-3. We see good agreement between 1D and 3D results across the models.

Figure 1: Deformation of inner wall at mid length for an Isotropic elastic material Eq. (1)

Figure 2: Deformation of inner wall at mid length for a Neo-hookean material Eq. (2)

Figure 3: Deformation of inner wall at mid length for a Holzapfel-Gasser-Ogden material Eq. (3)

DISCUSSION

The good agreement of the 1D approach introduced here suggests that further integration of these approaches into 1D pulse wave propagation models of the vascular system may provide an efficient method for simulating blood flow and pressure dynamics while representing the vessel wall with state-of-the-art constitutive laws that can account for multi-component effects. The comparison only considered an idealized vessel geometry, and further comparisons using asymmetric geometries must be evaluated. Additionally, here homogeneous material parameters were assumed, but in the physiological case variations in material properties are expected. Future work should investigate how the 1D axisymmetric assumption performs when such variations are present. Additionally, as we conducted this work to verify and validate our 1D approach to solving deformation, we did not conduct a detailed comparison of the fluid structure interaction results with the flow and pressure gradient in the 1D domain. The comparison of 3D-FEA and FSI suggests for the present problem that the deformation depends only on the pressure, which is imposed at the outlet; however, in more complex geometries where the boundary conditions may be somewhat less dominant, discrepancies between 1D and 3D fluid mechanics may be significant. Yet, the previous comparisons [4] showed that for many quantities of interest, if the geometry and solid mechanics are in agreement then the fluid flows and pressures will also be within reasonable agreement between 1D and 3D models.

INTRODUCTION

Mechanical forces during embryonic and postnatal development are vital for successful limb and musculoskeletal tissue formation and maturation. Load bearing tissues such as tendons can respond to mechanical loading events to maintain tensional homeostasis. For example, tenocytes respond to altered loading by fine tuning the formation and degradation of extracellular matrix proteins [1]. Both excessive and insufficient loading are implicated in the disease etiology of tendons. Overuse tendinopathies, which commonly involve the Achilles tendon, account for 7% of musculoskeletal disorders in the US [2]. The most common treatment options are physical therapy and surgery. Manipulation of mechanical loads through implementation of rehabilitative loading exercises promotes repair processes that may culminate in improved restoration of normal tendon structure and function [3]. While loading has been shown to influence tendon composition in adults and healing tendons, it is less clear how mechanical forces influence Achilles tendon growth during early postnatal stages. Understanding the role of mechanical loading on developmental processes of tendon growth can 1) help to understand tissue optimization during development of healthy tendons and 2) provide mechanistic insight to guide new therapeutic treatments for adult tendon healing.

In the Achilles tendon, rapid tissue growth occurs in early postnatal stages. Growth of the Achilles is predominantly governed by cell proliferation and extracellular matrix (ECM) production. Here, we performed sciatic nerve resection (SNR) in neonatal mice (surgery performed on postnatal day 1 (P1)) to explore how a reduction in postnatal loading impacts Achilles tendon growth and how mechanical force affects extracellular matrix production during this critical time window. We hypothesized that reduced mechanical loading of the hindlimb after SNR would result in reduced growth and development of the Achilles tendon, and that this would be evidenced by changes in morphology and mechanical properties.

METHODS

All animals and procedures were approved by UPenn's IACUC. Unilateral left sciatic nerve resection (SNR) was performed on postnatal day 1 (P1) in male and female CD1 mice with evaluation on postnatal day 42. Gait Analysis. The CatWalk XT system was used to measure gait parameters in SNR and control mice at postnatal day 42. MicroCT. Excised hindlimbs from each group of mice were scanned on a Scanco μ CT45 scanner to measure tibia length. Biomechanical Testing. Achilles tendons were dissected, cross-sectional area was measured using a custom laser device, placed in custom grips, preconditioned, and loaded to failure (0.1%/sec). Structural and material properties were calculated using custom MATLAB scripts. Cryohistology. Hindlimbs were harvested, formalin-fixed, embedded in OCT, and cryosectioned (8 μ m) in the transverse plane using Cryofilm 2C. Fluorescent imaging with a nuclear counterstain followed by brightfield imaging with toluidine blue staining was performed. Image Analysis. Achilles tendon cross-sectional area and cell density were quantified using Fiji. Statistics. Gait parameters between SNR and control groups were compared via one-way ANOVA with Tukey's HSD post-hoc comparisons ($p < 0.05$). SNR limb vs. contralateral limb were compared via paired t-tests for all other assays ($p < 0.05$).

RESULTS

SNR resulted in sustained impairments in gait. CatWalk XT analysis on post-natal day 42 was used to assess changes in gait parameters that would inform hindlimb loading patterns. SNR mice exhibited sustained gait perturbations, including a >30% reduction in maximum stride intensity and a >70% reduction in paw print width, a hallmark of sciatic denervation ($p < 0.0001$, **Figure 1**).

Reduced loading from SNR resulted in muscle atrophy and bone shortening. Gross microscopic images revealed signs of marked muscle atrophy (red arrow, **Figure 2A**) of the posterior hindlimb muscles. The Achilles tendons also appeared smaller, with reduced birefringence. (**Figure 2A**). This model system has been shown previously to affect

bone growth, which led us to investigate differences in tibia length. We confirmed, as shown previously [4], via micro-computed tomography (μ CT) that the tibias in SNR limbs were shorter compared to injured contralateral limbs ($p<0.05$, **Figure 2B**).

Cross-sectional area, cell density, and mechanical properties were impaired following SNR procedure at P1. Histomorphometric analysis showed that Achilles tendon cross sectional area (CSA) was significantly decreased in the SNR limbs ($p<0.05$, **Figure 3**). The total number of cells per cross section was also reduced ($p<0.05$) while there was an increasing trend for cell density ($p=0.08$) in the SNR group. To further examine the role of early postnatal loading in Achilles tendon growth and maturation, we performed uniaxial tensile testing to failure. The failure force, stiffness, and modulus were all significantly reduced in the Achilles tendon of the SNR limb ($p<0.05$, **Figure 4**), with a decreasing trend in maximum stress ($p=0.1$).

DISCUSSION

The role of physiologic mechanical loading in maintaining Achilles tendon homeostasis is well established and aberrant loading conditions can lead to disease, such as overuse tendinopathy. The importance of applied loading to Achilles tendon during periods of active cell proliferative- and matrix-driven growth are less studied. Using a SNR model, we found persistent gait alterations with posterior muscle atrophy and tibia shortening, which is consistent with previous findings [4]. We also found that the reduced loading had profound effects on the growth and maturation of the Achilles tendon. The marked reduction in postnatal loading produced tendons with smaller cross-sectional area and increased cell density. These structural changes corresponded with reduced stiffness, failure force, modulus, and failure stress. The reduced tendon cross-sectional area with a trending increase in cell density suggest that matrix production was predominantly affected in the SNR group. However, future studies will investigate cell proliferation changes in this model system. Interestingly, both structural and material properties were reduced, even with the changes in cross-sectional area, suggesting a deficit in the quality of tissue produced, a finding that will be investigated further in future studies.

INTRODUCTION

The human female pelvic floor consists of skeletal muscles and connective tissues that work synergistically to mechanically support the pelvic organs (including the urethra, vagina, and rectum) and to facilitate physiologic functions (including urination, childbirth, and defecation). The term pelvic floor muscles (PFMs) is used to refer to many different pelvic skeletal muscles. The levator ani (LA) are the largest and most studied, but the term can also include the coccygeus (posterior/superior to the LA) and superficial perineal muscles (inferior to the LA). The PFMs remodel during pregnancy, must stretch extensively to accommodate vaginal childbirth, and their dysfunction has been associated with the development of pelvic floor disorders.¹⁻³ Their mechanical behavior impacts and is impacted by all of these processes and conditions, yet little is known about the passive mechanics of the human female PFMs.

Existing studies have focused on the LA and both the muscle and muscle fiber bundle level have been evaluated.^{4,5} One study found differences with age evaluated by comparing older and younger women, but the other did not see a correlation with age within a postmenopausal cohort. However, the PFMs have only been evaluated in a limited number of studies, and these studies did not include superficial perineal muscles. Therefore, we aimed to characterize the passive mechanical behavior of deep and superficial PFMs from female human cadavers.

METHODS

PFMs were dissected from fresh-frozen female cadavers obtained from Anatomy Gifts Registry with approval from the Committee for Oversight of Research and Clinical Training Involving Decedents at the University of Pittsburgh. These dissections were carried out by exposing the superficial muscles, moving posteriorly towards the coccyx; exposing the posterior surfaces of the deep pelvic floor muscles; removing the pelvic viscera except for the most distal portions that are attached to the PFMs; separating the superficial perineal muscles from

the bony pelvis; and separating the LA from the bony pelvis and pelvic sidewalls. This resulted in the removal of the pelvic floor *en bloc*, which was frozen in saline soaked gauze at -20°C. These samples were frozen *en bloc* because the dissection of the pelvic floor and the harvest of individual muscle samples was substantially time consuming and muscle orientations could more easily be maintained if harvested immediately before mechanical testing.

Samples were moved to a refrigerator to thaw two days prior to mechanical testing and then finished thawing at room temperature immediately prior to tissue harvest. During and following harvest and leading up to testing, samples were kept hydrated by periodically spraying them with 1x phosphate buffered saline. Individual PFMs were isolated. Muscle samples included the left and right ischiocavernosus (IS), bulbocavernosus (BC), transverse perinei (TP), and LA. Due to size and shape, some PFMs could not be tested whole. Such samples were divided into sections cutting with the orientation of the fibers and along natural breaks between fibers when present to create samples of sufficient size while minimizing variations in the sample's width.

The length, width, and thickness of each sample were measured before and after mechanical testing. Length and width were measured via digital calipers, and thickness via laser micrometer. Samples were dyed blue and speckled with white spray paint to allow for regional, non-contact strain measurements via 3D digital image correlation (DIC). This DIC system included two CCD cameras (Basler ace acA2440-75µm, Basler Inc., Exton, PA) that captured high resolution images of each specimen during testing (**Figure 1**). Tensile tests were performed with an Instron uniaxial testing system equipped with a 50 N load cell at a rate of 0.1 mm/s (after a 0.1 N preload) until failure or tearing at the clamps.

Data from the DIC system and Instron were aligned and noise reduced with a MATLAB script. The DIC system calculates heterogeneous strains across a manually selected region using the speckle pattern to track deformation (**Figure 1**). The strain values used

were an average over a small circular sub-region (diameter < 1 mm) selected based on the best speckle visibility and how long it remained within the field of view. Stress was calculated using the Instron's load data and the widths and thicknesses measured before testing. The resulting stress-strain curves were sampled at specified stress values and compared across muscles.⁶ Lagrangian strains in both the main *in vivo* loading direction (axial strain) and perpendicular to the loading direction (transverse strain) were evaluated.

Figure 1: An image depicting A) the mechanical testing and DIC system setup and B) an example DIC image and strain map.

RESULTS

The PFM of 8 donors were included in this study (white, age 64.8 ± 9.1 years, BMI 25.4 ± 4.7 kg/m²). During testing, it was noted that the LA samples were the largest, while the IS samples were the thinnest. In terms of width, the TP samples were the most non-uniform (being more triangular-shaped than the other PFMs), and the IS appeared to have the most consistent widths throughout the sample.

Note that the data shown here only includes 4 samples of each muscle type as analyses are still in progress. In the toe region, the LA and TP experienced the highest axial strains, while the IS exhibited the lowest (**Figure 2**). Additionally, the TP axial strains had the greatest variability, encompassing almost all of the other PFMs' values. In the transverse direction, the LA experienced remarkably larger strains than the superficial PFMs and the greatest variability by a large degree.

DISCUSSION

This study quantified the mechanical behavior of superficial and deep human female PFMs. This adds to existing levator ani data from a small number of studies, but also introduces a novel assessment of local strains using DIC methods. Additionally, this study generated mechanical data for the previously uncharacterized superficial PFMs.

The LA demonstrated axial behavior more similar to the superficial muscles than expected. They are considered to be much larger contributors to the mechanical support of the pelvic organs than the superficial PFMs, but that difference isn't apparent based on this passive behavior. This idea would likely be better reflected in the structural properties. Though LA can be divided into multiple distinct muscles (e.g., iliococcygeus), they were evaluated together in this analysis, which could have contributed to the large variability in LA transverse strains. Furthermore, the axial strains of the superficial PFMs were not as similar as expected. While the TP and BC had comparable axial strains at lower stress values, their distributions grew more divergent

with increasing stress, potentially due to the distinct geometry of the TP.

Studying female PFM biomechanics is difficult, especially in living women, due to the PFMs often having complex geometry and being located deep enough in the body to make biopsy or minimally invasive investigation challenging. Therefore, cadaveric PFM data is quite valuable, though still rare. We observed that non-uniform muscle structure further complicates the resulting mechanical behavior and quantifications. Many samples were embedded with pockets of fat, creating regions of lower muscle fiber density. Fibers in regions like this would tear, but the tissue as a whole would recover and stress would continue to increase. This occurred quite frequently throughout our testing, particularly in LA samples, which was also the PFM that experienced the greatest transverse strains. However, this is not well documented in the literature. Further evaluation of and a system for quantifying these events may need to be conducted.

This study provides important insight into the passive mechanical behavior of superficial and deep female PFMs. Moreover, resulting material property data can be used in finite element simulations of the female pelvic floor to improve models that incorporate the superficial perineal muscles in addition to the more commonly simulated LA.

OBESITY AFFECTS THE BIOMECHANICS OF THE POSTERIOR KINETIC CHAIN DURING MANUAL LIFTING

INTRODUCTION

One out of three adults are obese in the United States [1]. Obesity is considered a major health issue that constantly appears as contributor to musculoskeletal injuries in the workplace [2-4]. Particularly, workers with elevated body mass index (BMI) are more susceptible to injuries affecting the posterior kinetic chain [5-7]. Despite this escalating problem, recommended weight limits (RWL) for manual lifting tasks are still designed based on average body weight individuals as per National Institute of Occupational Safety & Health (NIOSH) guidelines [8]. The recommended NIOSH lifting equation (RNLE) calculates RWL with the objective of safely regulating energy expenditure and musculoskeletal loads during manual lifting [9]. However, the adverse effects of elevated BMI on the prevalence of musculoskeletal injuries in manual workers are not considered in designing lifting tasks that account for a major portion of activities demanded from manual work occupations. As a result, the present study measured and compared parameters associated to the biomechanics of the posterior kinetic chain in individuals with different BMI categorization while performing manual lifting activities at the RWL. We hypothesize that the execution of manual lifting at RWL would produce forces and moments in L5-S1 above biomechanical safety limits for obese individuals.

METHODS

30 people were enrolled. Subjects were stratified into groups of 10 for 3 BMI classifications based on the definitions of the World Health Organization [10]: normal weight ($18.5 \leq \text{BMI} \leq 24.9$), overweight ($25 \leq \text{BMI} \leq 29.9$), and obese ($\text{BMI} \geq 30$). Individuals standing in front of a box were required to move it from the floor to a table 30" high. Four repetitions of this lift were performed with rest allotted in between lifts. A 'freestyle' lifting technique was allowed. The geometrical setting of the task is represented in Figure 1.

Figure 1: Geometrical setting for experiment divided in three stages: (A) Initial lifting phase. (B) Maximum height. (C) Deposit phase

The weight of the box was calculated to be equivalent to the RWL as defined in the revised NIOSH lifting equation:

$$\text{RWL} = \text{LC} \times \text{HM} \times \text{VM} \times \text{DM} \times \text{AM} \times \text{FM} \times \text{CM} \quad (1)$$

Body biomechanics was evaluated via a ViconNexus® Motion Capturing System integrating eight MCam cameras and two Kistler force plates. Thirty-nine reflective markers were placed on subjects according to Vicon's Plug-in Gait Full Body (PIGFB) model [11]. Kinematic data and ground reaction forces were collected at 500 Hz, processed with the PIGFB biomechanical model, and were enhanced by a previously validated custom spinal specific BodyBuilder® plug-in [12]. Data post-processing provided three parameters associated to the biomechanics of the lumbosacral joint: anterior-posterior (A/P) force, axial compression force, and bending moment. A two-way ANOVA compared these parameters across BMI classification and gender, and linear regressions investigated potential correlations between these parameters and BMI.

RESULTS

BMI classification significantly affected all L5-S1 forces and moment parameters as per the two-way ANOVA analysis: A/P shear force ($p \leq 0.001$), compression force ($p = 0.002$), and bending moment ($p = 0.016$). Linear regression models helped understand the relationships between BMI and L5-S1 forces and moments: A/P shear force ($R^2 = 53.19\%$, $p \leq 0.001$), compression force ($R^2 = 46.60\%$, $p \leq 0.001$), and bending moment ($R^2 = 31.02\%$, $p = 0.002$). Notably, more than half of obese individuals exceeded the shear safety limit, showing that clinically elevated BMI affects the biomechanics of the posterior chain. Forces and moment values for L5-S1 are represented in Figure 2 and listed in Table 1.

Figure 2: Values of biomechanical stress and moment classified per BMI: (A) A/P shear force on L5-S1, safety limit line at 700 N. (B) Axial compression force on L5-S1. (C) Bending moment on L5-S1.

		Normal (n=10)	Overweight (n=10)	Obese (n=10)	Subtotal (n=30)	P-Value
A/P Shear Force	Subtotal (n=30)	589.2	543.2	763.5	633.4	0.001*
	Group	B	B	A		
Axial Compression	Subtotal	369.0	402.3	542.4	436.6	0.002*
	Group	B	B	A		
Bending Moment	Subtotal	22.1	27.0	37.3	29.1	0.016*
	Group	B	B	A		

Table 1. Peak forces and moment for L5-S1 versus BMI. Marginal means for BMI classifications are grouped using a Fisher Pairwise comparison. A p-value for the ANOVA test comparing each biomechanical variable with BMI class is also reported, with (*) indicating statistically significant difference.

DISCUSSION

Our previous research showed that 80% of obese individuals exceeded physiological stress safety limits during manual lifting [13]. Moreover, previous investigations had identified a need to consider physical attributes when calculating RWL [14-16]. However, to the authors' best knowledge, this is the first study evaluating the degree to which the RWL guarantees the L5-S1 biomechanical safety limits for both axial and A/P shear spinal forces. Biomechanical stresses is the most understudied cause that links obesity and occupational musculoskeletal injuries in the posterior chain [17]. Specifically, L5-S1 is the most common location of degenerative spinal pathology and most highly correlated with injury [18-20].

In the present study, the magnitudes of these L5-S1 parameters were significantly dependent on BMI group. Figure 2 illustrates the differences in L5-S1 A/P shear force in reference to the safety limits: the A/P shear force of the obese group surpassed the safety threshold (700 N) proposed by Gallagher [21] by 9 percent. Overall, the relationship between L5-S1 shear spine loads and BMI when lifting at RWL confirms our hypothesis: spine loads in obese individuals exceed biomechanical safety limits under specific loading conditions when compared to overweight and average weight individuals. Furthermore, BMI also affected the L5-S1 peak bending moment ($p = 0.016$): values for obese subjects were 30 percent larger than overweight individuals and 65 percent larger than normal individuals. Our results agree with those reported by Corbeil et al, where peak moments at L5-S1 were up to 60 percent larger for obese individuals [22]. Overall, these results provide a groundwork for future studies to consider physical characteristics in coefficients for the RNLE. Such efforts could help to reduce the risk of biomechanical stresses to the posterior chain and lead to a reduced rate of lower back injury among manual laborers.

INTRODUCTION

Adaptive immunity and peripheral tolerance depend on antigen recognition within the lymph node. This process is essential to the development of a robust immune response to harmful pathogens. Dysfunction in this process can lead to immunodeficiency as well as autoimmune disorders. There are two mechanisms by which antigen can arrive at the lymph node. Firstly, it can be captured by dendritic cells within the tissues and carried into the lymph node. Secondly, it can be directly sampled from afferent lymph by resident dendritic. Previous works have shown that small molecular weight antigens can rapidly enter the lymph node parenchyma via the conduit system [1][2]. The conduit system is a series of pathways through the lymph node comprised of bundles of collagen fibers enclosed by fibroblastic reticular cells (FRC).

It is unclear what processes drive this transport and the mechanisms responsible will inform the factors effecting the deposition of antigen within the lymph node. If fluid flowing through the conduit system predominantly carries antigen by advection, then the deposition of antigen will be dictated by the upstream lymphatic flow. Conversely, if this process is driven by diffusion, then the antigen will travel in all directions within the network and its deposition will depend on the conduit network structure. Understanding this process will allow the design and development of vaccines and anti-inflammatory interventions which are optimized to inhibit or encourage antigen recognition by effecting the mechanical process of deposition. This work sort to study this transport by combining FIB-SEM images of the conduits with *in silico* models of the fluid flows and mass transport within the conduit system.

Figure 1: A) An example FIB-SEM image with the fibers and FRC indicated. B) An example idealized geometries with differing fiber densities. C) An example node-scale conduit network with the model setup indicated on the left and an inset revealing the structure.

METHODS

FIB-SEM images were taken of the conduits within murine lymph nodes. The walls and fibers were segmented and idealized to produce many different cross-section geometries, see Figure 1.A and B. 2D fluid solvers were used to calculate the fluid velocity distribution over these geometries in order to estimate the fluid resistance of a conduit section. A series 1D lattice networks representing the conduit system of an entire lymph node were generated with a 15° periodic symmetry, see Figure 1.C.

These networks were constructed with constraints on the minimum and maximum nodal index, edge length and the density. The individual sections of these networks were given properties derived from the 2D study. A circular region in the center was used to represent the high endothelial venules and an outer region was chosen to represent the subcapsular sinus. By imposing a pressure difference between these region the flow rates through the conduit could be found. These flow rates were used by 1D advection-diffusion solvers to calculate the transport of an antigen, presented at the subcapsular sinus, through the system, see Figure 3.

RESULTS

The relationship between flow and resistance was found to be fairly predictable, for individual cross sections between area fractions of 0.5-0.9. Comparing antigen transport between a zero flow model and one that would maximize flow – conduit density 50%, 0.9% cross-sectional area-fraction and 3 μm diameter [3]. The maximum difference in antigen concentration, during 15 minutes of exposure, was less than 0.01%.

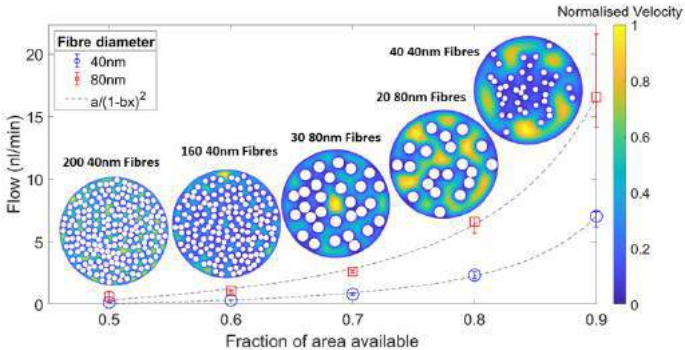

Figure 2: Normalized fluid velocities and flows for a 1 cmH₂O /cm gradient for differing area fractions and fiber diameters, insets show example geometries.

DISCUSSION

Wherever possible assumptions were made that would maximize the effect of flow. However, for all models considered, no significant effect of flow on the transport of antigen could be established. While flow is present within the lymph node conduit system, it is not sufficient to affect the transport of antigens. Work is underway to explore the role of the network structure such as anisotropy and small-world property, as well as the role of anomalous diffusion within and without the conduit system.

INTRODUCTION

Calcific aortic valve disease (CAVD) is a progressive disease of the aortic valve (AV) in which the aortic valve develops calcium deposits that gradually stiffen the valve [1]. For severe CAVD and aortic stenosis, patients must receive an AV replacement, either a mechanical valve or a bioprosthetic valve [1]. Currently, there is no pharmaceutical treatment for CAVD [1].

A crucial risk factor for CAVD is a congenital valve defect known as bicuspid aortic valve (BAV) [1], [2]. BAV is present in roughly 1-2% of the population and is characterized by the development of an aortic valve with two leaflets rather than the physiological three [2]. BAVs are around twice as common in men as women [2]. Despite the relatively low abundance of BAV in the general population, this defect is present in roughly 50% of patients undergoing AV replacement for aortic stenosis [2].

The leaflets of both TAV and BAVs consist of collagen, elastin, and glycosaminoglycans, which is maintained by contractile cells known as aortic valve interstitial cells (AVICs) [1]. AVICs mechanically sense the microenvironment of the AV with actin stress fibers [1]. In CAVD, the contractility of the AVICs may increase due to pathological activation. Activated AVICs recruit α -smooth muscle actin (α SMA) to stress fibers, leading to increased contractile function. These AVICs may then transition into an osteoblast-like state and deposit calcium into nodules which gradually stiffens the AV.

The microenvironment of BAVs contains pathological strains and disorganized protein structure, especially in the Raphe region. AVICs experiencing atypical strains may rapidly progress into a diseased phenotype [2]. The native activation of AVICs originating from CAVD patients is used to study the functional differences between BAV and TAV. It is not known whether BAVICs are intrinsically more activated than TAVICs, or whether differences in disease progression originate from the different microenvironments of the AV types.

METHODS

The AVICs were assessed in full 3D method for both global and local changes in basal cell characteristics.

Cell Extraction and Culture: Human AVICs were obtained from CAVD patients with TAV and BAV undergoing AV replacement. AVICs from the Raphe region of BAVs were studied (RBAVs), as well as from the BAV non-Raphe region (NRBAV), from a calcified region of a TAV (CTAV), and from a non-calcified region of a TAV (NCTAV). The AVICs were grown in 3D PEG hydrogels with CRGDS adhesive peptides and MMP-degradable crosslinkers, interspersed with 0.5 μ m fluorescent markers as previously described [3].

3D Imaging: A confocal microscope was used to image individual cells randomly selected from the gels in their Normal (N) state and Inactivated (I) state, which is the addition of Cytochalasin-D (CytoD), a drug which depolymerizes stress fibers [3].

Marker Recovery and Displacement: The basal tonus, or intrinsic contractility, of the AVICs was measured using 3D-TFM. The markers were recovered and tracked from Normal to Inactivated (CytoD treatment) with FM-Track [3]. AVIC surface meshes were computed by cell-recognition and surface smoothing.

Data Analysis: The AVIC surface meshes were reconstructed using spherical harmonic shape fitting as previously described [4]. This technique condensed the 3D geometry of the membrane into a spherical harmonic series. Stretches and displacements at the tip of the protrusion were computed for each AVIC experimental group.

RESULTS

Total AVIC Shape Change: All AVICs expanded outward to some capacity in the I state relative to the N state (Fig. 1). Spherical harmonic analysis was used to reconstruct the AVIC surface meshes. The resultant spherical harmonic coefficients represent the contribution of each term in the spherical harmonic series. Only coefficients of order

Figure 1: AVIC shape change from N to I. A) AVIC surface mesh reconstruction in the Normal state. B) AVIC surface mesh reconstruction in the Inactivated state. C) Surface displacements representative of AVIC deformation.

ten and below were shown to contribute to functional shape change. The difference of these coefficients from N to I was computed for each group. NCTAVs were found to have the highest magnitude of change and NRBAVs were found to have the lowest magnitude of change (Fig. 2). Additionally, different directions of deformation were assessed for trends in polarity of the AVICs. TAVICs were found to have similar magnitudes in two principal directions, while BAVICs deformed in primarily one direction.

AVIC Protrusion Displacement: AVICs have been shown to have piston-like deformation, in which the tip of the protrusion relaxes radially outward from the AVIC surface. The largest magnitude of displacement occurs at the protrusion tips (Fig. 1C). The displacements at the surface tip of the protrusion were computed for each experimental group (Fig. 3A). NCTAVs had the highest magnitude of displacement at the protrusion tips. The protrusion tip deformation shared the same trend as total shape change in which the group with the most displacement was NCTAV, followed by CTAV, RBAV, and lastly NRBAV (Fig. 3A).

Sex-Specific Distinctions: Female AVICs were found to have higher displacements on average than male AVICs (Fig. 3B).

DISCUSSION

The basal contractility of AVICs from varying disease states of CAVD has been shown to differ between experimental groups and sexes. The implications of this finding are in the contractile stress fibers of the AVICs, the extent of AVIC activation, and recruitment of α SMA to those stress fibers.

Results of both the spherical harmonic analysis and protrusion displacement analysis show the same trend in which TAVICs are more natively contractile than BAVICs. Of the TAVICs, NCTAVs had the highest displacements at the protrusion tips, indicating the highest basal contractility. The next highest basal contractility was measured to be the CTAVs, followed by the RBAVs. The least contractile group was found

Figure 2: Mean magnitude of change in spherical harmonic coefficient from N to I states.

Figure 3: Mean displacements at the protrusion tip. A) AVICs from TAVs and BAVs. NCTAVs have the highest displacements at the protrusion tips. B) Females on average have higher displacements at protrusion tips than males.

* P-value < 0.05; ** P-value < 0.005

to be the NRBAVs. On average, TAVICs were found to be more activated than BAVICs. Diseased TAVICs may have a higher contraction strength than BAVICs due to this pathological activation, which can be speculated to be because of increased α SMA recruitment.

In addition, AVICs from BAVs were shown to form stress fibers differently than AVICs from TAVs. Based on findings that TAVICs basal contractility was primarily in one direction and BAVIC basal contractility was in two directions, a possible explanation is that TAVICs form stress fibers that align in two directions, while BAVICs form stress fibers that align in one direction. The minor direction(s) of deformation occur because of compensatory isovolumetric effects, not inactivation of stress fibers from CytoD. The results of this study suggest that the cells from TAVs and BAVs behave differently in the same microenvironment. This finding in consideration with the prior finding that TAVICs are more contractile suggests that the rapid disease progression in BAVs could be due to microenvironmental effects on the AVICs, not intrinsic activation of BAVICs.

Sex-specific functional differences were observed, namely that female AVICs experience greater magnitude of protrusion displacement (Fig. 3B). This finding agrees with published findings that female VICs have higher basal levels of α SMA than male VICs [5]. The interplay between the prevalence of BAVs in males and the higher activation of female AVICs is a direction of future research.

In TAVs, CAVD development may begin in AVICs, while in BAVs CAVD develops first from the microenvironment, not the AVICs. Overall, this study is the first to compare excised human AVICs for functional differences in varying CAVD states. The findings that there are sex specific differences is crucial to understanding the disparity of disease and possible need for distinct treatment.

ACKNOWLEDGEMENTS

The author would like to acknowledge Dr. Ferrari for providing access to the excised human AVICs.

A NEURAL NETWORK FINITE ELEMENT APPROACH FOR HIGH-SPEED CARDIAC PRESSURE-VOLUME SIMULATIONS

INTRODUCTION

Comprehensive patient-specific computational models continue to be developed for cardiac simulations of health and disease [1-3]. However, due to the complex multiphysics and multiscale nature of cardiac biomechanical function, traditional finite element methods remain prohibitively slow for clinical applications. Furthermore, reduced order models are not ideal for clinical applications due to the loss of detail and potential loss of accuracy, especially for patient-specific clinical applications.

To meet the requirements of speed as well as accuracy, we have developed and utilized a novel neural network finite element (NNFE) approach for soft tissue simulations that can produce simulation results within clinically relevant timeframes [4]. The NNFE approach is a physics-based approach for rapid simulations that uses the neural network (NN) to represent the nodal displacements, and finite elements to map the displacement output from the NN on the problem domain, as well as to enforce boundary conditions and perform numerical integrations. In other words, this approach does not rely on data generated from physical experiments or simulations for training, rather, the NNFE model is trained to learn the governing PDE. In this work, we present a feasibility study using an extension of the NNFE approach towards complete organ level cardiac simulations to predict the P-V loop responses of the left ventricle, accounting for active contraction and transmural fiber distributions.

METHODS

The left ventricle was represented as a prolate spheroid as a first step scenario and was discretized with unstructured tetrahedral elements. The basal plane was constrained to in-plane motion only, one point on the basal plane was completely fixed, and an adjacent point was constrained radially, while pressure was applied to the inner surface. Fiber distributions were described by a rules-based approach to approximate the -60 to 60 degree transmural gradient (Fig 1). The

Figure 1: Fiber orientations in the myofiber and sheet directions respectively.

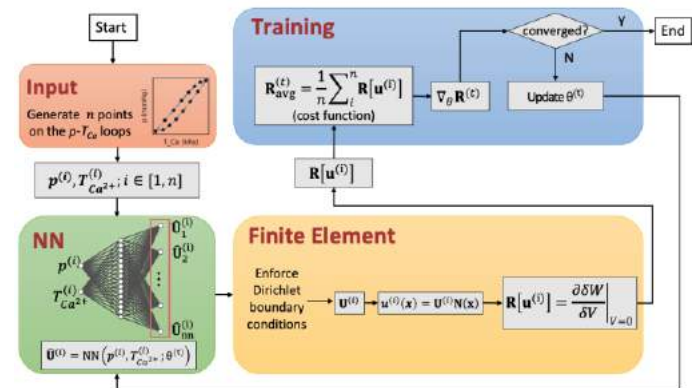

Figure 2: The NNFE training pipeline

passive mechanical properties of the myocardium were modeled with an incompressible transversely isotropic Fung-based hyperelastic material model, and the active contraction was modeled as an additional stress based on the Hunter-McCulloch-Ter Keurs model with minor

modifications. The material constants were taken from an ovine heart model [1]. Briefly, the weak form of the governing PDE is

$$\delta W(\mathbf{u}, \delta \mathbf{u}) = \int_{\Omega_0} \left(\frac{\partial \Psi}{\partial \mathbf{E}} + \mathbf{S}_{act} \right) : \delta \mathbf{E} d\Omega - \int_{\Gamma_0} \mathbf{T} \cdot \delta \mathbf{u} d\Gamma = 0 \quad (1)$$

where, $\mathbf{u} = \mathbf{UN}$ is the displacement field over the domain Ω , \mathbf{U} are the nodal displacements and \mathbf{N} are the basis functions, $\delta \mathbf{u} = \mathbf{VN}$ is the virtual displacement field and \mathbf{V} are the virtual nodal displacements, Ψ is the strain energy density function describing the passive behavior of myocardium, \mathbf{E} is the Green-Lagrange strain tensor, \mathbf{S}_{act} is the 2nd Piola-Kirchhoff active contraction stress and \mathbf{T} is the traction vector. The residual of the governing PDE is

$$R = \frac{\partial \delta W}{\partial \mathbf{v}} \Big|_{\mathbf{v}=0} = 0 \quad (2)$$

The NNFE model was setup to take pressure p and active contraction $T_{Ca^{2+}}$ as the input and predicted the nodal displacements \mathbf{U} in the output layer (Fig 2). In addition, the NN had one hidden layer with 16 neurons. We trained the NN by minimizing the residual of the governing PDE (Eq. 2, Fig 2) using the first-order gradient based optimization algorithm Adam [5] along with learning rate scheduling. Moreover, while our previous approach utilized a reduced order model [6] to train the neural network, no model order reduction was required in this approach, the NNFE model was trained over the full order model. We trained the model over two pressure-volume (P-V) loops and predicted the P-V relationship for a third loop. We compared the results of the NNFE model against an identical simulation setup in FEniCS [7].

RESULTS

The NNFE model predicted the displacement and the corresponding PV loop (Fig. 3). The mean nodal error between the NNFE solution and the FE solution was 2.32×10^{-2} mm, with a standard deviation of 4.53×10^{-2} mm (Fig. 4). The trained NNFE model could accurately produce the twisting experienced by the left ventricle under active contraction. The trained NNFE model took 2-3 seconds for producing the results for each state, whereas FEniCS took 10-20 min.

DISCUSSION

We presented a novel NNFE approach to produce the active contractile behavior of a left ventricle under a given PV loop. Although the NNFE method does take longer to train, this is not a limitation, as the NN only needs to be trained once over a range of boundary conditions. Once trained, the NN can produce results for any boundary condition within the training range without a need for retraining. Consequentially, the NNFE approach is well-suited for many-query problems, such as patient-specific surgical planning, where one needs to solve very similar problems repeatedly with only small changes to the inputs. For such applications, the training can be done in advance, and when presented with the patient-specific data, rapid simulation results can be produced with the trained model.

Our results demonstrate the first application of the NNFE approach for a biomedical application at an organ level. We will use this model to study the effect of infarcts in different locations of the ventricle on cardiac behavior. We are also working on extending this method to study the effects of inotropy on cardiac behavior by varying the slope of the end systolic P-V relationship. Our results represent a small but an important first step towards a digital twin. In the future, geometry and material property variations will be included. While still in its early stages, this approach paves the pathway for high-speed patient-specific clinical simulations.

INTRODUCTION

Intracranial aneurysms (IAs) are weak bulging spots in the cerebral vasculature, that when ruptured, are associated with high mortality and morbidity rates. Currently, the rupture risk of a newly-discovered IA is evaluated based on its size at the time of imaging and the clinical parameters of the patient. Yet, IA size is subjective, and 49% of all ruptured IAs are small [1]. Recently, vessel wall enhancement (VWE) has emerged as a potential imaging biomarker for IA risk stratification. This is a phenomenon where higher signal intensity is observed on contrast enhanced MRI (CE-MRI) compared to a baseline non-enhanced MRI (NE-MRI). Aneurysms exhibiting VWE have been shown to be more unstable and prone to rupture [2]. However, the underlying pathobiology of VWE is poorly understood.

Past studies have shown that VWE is associated with aberrant intra-aneurysmal flow and wall forces, which could lead to disequilibrium in the IA wall, thus potentiating its growth or rupture. To estimate the forces being exerted on the IA wall, tools such as computational fluid dynamics (CFD) and finite element analysis (FEA) are used. In this study, we sought to investigate the underlying relationship between VWE, physical forces in the IA wall and the histopathology of the aneurysm. To this end, we used intraoperative imaging obtained during aneurysm clipping to identify different wall phenotypes (i.e., atherosclerotic, normal, and thin-walled regions), and performed patient-specific FEA and CFD to quantify hemodynamics and wall stresses in the IA tissue. We then quantified the differences in hemodynamic forces and wall stress between different wall phenotypes.

METHODS

We retrospectively collected MRI scans of patients who had undergone VWE imaging protocol at our center and were treated using surgical clipping (Study 00004370). Intraoperative videos taken during microsurgical clipping were used to identify the frame where the IA was best visualized. From this image, different IA wall phenotypes were

quantified (here, purple crimson/pinkish = ‘Normal’, dark red = ‘Thin’, and tan/whitish/yellowish = ‘Thick/atherosclerotic’) using an objective and automated image processing pipeline as described previously [3]. We used a previously-developed pipeline to generate 3D maps of normalized VWE for each case using a combination of time-of-flight MRA and CE-MRI [4] (see workflow in Figure 1). The signal intensity on the IA sac in the CE-MRI image was normalized to the average intensity in the corpus callosum of the same CE-MRI scan (Equation 1).

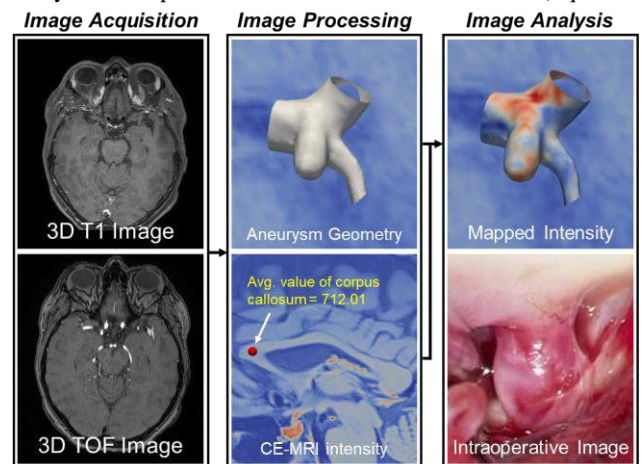

Figure 1: Workflow for 3D mapping of VWE – We register the T1 CE-MRI and TOF MRA image. We compute the average intensity at the genu of corpus callosum and use it to normalize the mapped intensity. We compare mapped VWE intensities of different wall phenotypes observed on intraoperative imaging.

$$CC_{ratio} = \frac{\text{Avg. Intensity of Aneurysm Sac}}{\text{Avg. Intensity of CC}}$$

Next, we used the segmented MRA image to perform CFD and FEA. CFD was performed as described in previous studies [5]. For FEA, we used a uniform wall thickness of 86 μm and a uniform pressure of 100 mm Hg. We computed the sac averaged normalized wall shear stress (WSS) and sac averaged von mises stress. We then analyzed the median VWE intensity, hemodynamic quantities and stress values in regions of different wall phenotypes.

RESULTS

Two patients who received VWE MRI scans were treated using surgical clipping. For both cases (Case 01 and Case 02), a sufficient proportion of the total sac area was visible on intraoperative imaging. Of note, Case 01 had the top of the dome covered entirely during the intraoperative video. For Case 01, thick regions showed the maximum intensity of 0.865. Normal regions had an intensity of 0.824 which was less than the thick regions. The least intensity values were for thin regions of 0.748.

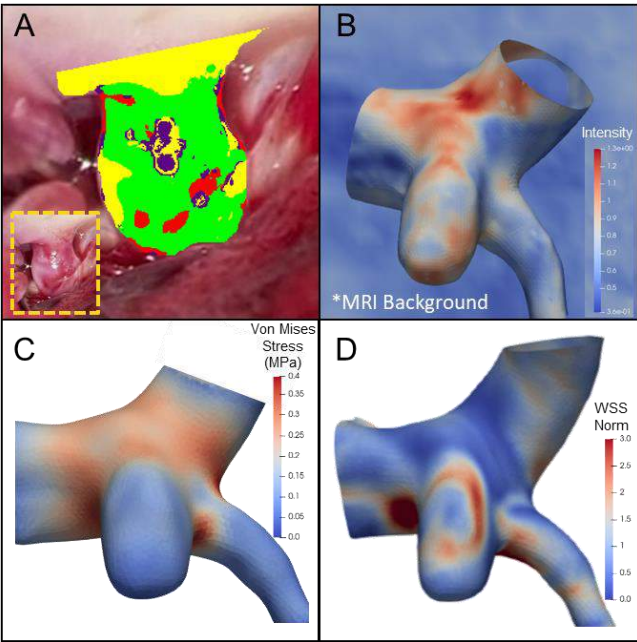

Figure 2: Aneurysm presentation, imaging quantification, and stress calculation for Case 01. Qualitatively, we observed a spatial relationship between the wall phenotype on intraoperative imaging (A), the VWE intensity (B), Von Miese stress from FEA (C), and WSS_{Norm} from CFD (D).

For case 02, thick regions showed the intensity of 1.04. For thin and normal regions, the intensity was slightly lower (1.02 and 0.9856, respectively). In case 02, the highest intensity was shown by thick regions, as in Case 01, but the normal regions had the lowest intensity. Thin regions intensity was higher than that in the normal regions.

From CFD analysis, we found that in Case 01, thick atherosclerotic regions had a lower normalized wall shear stress (WSS_{Norm}), higher relative residence time and a higher negative wall shear stress divergence (WSSD). However, in Case 02, we observed that this trend was reversed where thick, atherosclerotic regions had high WSS_{Norm} and low RRT. However, WSSD was still negative in thick regions.

Through our FEM analysis, we found that thick regions consistently had higher stress values in the IA wall as compared to the thin and normal regions in both Case 01 and Case 02.

Table 1: Median VWE, hemodynamic and stress values in different IA wall phenotypes as observed on intraoperative videos

	Thin Wall	Normal Wall	Thick Wall
Case 01 (Percent Wall)	9.3%	68.3%	14.0%
Norm. VWE Intensity	0.748	0.824	0.865
WSS _{Norm}	1.427	1.154	0.578
RRT (Pa ⁻¹)	0.056	0.069	0.140
WSSD (Pa/m)	-221.35	-381.74	-586.62
Von Mises Stress (MPa)	0.109	0.142	0.153
Case 02 (Percent Wall)	16.6%	53.8%	26.3%
Norm. VWE Intensity	1.020	0.986	1.04
WSS _{Norm}	0.1822	0.325	1.438
RRT (Pa ⁻¹)	1.466	0.810	0.182
WSSD (Pa/m)	47.587	289.995	-966.34
Von Mises Stress (MPa)	0.245	0.270	0.302

DISCUSSION

In the current multi-modal analysis of IA wall phenotypes, we found that thick regions observed on intraoperative images had higher VWE intensity. Past histopathological studies have also found similar trends. A study by Matsushige et al. found that IAs exhibiting focal VWE had an intraluminal thrombus at the location of VWE [6]. Furthermore, we found that the thick regions had a lower WSS_{Norm}, higher RRT and higher negative WSSD. Previous studies exploring the relationship between hemodynamics and intraoperative wall appearance found that low WSS and high RRT were related to recirculation zones in the IA, which could promote lipid deposition and atherosclerosis [7]. We also found that the thick regions had a higher negative WSSD in both cases. WSSD is indicative of the orientation of WSS vectors and the stretch force on the wall. A higher negative WSSD promotes contractile forces in the IA tissue that could promote thicker walls with atherosclerosis [8]. Finally, through FEA we consistently found that thinner regions in the IA sac had higher values of stress which could lead to damage of mural cells and hence thinner wall.

There are several limitations to this study which we are currently addressing. Firstly, our sample size of n=2 was too small for statistical analyses. Secondly, the 3D geometry of the IA was manually oriented to match the intraoperative videos which can introduce subjectivity.

INTRODUCTION

Osteoarthritis (OA) is a common and debilitating disease caused by the breakdown of articular cartilage. The composition of healthy articular cartilage is optimized for its mechanical performance, comprised of water and negatively charged sulfated glycosaminoglycans (GAG) constrained by a fibrous type-II collagen network (COL). Early-stage cartilage degeneration is characterized by changes in the composition of the tissue—notably loss of sulfated GAG and/or tissue swelling—contributing to mechanical softening, followed by more severe erosion of the collagen network. Biochemical assays and histological staining have long served as gold standards for characterizing cartilage composition in response to pathologic degeneration or treatment [1]. However, these methods are sample destructive—as such, they are incompatible with clinical assessments or repeated-measure analysis of compositional changes in ex vivo and in vivo pre-clinical investigations.

Raman spectroscopy is an inelastic light scattering technique that yields a non-destructive, quantitative, point-wise optical fingerprint of a tissue's molecular building blocks (amides, sulfates, carboxylic acids, and hydroxyls), thus allowing recognition of the predominant molecular constituents of articular cartilage: GAG, COL, and H₂O. In our prior work, we established the capability of optical biomarkers derived from Raman probe-based measures to correlate with the composition (GAG, H₂O) and mechanical properties of articular cartilage tissue specimens, thus establishing the potential of Raman to be used as a novel tool for non-destructive assessments of cartilage health in pre-clinical and clinical investigations [2]. However, Raman biomarkers are defined in spectral intensity units, and as such, provide only semi-quantitative assessments of tissue composition.

In the current study, we explore the capability of using compositional tissue phantoms to convert acquired relative Raman biomarkers from cartilage tissue specimens to absolute biochemical concentration values. Tissue phantoms are composed of hydrogels with prescribed ratios of the key constituents of cartilage and used to generate

a high-quality training data set that converts non-linear, relative Raman biomarker measures into absolute biochemical concentrations of GAG, COL, and H₂O. This conversion algorithm is validated with an in vitro model system, whereby live cartilage explants are monitored in response to a range of biochemical compositional changes akin to those present in early OA, consisting of—1) GAG depletion induced by media supplementation of the catabolic cytokine interleukin-1 α (IL-1 α) [3], and 2) cartilage swelling induced by culture in the absence of the corticosteroid dexamethasone (DEX) [4]. Phantom-calibrated quantitative Raman measures are compared to standard assay techniques for validation.

METHODS

Explant Culture: Cylindrical disks ($\varnothing 3 \times 2$ mm) of deep zone cartilage were harvested from immature bovine femoral condyles. Explants were cultivated in high glucose DMEM (1mM Na pyruvate, 50 μ g/mL L-proline, 1% PS/AM antibiotic/antimycotic, 50 μ g/mL ascorbate-2-phosphate, 0.1% BSA) \pm DEX (100nM) to induce a variable degree of tissue swelling and \pm IL-1 α (50ng/mL) to induce a variable degree of GAG depletion. After 0, 6, 10, or 14 days of culture, explants were subjected to Raman, mechanical (compressive Young's modulus [E_Y], and biochemical analysis (H₂O content and DMMB-measured GAG content). Additional groups were cultured for 15 days without IL-1 α , followed by IL-1 α for subsequent 6 days in an attempt to induce GAG depletion after significant swelling.

Phantom production: GAG (bovine trachea chondroitin sulfate; Sigma) and hydrolyzed collagen (gelatin from bovine skin; Sigma) powders were mixed at prescribed ratios in PBS in Eppendorf tubes to produce 25 phantoms with every combination of 5 concentrations of GAG (0%, 2.5%, 5%, 7.5%, and 10%), 5 concentrations of collagen (0%, 5%, 10%, 15%, 20%), and corresponding H₂O (H₂O%=100%-GAG%-COL%) (fig 1d). Tubes were mixed at 10-30 RPM (56°C) for 3 hours, followed by casting 50 μ L of each phantom into an aluminum sample pan for Raman analysis.

Raman Spectroscopy: Raman spectra of explants and phantoms were acquired via a commercial RIP-RPB-785 probe (Ocean Insight), a 785nm fiber-coupled laser (Innovative Photonic Solutions), and a QEPro spectrometer (Ocean Optics). The spectral fingerprint range (800-1800cm⁻¹) was preprocessed and subjected to a multivariate least-squares linear regression model to calculate the relative contribution, or ‘scores’ of the predominant cartilage constituents (GAG, COL, and H₂O) using equation: $\text{Cartilage}_{\text{spectra}} = \text{GAG}_{\text{score}} * \text{GAG}_{\text{REF}} + \text{COL}_{\text{score}} * \text{COL}_{\text{REF}} + \text{H}_2\text{O}_{\text{score}} * \text{H}_2\text{O}_{\text{REF}}$, where **GAG_{REF}** **COL_{REF}** **H₂O_{REF}** are the spectra of purified reference chemical [2] (Fig 2a,b). The areas under the OH and CH₂ peaks in the Raman high-wavenumber region was measured to yield two additional metrics related to tissue hydration and organic content, respectively.

Phantom Calibration: The concentration of each constituent was estimated using a 2D polynomial curve-fit of two Raman metrics using the Matlab curve fitting toolbox (poly22 sfit object). A representative curve-fit it depicted in Fig 2D. Raman scores were selected by minimizing model error against known constituent concentrations in phantoms. Model performance was then validated against assay-measured GAG and H₂O contents in cultured explants.

RESULTS

Explant model: The following explant trends were observed (Fig 1A-C): For +Dex/-IL1 α , explants exhibited only modest changes in GAG, H₂O, and EY over time. For -Dex/-IL1 α , explants increased H₂O and lost EY over time. For +Dex/+IL1 α , explants lost GAG & EY but increased H₂O over time. For -Dex/+IL1 α , explants exhibited a further loss of GAG & EY and increased further in H₂O over time. These different treatment groups were able to produce explants with a wide range of compositions (Fig 1D), which allowed for assessment of the phantom conversion function over a wide range of compositional states.

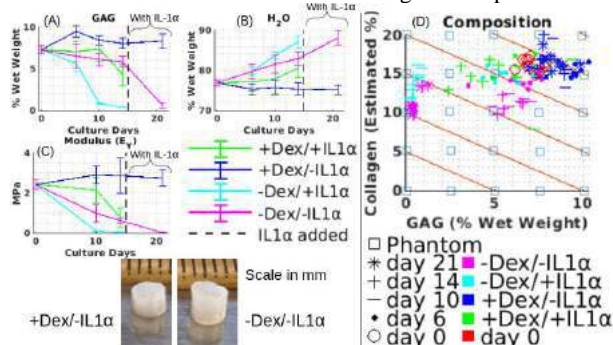

Figure 1:(A) GAG content, (B) H₂O content, and (C) EY of treated explants over time. The dashed line at day 15 is when IL-1 α was added to groups previously cultured without it. (D) Composition of all explants in terms of GAG and estimated collagen content.

Diagonal orange lines are isolines of equal H₂O concentration.

Raman phantom conversion: The spectral contribution of cartilage constituents generally reflected their concentration in the tissue—e.g., a lower GAG score observed for IL-1 α treated explants (Fig 2A&B) and higher OH area observed for -Dex explants (Fig 2C). Raman biomarker scores exhibited moderate-to-strong correlation with direct assay measures ($R^2=0.77$ to 0.84 ; Fig 3A-C). After phantom training set conversion, Raman was able to predict real concentration with a high degree of accuracy (Fig 3D-E). The 95% confidence interval for GAG was $\pm 2.5\%$ - 2.3% of the assay measured value. Similarly, the 95% confidence interval of H₂O estimation was $\pm 2.2\%$ - 3.1% . by correcting for cross talk from overlapping spectra, as seen in the improved R^2 .

DISCUSSION

This work advances a novel Raman assay platform for achieving non-destructive quantitative measures of cartilage biochemical composition. The in vitro cultivation of cartilage explants serves as a unique model

to explore the ability of phantom-trained Raman measures to accurately predict concentrations of biochemical constituents in cartilage for a wide range of degenerative states, where the relative proportions of GAG, COL, and H₂O vary in the tissue. The temporal application of Dex depletion and/or IL-1 α exposure, allows for a parametric variation of combined tissue swelling and GAG depletion serving to test the technique’s ability to measure the degenerative modes observed in OA pathology. Our phantom-training set provides a mapping function that converts Raman biomarker scores to highly accurate measures of the concentration of biochemical constituents in cartilage, as evidenced by tight 95% confidence intervals when comparing predictions to direct assay measures of GAG and H₂O. In the future, we aim to further compare predictions of COL to assay measures.

This platform can serve as a standardized analytical tool to non-destructively quantitatively measure the composition of cartilage in response to degeneration and treatment across a range of preclinical and clinical R+D model systems, spanning from ex vivo explant studies, to in vivo animal studies, to RCT clinical trials. Clinically, quantitative Raman monitoring of patients can be performed arthroscopically for measures of cartilage composition in patients, allowing for earlier and more precise determination of tissue pathology and evaluation of tissue response to treatment.

AN ANTHROPOMORPHIC, ACTUATED WRIST FOR ACHIEVING BIOMIMETIC MOTION OF A ROBOTIC HAND

INTRODUCTION

A functionally accurate artificial hand has long been a major focus for roboticists, and critical to that goal is a robotic wrist that can match the human wrist for strength and range of motion. The wrist provides the hand with the majority of its flexibility, allowing for a much finer degree of positioning than is achievable with the shoulder and elbow joints alone. As such, a robust artificial wrist that can achieve most or all of the natural wrist's range of motion is an invaluable development for prosthetics, anthropomorphic or surgical robotics, and other areas where human-like motions would be desirable.

The difficulty of replicating the human wrist lies in its complexity. The wrist proper, consisting of the eight carpal bones and associated anatomy, has two degrees of freedom (DoFs): flexion/extension of the palm, and radial/ulnar deviation (abduction/adduction) of the hand. Additionally, the wrist joint is commonly understood to include the distal heads of the radius and ulna, which add pronation/supination as a third DoF. The precise ranges of motion of these DoFs vary from individual to individual; average values for each are given in Table 1. Achieving these values is not in itself prohibitive; indeed, a standard 3-axis gimbal can approximate or even greatly exceed the natural wrist's range of motion. However, active actuation of such a design poses challenges for maintaining an anthropomorphic footprint, especially for applications where strength and durability are key design factors.

As such, most prosthetic wrists currently on the market are single-DoF devices that include only pronation/supination, either actively or passively actuated. More advanced prostheses, such as the Fillauer Four Function Wrist, incorporate flexion/extension or ab/adduction, but these almost always employ passive friction joints which are externally actuated—typically by the user's other limb or by the environment—and can be locked to pre-position the hand for a given task [1]. Fully actuated devices that can match the natural wrist's three degrees of freedom are more commonly encountered in industrial or research settings, but are typically large, heavy, and deferential to function over

form. Devices such as the Omni-Wrist III achieve a biomimetic range of motion via multi-axis motion platforms rather than a more naturalistic gimbal [2], but the complex linkage structures of these wrists pose challenges for presenting an anthropomorphic form factor. Our project's goal is to address each of these shortcomings, developing a strong, durable three-DoF wrist that is actively actuated and conforms to the anthropomorphic appearance needed for prosthetics and humanoid robotics. Our primary motive is to support the work by Johnson *et al.* in developing a robotic hand to communicate with DeafBlind individuals using tactile American Sign Language (ASL) [3]; however, we hope the resulting wrist can serve as a flexible platform for applications with similar requirements.

METHODS

The wrist was designed to achieve at minimum the range of motion given in Table 1, and to do so via self-actuation. The actuators used are Dynamixel servomotors, chosen for their flexibility, speed, ease of control, and low cost. All structural components are 3D-printed in nylon. To achieve the required degrees of freedom, the wrist uses three joints arranged in series: first pronation/supination, then ab/adduction, and finally flexion/extension just below the end effector (Fig. 1A).

To accommodate cable pass-through, the pronation/supination joint (Fig. 1B) uses an internally driven ring gear. A lower support plate holds the drive motor, a single Dynamixel XL330-M077-T, and provides an attachment point for the wrist to a base; an upper plate houses the ring gear and connects to a forearm structure. A needle-roller thrust bearing between the two support plates supports transverse loads, and a central shoulder screw-ball bearing assembly connects the plates and supports lateral loads. The support plates are slotted to accommodate a 12mm-diameter cable bundle through 180° of motion, and a 3:8 gear ratio allows the joint to rotate 180° in 1.1 seconds (chosen to achieve a speed of 1 letter per second with the Tatum ASL hand). The joint is located 130mm below the next joint axis, chosen to center the

rotation roughly halfway down the average forearm; a shorter or longer distance could be used if required.

The ab/adduction and flexion/extension joints (Fig. 1C) each form one yoke of a modified universal joint structure, with the central crosspiece designed to approximate the structure of the eight carpal bones. To match the natural wrist's centers of rotation, the crosspiece separates the joint axes by 20mm. Both joints ride on ball bearings for free movement, and the crosspiece is hollow to allow for cable pass-through into the end effector. The joints are Bowden cable-driven using nylon-coated steel wire rope, running through surgical spring guides to remotely mounted Dynamixel XC330-M288-T motors. The cables for the ab/adduction joint terminate in the crosspiece, with their spring guides anchored in the forearm; the flexion/extension cables form a continuous loop through the base of the end effector itself, with their spring guides anchored in the crosspiece. This staging of the joints completely decouples the axes from each other, allowing the wrist to rotate in any one axis without affecting the rotation of the other two.

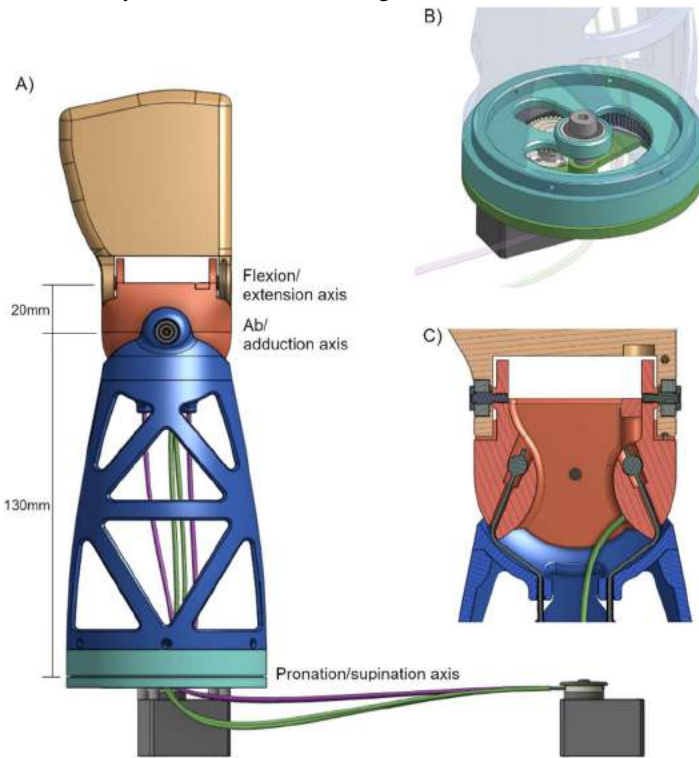

Figure 1: (A) Overview of the proposed wrist, with separation between axes indicated. (B) Detail of pronation/ supination joint, showing gearing and cable passthrough. (C). Section through crosspiece, showing cables and spring guides for the flexion/extension and ab/adduction joints.

RESULTS

As the wrist was designed to support the development of a robotic hand that can communicate in tactile ASL, validation trials with DeafBlind individuals constituted a valuable performance metric. These trials consist of the user holding the back of the robot's hand while it signs letters, allowing them to feel its motions. Results were very promising: the users achieved a letter recognition rate upwards of 90% (N=5), indicating that the wrist's motions felt comparable to those of a natural wrist.

Objective testing was also performed to validate the wrist's range of motion and durability. The wrist exceeded its motion targets in

flexion, abduction, and pronation/supination, but failed to achieve its targets for extension and adduction (see Table 1). To assess durability, each joint was run through its full range of motion in two-second intervals. The gear-driven pronation/supination joint proved durable, readily performing 10,000 cycles and showing no signs of wear. The cable-driven joints, however, each lasted roughly 5,000 cycles before the cables frayed to the point of breaking. The tactile ASL end effector uses two wrist motions each for the letters g, h, j, p, q, y, and z, which collectively have an estimated English frequency of 11% [4]; with a 5,000-cycle lifespan, we would thus expect the hand-wrist unit to form roughly 23,000 letters before servicing was required.

Table 1: Typical ranges of motion for the natural wrist [1], along with those achieved by the designed wrist

Motion	Range of motion		
	Natural wrist	Designed wrist	Percent difference
Flexion	75°	94°	+25.3%
Extension	75°	73°	-2.7%
Abduction	20°	37°	+85.0%
Adduction	45°	37°	-17.8%
Pronation	76°	90°	+18.4%
Supination	85°	90°	+5.9%

DISCUSSION

We feel that the designed wrist successfully captures human motions in all three axes and represents a strong foundation for further refinement. One priority is to improve the range of motion for extension and adduction; minor mechanical alterations should be sufficient. The other major priority is improving the durability of the cable-driven axes, as the estimated 23,000 letters is insufficient for lasting use. Potential solutions include smoothing edges to reduce concentrated stresses, experimenting with lubrication and material selection to reduce friction, or increasing cable diameter. Additionally, future trials will assess the wrist's exerted force in comparison to that of a human wrist, as concrete force measurements would be useful for generalizing the wrist as a platform for various end effectors.

Despite these ongoing focuses, the design shows promise towards an anthropomorphic, actuated wrist that can mimic natural motions. Through further iterations, we hope to increase the wrist's durability in order to stand up to day-to-day wear on a prosthetic or humanoid robot. With the success seen in trials with DeafBlind users, our proposed wrist shows great potential for achieving proper biomimetic functionality in an anthropomorphic form factor; additional generalizations would make it usable as a multi-purpose wrist platform for humanoid robotics.

ACKNOWLEDGEMENTS

We would like to thank Tatum Robotics for commissioning this project, along with Northeastern University and the Institute for Experiential Robotics at NEU for their ongoing development support.

MICROMECHANICAL RESPONSE OF FIBROUS NETWORKS SUBJECTED TO FAR FIELD AND LOCAL CONTRACTILE FORCES

Ashutosh Mishra (1), Hamed Hatami-Marbini (1)

INTRODUCTION

The primary structural component of wide number biological and non-biological materials is a network of randomly interconnected semiflexible cross-linked fibers. These random fibrous networks can be found in non-living materials such as paper, cloth and in the biological materials such as cytoskeleton and soft tissue [1]. These random structures in biological materials provide the structural integrity and facilitate cellular movement [2]. One such biological material made up of random fibers is the extracellular matrix (ECM) which is ubiquitous in all tissues and organs. The ECM is made-up of multiple macromolecules namely the proteoglycans and fibrous proteins such as collagen, elastins, fibronectins, and laminins [2]. The collagen among others is the most abundant fibrous protein and can be found in the ECM of cornea, cartilage, tendons, and ligaments providing strength, facilitating tissue development, cell migration, and cell adhesion, playing a vital role in multiple physiological processes such as the fibrosis and wound healing [4].

One of the striking feature of these biological random networks, which is not found in synthetic networks, is the nonlinear strain stiffening behavior, wherein the stiffness of the network increases with increase in applied strain. A number of studies over the years have shown the presence of residual stresses or the prestress in biological networks. For instance, the presence of prestress in arteries is important for maintaining the state of homogenizing strain and providing reinforcement [5], or the prestress realigns and straightens collagen fibers in ECM towards the direction of the applied force. The fibrous networks under prestress behave differently than the relaxed networks. In particular, the prestress is known to stiffen or soften the networks under extension or compression and thereby affecting their mechanical response [6-7].

In addition to the far-field force and internal prestress, the biological networks could also experience local contractile forces applied by the shape changing contracting cells resulting into local

stresses and deformation field. Studies have shown that these local forces can give rise to prestress in networks, which in turn play a role in remodeling the network architecture and facilitating long-range displacement propagation [8][9]. It would be interesting to combine the two effects namely the prestress and local contractile forces and study the mechanical response of the random fibrous network as it can provide better insights into the mechanical behavior of biological networks and understanding the cell mechanosensing, long-range displacement propagation, and cell-matrix interactions.

METHODS

A 2D model is created from a regular triangular lattice network of size $W \times W$, fiber length l_0 and connectivity 6. The biological networks are subisostatic structures and their connectivity is often between 3 and 4. Thus, the triangular lattice network is diluted by removing fibers with the probability of $1-P$ until the connectivity is under the Maxwell's threshold value of 4. P is the probability of fibers that are present in the networks. In this work, we use networks with average connectivity of about 3.3, which is comparable to the typical connectivity of collagen networks. The fibers in the network are modeled as athermal planar beam elements having circular cross-section with area A , elastic modulus E and moment of inertia I . The axial modulus μ and bending modulus κ of the fibers are $\mu=EA$ and $\kappa=EI$, respectively. The dimensionless bending rigidity is defined as $\bar{\kappa} = \kappa/\mu l_0^2$ and is considered to be 10^{-4} in this study unless stated otherwise. Furthermore, the fibers in the network are meshed into multiple elements to capture the deformation of the fibers accurately.

First, the effect of prestress on the shear response is studied. To analyze the network under prestress (ϵ_{ps}), the network is uniaxially stretched or compressed by displacing the nodes at the top horizontal boundary either vertically upwards or downwards. The nodes at the bottom horizontal boundary are fixed. Then, the shear strain is applied by displacing the nodes at the top horizontal boundary following the

procedure stated in our previous work [7-8]. A finite element software is used to obtain the solution and displacements of all nodes. The shear stress is then calculated by dividing the sum of forces in the fibers intersecting the top horizontal edge by W . The differential shear modulus $K = d\tau/d\gamma$ is calculated using shear stress-strain curves, where τ is the shear stress and γ is the applied shear strain.

Figure 1: Random fibrous network generated from regular triangular lattice with fibers removed from the center to include the contractile cellular forces

To study the effects of local contractile forces, fibers are removed from a circular region with radius r from random fiber networks, Figure 1. The size effects are curtailed by selecting the radius r such that the ratio of W/r is greater than 40. Next, the cellular contraction forces are applied by isotropically displacing the nodes at the boundary of the empty central circular domain radially inward while keeping the nodes at the network boundary constrained at their respective position. The contraction of 25% in increments of 5% is applied. To track the propagation of displacements within the fibrous networks, the radial displacements U_R vs the radial distance R is plotted and the data is fit to the following equation [9].,

$$U_R = AR^{-n} + BR^n \quad (1)$$

The unknown variables A , B , and n are found using a nonlinear least square fitting algorithm.

RESULTS

The differential shear modulus of the network under applied shear strain for different values of prestress studied on network without the central inclusion region is shown in Figure 2. It is seen that the nonlinear variation of shear modulus is a function of the applied prestress. Furthermore, the radial displacement U_R as a function of radial distance R is plotted in Figure 3(a) for networks with a contractile local force. It is seen that the radial displacement significantly decreases with increasing the distance from the center of the network. The rate of decay n depends on the amount of contractile force and applied prestress. Figure 3(b) shows dependence of the decay rate n as a function of contractile deformation. It is noted that $n=1$ is the displacement decay rate that is obtained from the classical linear elasticity theory.

DISCUSSION

The results here clearly show that the shear modulus and the onset of strain-stiffening is a function of applied axial prestress to the networks, Figure 2. When the applied axial prestress is tensile, the shear modulus is observed to increase proportional to the magnitude of prestress. However, the shear modulus is observed to decrease with compressive prestress. This indicates that the shear modulus of networks become stiffer with the prestress extension and softer during the prestress compression. This behavior is because prestressing the

network reorients fibers in the direction of (or away from) loading thereby increasing the shear response in tension (or decreasing it in compression). With increasing the local contractile deformation, the displacement is seen to propagate further in the networks, Figure 3. The possible mechanisms for such behavior are compression weakening and fiber reorientation [9]. These are interesting findings and lay the foundation for ongoing investigations where combined effects of prestress and local contraction on the fibrous networks are investigated, aiding us in better understanding of interesting mechanical response of fibrous biological networks such as ECM and cytoskeleton.

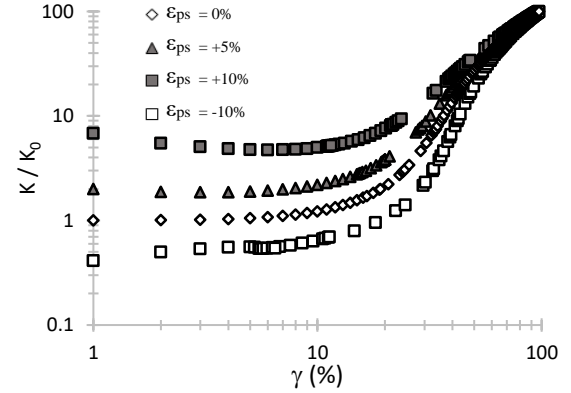

Figure 2: The effect of axial prestress strain ϵ_{ps} on the normalized differential shear modulus where K_0 is the initial shear modulus.

Figure 3: (a) Radial displacement U_R vs radial distance R . The solid line is the numerical fit that is obtained from equation (1); this figure is plotted for 20% contraction. (b) The change in the values of n in equation (1) with changing contraction percent.

INTRODUCTION

The main role of dendritic cells (DCs) lies at the interface between the innate and adaptive immune systems. DCs are antigen-presenting cells: upon encountering an antigen while patrolling tissue, they capture and process the antigen and then migrate to a lymph node where they present the antigen, material to T cells. In order to migrate, DCs move up gradients of the chemokines CCL21 and CCL19, the two ligands of the receptor CCR7 that is expressed on the surface of DCs.

We present a mechanistic model of CCL21 gradient formation and DC migration within the interstitium during and after an inflammatory challenge. The model accounts for diffusion and advection of CCL21, binding of CCL21 to extra-cellular matrix (ECM), CCL21 cleavage by DCs, binding of CCL21 to CCR7 on DCs, random motion of DCs (modelled as diffusion), DC maturation, and haptotactic migration in response to CCL21 gradients. We simulate inflammation by varying parameters (representing certain biological processes, such as the rate of DC maturation) thought to take significantly higher values in inflammation compared to homeostasis.

Model parameter values are obtained from the literature where possible, including our previous works [1] and [2]. For the remaining unknown parameters we either infer their values from preliminary experimental data (in particular, specifically designed cleaving assays) or we perform simulations over a wide range of parameter values, allowing us to assess the sensitivity of key model outputs with respect to these parameters.

METHODS

Our model consists of a system of 7 coupled PDEs governing the dynamics of CCL21 and DCs in the interstitium. These are supplemented

with boundary conditions that impose chemokine and cell concentrations or fluxes at blood vessel (b.v.) and lymphatic vessel (l.v.) boundaries. For brevity, in (1) we show only the dimensionless equations governing the concentrations of unbound full-length chemokine, C_u , and mature DCs with ECM-bound chemokine bound to their CCR7, ϕ_{C_b} . The latter are the subset of DCs that migrate up local bound CCL21 gradients.

$$\partial_t C_u = \nabla^2 C_u - \mathbf{P} \mathbf{e}_u \cdot \nabla C_u - \alpha^+ \bar{E} C_u + \alpha^- C_b \quad (1a)$$

$$- N_{R7} \beta^+ C_u \phi_m + \frac{\bar{\phi}}{C} N_{R7} \beta^- \phi_{C_u} - \sum_{\ell=i,m} \gamma_{u,\ell} \phi_{\ell} C_u,$$

$$\partial_t \phi_{C_b} = \nabla \cdot (D_{\phi_{C_b}} \nabla \phi_{C_b}) - \nabla \cdot (\chi_b \phi_{C_b} \nabla C_b) + \alpha^+ \bar{E} \phi_{C_u} \quad (1b)$$

$$- \alpha^- \phi_{C_b} + \frac{C}{\bar{\phi}} \beta^+ C_b \phi_m - \beta^- \phi_{C_b}.$$

The haptotaxis term in (1b), $-\nabla \cdot (\chi_b \phi_{C_b} \nabla C_b)$, is of Keller-Segel form [3, 4] and models how DCs move up gradients of chemokine concentration. A number of variants of the Keller-Segel model can be found in the literature; see e.g. [5]. The Péclet number Pe , which is defined as the ratio of advective and diffusive fluxes, characterises the strength of the interstitial flow that advects unbound and soluble CCL21.

For simplicity, we consider the system (1) in one spatial dimension. We impose a flux of immature DCs (ϕ_i) into the interstitium from the b.v., and assume that migrating mature DCs (ϕ_{C_b}) move into the l.v. as soon as they reach it. All other types of DC have zero flux across the b.v. and l.v. boundaries. We assume unbound full-length chemokine (C_u) has (dimen-

sionless) concentration of unity at the l.v., and concentration zero at the b.v..

Initially, all parameters are set to their homeostasis values and simulations are run until a steady state is reached. Then a state of inflammation is simulated by increasing the immature DC ingress rate and DC maturation rate (Figure 1A). We also allow for a lag between the onset of inflammation and the increase in the DC ingress rate. This is to account for effects seen in preliminary experiments on the rat small intestine [personal communication, Nibbs RJB (2020)], data we used to estimate a number of homeostasis parameter values. When the period of inflammation ends, parameters are set back to their homeostasis values.

Figure 1: A: An illustration of the homeostasis–inflammation cycle and the corresponding changes in parameter values and ratio definitions. B: DC flux into l.v. for $Pe = -5$. C: DC flux into l.v. at the 2nd peak in panel B vs. ingress ratio, coloured by cleavage rate

RESULTS

We ran 600 simulations each for $Pe = \pm 5$. The flux of DCs into the l.v. for simulations with $Pe = -5$ is shown in Figure 1B, and Figure 1C shows how the DC flux at its 2nd peak depends on both the ingress ratio and cleavage rate. For each simulation, the delay in onset of the inflammation ingress rate, the cleavage rate, and the inflammation values for the immature DC ingress rate and maturation rate are drawn randomly. We then used Sobol indices to quantify the relative impact of the varied parameters on key outputs of the model. For example, Figure 2A shows how, for interstitial flow in either direction, the total number of cells that migrate into the lymphatic vessel over an entire simulation depends most significantly on the value of ingress ratio, with the other parameters playing smaller roles. Interestingly, the cleavage rate appears to have little effect when interstitial flow is towards the l.v. ($Pe < 0$), but its influence is stronger for opposite flow ($Pe > 0$). Figure 2B–E give a qualitative picture of how migrating cell numbers depend on parameter values to complement the Sobol indices: here we see that the total number of migrating cells increases with ingress ratio, which cannot be determined from Sobol indices alone.

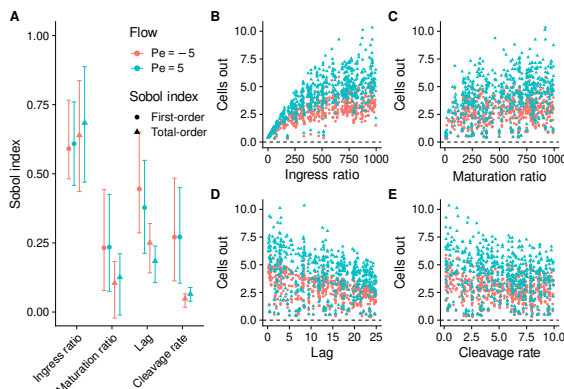

Figure 2: The influence of parameters on the total number of DCs that migrate into the lymphatic vessel. A: Sobol indices quantifying the relative impact of each parameter. B–E: Scatter plots of the total number of cells for each simulation vs. parameter values

To assess the qualitative effects of the unknown parameters on the spatial concentration profiles of ECM-bound CCL21 and migrating DCs we

ran another ensemble of simulations, with all combinations of the minimum and maximum parameter values in the previous ensembles, along with a range of Pe values representing different interstitial flow speeds and directions (Figure 3). In the homeostatic steady state, we observe that increased cleavage rate has a qualitatively similar effect on the bound CCL21 gradient as a reduction in Pe (Figure 3A). By the end of inflammation, spatial profiles for different parameter values reveal interactions between parameters (Figure 3B). For example, increasing the ingress ratio from 2 to 1000 significantly amplifies the effects of cleavage, whereas increasing the maturation ratio by the same amount has somewhat the opposite effect.

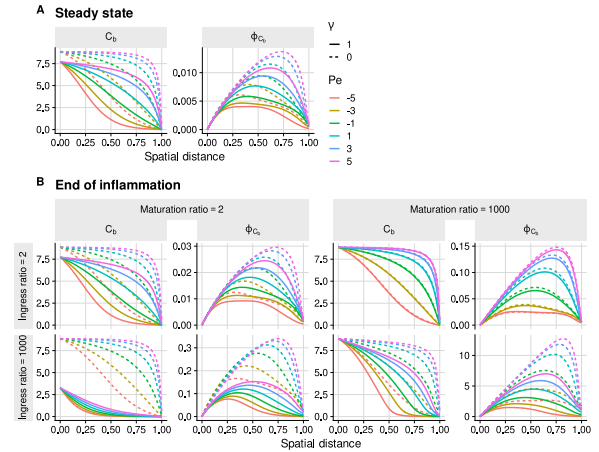

Figure 3: Spatial concentration profiles of ECM-bound CCL21 and migrating DCs

DISCUSSION

We have developed a mechanistic model of CCL21 gradient formation and dendritic cell migration towards lymphatics via haptotaxis and have evaluated their response during and after inflammation. For some parameter values that are not readily available we performed model simulations over a wide range of parameter values, and used sensitivity analysis to quantify the effects of parameters on biologically relevant model outputs such as the total number of DCs that migrate into the l.v.. Analysis of the spatial concentration profiles of ECM-bound CCL21 revealed that stronger flow towards the l.v. and a higher cleavage rate can have similar qualitative consequences on the bound CCL21 gradient. Furthermore, we found that the effect of CCL21 cleavage can depend strongly on the values of other parameters.

A first peak in DC flux across the l.v. during inflammation is to be expected, but the appearance of two peaks might not be (Figure 1B). However, this has been observed experimentally in inflammation of the rat small intestine.

Although we have included a number of biological processes in our model, it has a number of limitations, including: restricted to a 1D domain; DCs treated as a continuous density rather than individual agents; neglecting the effects chemotaxis according to soluble CCL21 gradients and chemokinesis.

INTRODUCTION

Charcot neuroarthropathy of the foot is a common degenerative disorder that occurs in patients with longstanding neuropathy due commonly experienced in diabetic patients. This progressive disease leads to severe deformities of the foot and limits a person's ambulatory capacity. Surgery is often the only therapeutic option and involves osteotomies to realign the bones of the foot and fusion with an intramedullary (IM) device to stabilize the arch. Success of this treatment depends on the ability of the device to obtain and maintain compressive force across the tarsals throughout the healing process. Commonly employed static devices experience loss of compressive forces due to bone resorption (often 3-5 mm) combined with patient weight-bearing[1], [2], which can lead to non-union, the need for revisional surgery, and even amputation. To address these issues, a sustained dynamic compression midfoot fusion device was developed using a pseudoelastic nickel titanium (NiTi) element. This NiTi element is housed within a titanium outer body and has been designed to contract up to 4mm thereby applying sustained dynamic compression across the fusion site despite bone resorption and/or joint settling. Human clinical studies have demonstrated the ability of dynamically compressive devices to continuously adapt to bone resorption[3], however, to our knowledge, there is currently no large animal model for tarsal arthrodesis and implant response to bone resorption. Therefore, this study investigated the use of a sustained dynamic compressive device designed to maintain bone-on-bone contact and compression between the tarsals throughout the healing process and alleviate the complications experienced that result from bone resorption and device loosening in a large animal (ovine) model. The aim of this study was to investigate the ability of a sustained dynamic compression IM nail to adapt to bone resorption across the tarsal joints in ovine models with normal bone quality and diminished bone quality induced by the placement of an external fixator.

METHODS

This study utilized 32 skeletally mature Rambouillet Cross ewes due to comparable anatomy and physiology of the ovine metatarsal and tarsal bones to those of humans. Animals were randomly allocated into 4 treatment groups with 8 animals in each group as outlined in **Table 1**.

Table 1: Animal Allocation and Treatment Groups

Group 1 (n=8)	Dynamic nail, 4-mo, partially unloaded with external fixator
Group 2 (n=8)	Dynamic nail, 4-mo, no unloading
Group 3 (n=8)	Dynamic nail, 8-mo, partially unloaded with external fixator
Group 4 (n=8)	Dynamic nail, 8-mo, no unloading

Approval for the surgeries performed on these animals was granted by the Colorado State University Animal Care and Use Committee (Approval No. #1199) and in accordance with the Animal Care and Use Review Office (Approval No. # PR191551). Surgery was performed under general anesthesia and aseptic conditions. Groups 1 and 3 underwent surgery to place an external fixator spanning from the tibia to the distal end of the metatarsus to unload the hock joint for one month prior to nail implantation[4]. The fixator was removed immediately prior to the implantation of the nail. The dynamic IM nail was inserted through the calcaneus and advanced to span the calcaneus-tarsus-metatarsus complex and fixed using transverse screws (**Figure 1**).

Figure 1: Radiograph of implanted dynamic nail.

Serial radiographs were taken every four weeks to track bone resorption and/or joint settling (**Figure 2**).

Figure 2: *In vivo* radiographs were taken at the time of device implant and every four weeks until sacrifice. Outlined regions indicate the gap over which device compression occurred.

The animals were allowed to move freely, eat ad libitum, and were sacrificed at either 4 or 8 months post-implantation. Using the radiographs that were taken throughout the course of the study, each image was analyzed using ImageJ software. The measurements taken from each image were scaled with reference to the diameter of the nail which was identical in each animal.

RESULTS

Over 8 months, an average of 2.17mm (SD=0.51) of device compression occurred in group 1, 2.31mm (SD=0.37) in group 2, 2.13mm (SD=0.67) in group 3, and 1.57mm (SD=0.42) in group 4 (**Figure 3**).

Figure 3: Average total retraction distance experienced by each treatment group.

The majority of compression occurred between the time of implant and 4 months post-op. Additionally, all of the animals experienced ≤ 4 mm of resorption, and none of the nails reached the maximum 4mm travel distance, even after 8 months *in vivo* (**Figure 4**).

Figure 4: NiTi element retraction distance tracked as a function of time in each animal.

DISCUSSION

Sheep are widely considered to be one of the most valuable translational models to study bone and cartilage remodeling due to their size and biological healing responses, both of which resemble humans. They also allow for full size medical devices to be researched *in vivo* while experiencing similar mechanical forces. The animals tolerated the procedure well and recovered rapidly post-implantation with no signs of infection or other complications. Evaluating the resorption experienced across a joint can help determine whether the joint is experiencing sustained compression throughout the fusion process. The data gathered suggest this novel nail may be a viable option for achieving sustained compression across the hock joint in an ovine model. These data additionally support the idea that this NiTi element is capable of accommodating resorption patterns typical of clinical patients with deteriorated bone quality brought on by conditions such as Charcot neuroarthropathy.

INTRODUCTION

Human bone marrow aspirate concentrate (hBMAC) is a readily available source of mesenchymal stem cells (MSCs) that is a common regenerative medicine treatment for various orthopedic applications. Senescence is a cell fate characterized by the loss of metabolic function, proliferative capability, and increased resistance to apoptosis which leads to tissue decline. Fisetin is a naturally occurring flavonoid with demonstrated senolytic activity through the targeted elimination of senescent cells. The purpose of this study was to investigate the therapeutic effect of fisetin on senescence in bone marrow derived MSCs (BM-MSCs) and hBMAC. We hypothesized that fisetin would decrease senescence in both hBMAC and cultured BM-MSCs, which we posit may improve the quality of the hBMAC orthobiologic product. The utilization of fisetin to improve patient derived products requires a therapeutic index. Here, we demonstrate that 50 μ M of fisetin was able to reduce senescence signatures in BM-MSCs and hBMAC in as little as 2 hours.

METHODS

BM-MSCs were obtained from ATCC used for *in vitro* experiments to determine dose and time course. BM-MSCs were cultured in normal growth media (Low Glucose DMEM, 10% MSC FBS, 1% Penicillin/Streptomycin, and 10 ng/mL FGF). Cells were treated with 50 μ M of the senescence inducing agent etoposide for 24 hrs then treated with 50 μ M of fisetin for 24hrs. Senescence was determined using the β -gal staining kit (Cell Signaling Technology) and further verified using the senescence stain C12FDG staining via flow cytometry (Sigma-Aldrich). Cells were pretreated with Bafilomycin for 1hr prior to C12FDG

staining for 1hr then washed, collected, and analyzed with a Guava EasyCyte flow cytometer. Gene expression was determined for senescence transcripts *p21*, and inflammatory transcripts *IL-1 β* and *IL-6* via qPCR. For hBMAC, samples were obtained from our clinic (**IRB#2020-50**). To confirm the efficacy of fisetin treatment for reduction of senescence; the combination of four different time-courses (0, 2, 6, 24 hrs) and four dose concentrations of fisetin (0, 20, 50, 100 μ M) were investigated. All the data points are presented as the mean \pm standard deviation (SD). Statistical significances were calculated based on one-way analysis of variance (ANOVA) and p-value < 0.05 was considered significant.

RESULTS

β -gal staining confirmed senescence induction with 24 hr etoposide treatment (50 μ M) that could be rescued by 24 hr etoposide treatment (50 μ M) (**Fig. 1A**).

Figure 1. Senescence induction and Fisetin treatment using human bone marrow derived mesenchymal stem cells

(A) Microscopic images of β -gal staining, (B) % SA- β -gal positive cells

Senescence induction by etoposide and reduction with fisetin in BM-MSCs was further confirmed by flow cytometry analysis using C12FDG staining highlighting the C12FDG assay as a valid detection method of senescence (**Fig. 2A**). qPCR analysis demonstrated elevated gene expression of the senescence marker *p21* as well as proinflammatory markers *IL-1B* and *IL-6* (**Fig. 2B**) indicating the efficacy of fisetin on reducing these specific markers (**Fig. 2B**).

Figure 2. Senescence induction and Fisetin treatment using BM-MSCs
(A) Delta % C12FDG positive cells using flow cytometry, (B) qPCR after after senescence induction (50 μ M of Etoposide, 24hr) with or without Fisetin treatment (50 μ M, 24hr). Mean \pm SD. Significant different: p< * 0.001, p< ** 0.0001, p< *** 0.001, p< **** 0.0001

We next tested senolytic efficacy in hBMAC which contains MSCs to see if senescence signatures could be reduced with senolytic drugs in a dose and time dependent manner. Interestingly, it was found that 50 μ M fisetin treatment of hBMAC could be an effective therapeutic dose capable of reducing senescent cell number within 2 hrs (**Fig. 3**). It was also interesting that 50 μ M did not significantly alter senescence reduction capability or increase cell death between 20 μ M and 100 μ M after 2 hrs (**Fig. 3A**) suggesting that higher doses of fisetin could be safe and tolerable. The time course also revealed a decrease in C12FDG cells even though there was no significant difference between 2, 6, or 24 hr time points (**Fig. 3B**).

DISCUSSION

Aging is the progressive physiological change that leads to the decline of fundamental biological functions and the onset of numerous age-related pathologies. Orthobiologics, specifically hBMAC has garnered significant attention for its regenerative properties and ability to help delay the onset of osteoarthritis. Here, we used BM-MSCs as a proxy for cell specific effects of senolytic treatments that target a fundamental property of aging, senescence. Our overarching goal was to link the therapeutic effect of fisetin on BM-MSCs and compare the outcomes through an *ex vivo* experiment and apply it to an upcoming *in vivo* experiment in a preclinical rat model of OA. FDA regulations regarding supplementation of specific drugs like fisetin applied to hBMAC presence a burden on an exciting, easily accessible source of a depleted senescent hBMAC product. Through our upcoming *in vivo* rat study, we hope to understand the translational aspects of our *in vitro* toxicity dose experiments to reveal why there is a wide range of efficacy of fisetin (0, 20, 50, 100 μ M) with no significant difference in the cell death. This could imply a large therapeutic index of fisetin in a biological setting. Understanding the metabolic process of fisetin will help bring treatments of this senolytic drug to life as we understand the optimal therapeutic effect in different biological specimens and cell types.

The ability to enhance hBMAC therapy in a timely and safe manner is important for the future therapies of orthobiologics. As we look to personalize medicine, fisetin treatment of hBMAC over a 2hr treatment course can improve the product given to patients. An *in vivo* rat study will be conducted via an osteoarthritis model to confirm these preliminary results and reveal the efficacy of this therapy in a biological setting.

TAILORING THE RELEASE PROFILE OF A SMALL MOLECULE AGONIST TO STIMULATE HEDGEHOG SIGNALING DURING TENDON-TO-BONE INTEGRATION

J. Marcelin (1), R. Madi (1), T. Kamalidinov (1), X. Jiang (1), S. Assi (1), D-H. Kim (1), S. Keith Lang (1), R. L. Mauck (1), A. Kuntz (1), N. Dymant (1)

INTRODUCTION

Tendon injuries frequently occur at the tendon-to-bone insertion site (i.e., enthesis) and tendon-to-bone repair often leads to disorganized scar tissue formation [1]. The hedgehog (Hh) signaling pathway is a critical regulator of enthesis fibrocartilage formation and maturation during growth and development [2-4]. Thus, this pathway is a promising target for improving tendon-to-bone repair by promoting the formation of a functionally graded zonal enthesis.

We previously demonstrated that stimulation of the Hh pathway via genetic activation or systemic Hh agonist injections promoted tendon-to-bone attachment formation following anterior cruciate ligament reconstruction (ACLR) [5]. Due to the important role of Hh in many tissues within the body [6], there is a need to develop localized therapies to avoid off-target effects while still effectively leveraging this pathway to improve repair outcomes. Therefore, we developed an electrospun scaffold release system containing various concentrations of SAG, a small molecule Hh signaling agonist, for use in the promotion of tendon-to-bone integration.

The objectives of this study were to incorporate SAG into the scaffold, measure the scaffold properties after incorporation, define the *in vitro* release profile and bioactivity of SAG, and determine whether these scaffolds could locally stimulate the Hh pathway and promote tunnel integration in a bilateral transverse tibial tunnel (TTT) surgical model.

METHODS

Scaffold Fabrication: A PCL solution (35 wt%) was prepared in DMF/THF with the Hh agonist (SAG) at different concentrations (0, 0.001, 0.01, 0.1 mg/ml). The solution (2mL) was spun from an 18G needle at 15kV onto a rotating mandrel (8 m/s, 2.5 ml/hr).

SEM: Fibril alignment and fibril diameter (100 fibrils per sample) were measured using the OrientationJ plugin in FIJI from images acquired on an FEI Quanta 600 ESEM.

Mechanics: Scaffold strips (1x20mm) were cut longitudinally,

weighed, and cross-sectional area was measured using a custom non-contact laser device. Strips were preconditioned and loaded uniaxially at 1%/s until failure (Instron 5542). Structural and material properties were calculated from the resulting load-deformation curves.

SAG Release Study: All animals and procedures were approved by Institutional IACUC. Both blank and SAG-infused scaffolds were placed in culture media (DMEM, 5% FBS, 1% pen/strep) in 50 ml tubes covered in aluminum foil on a shaker at 37°C for 28 days. The conditioned media (CM) was collected every other day by removing one half of the volume, which was replaced with fresh media, on days 1, 2, 4...28, and then frozen at -80°C. Bone marrow stromal cell (bMSC) cultures were prepared by flushing the bone marrow from femurs and tibias of four 6-week-old CD1 mice. These cells were expanded and then passaged into 24-well plates. CM collected on days 2, 8, 16, or 26 from each scaffold were delivered to the bMSCs for 4 days. RNA was collected from the treated cells and qPCR was conducted for the downstream Hh gene, *Gli1*, to determine the extent to which SAG released from the scaffolds induced downstream Hh activity. CM samples were compared to 3nM or 300nM of SAG added directly to the culture media.

Tunnel Integration Study: TTT surgeries were performed on 12 mice to test the effect of SAG release on Hh activity and tunnel integration. This procedure was utilized as a simpler, higher throughput model than the ACLR model we used previously [1,5]. Graft tail tendons were harvested from mice and a sterile scaffold was added to the graft bundle. A transverse tibial tunnel was drilled in the metaphysis using a 27G needle. The graft with the scaffold was passed through this tunnel and the samples were assessed on day 14 post-surgery.

Mineralized Cryosectioning, qPCR, and Imaging: Limbs were fixed, embedded, sectioned undecalcified with cryofilm. The medullary canal was microdissected from tissue sections for qPCR. On adjacent sections, alkaline phosphatase (AP) staining was imaged fluorescently on a Zeiss Axio Scan.Z1. AP area was normalized to the area of the

medullary canal and quantified.

Statistical Analysis: Fiber diameter, scaffold mechanical properties, and *in vivo* qPCR and AP activity were compared via one-way ANOVA ($p < 0.05$). Gli1 expression from *in vitro* release was compared via two-way ANOVA with Sidak's post-hoc tests ($p < 0.05$).

RESULTS

SAG incorporation affected fiber alignment but not diameter of electrospun PCL scaffolds: Using the OrientationJ plugin to measure fiber alignment from SEM images, we found that SAG incorporation reduced the overall fiber alignment ($SD_{\text{blank}} = 15.8^\circ$, $SD_{0.01} = 19.1^\circ$, $SD_{0.001} = 25.3^\circ$, $SD_{0.1} = 26.6^\circ$) in the scaffold (Fig. 1C). However, fiber diameters of the SAG scaffolds were not significantly different from the blank scaffold (Fig. 1D).

SAG incorporation increased maximum stress but not modulus: Even though the implanted PCL scaffold will be stress-shielded by the tendon grafts, we wanted to measure the effect of SAG inclusion on mechanical properties of the scaffold as mechanical changes may impact the release profile. We found that SAG incorporation did not alter modulus (Fig. 2A) but did increase maximum stress (Fig. 2B) in the highest concentration (0.1mg/ml) group compared to blank scaffolds.

Delivery of conditioned media to bMSCs increased Gli1 expression in a dose- and time-dependent manner: As expected, we found a significant increase in Gli1 expression with 3nM (2-fold) and 300nM (70-fold) added directly to the media ($p < 0.05$, Fig. 3A) vs control media. Additionally, Gli1 expression increased in the SAG scaffolds in a dose- and time-dependent manner ($p < 0.05$) (Fig. 3B). Gli1 expression did not change with time in the blank scaffolds and the expression levels were comparable to the control media (C in Fig. 3A). Gli1 expression was significantly higher for all SAG concentrations (0.001, 0.01, and 0.1 mg/ml) compared to blank scaffolds in CM collected on day 2, with expression levels being comparable to 300nM media for the 0.01 and

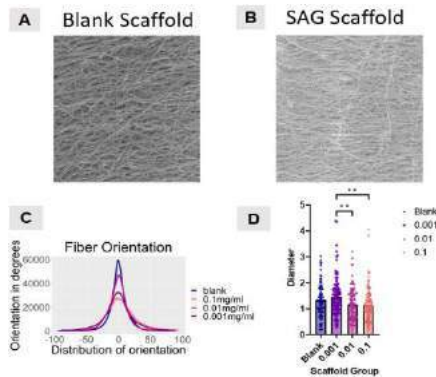

Figure 1: SEM of blank (A) vs. SAG (B) scaffold. Fiber orientation (C) and diameter (D) measurements.

Figure 2: Modulus (A) and maximum stress (B) values from uniaxial stress relaxation and failure tests of PCL scaffolds. ** $p < 0.01$.

Figure 3: Gli1 ddCq for controls (A) and blank vs the different concentrations of SAG at the four timepoints (B). ** $p < 0.0001$, * $p < 0.05$; # $p < 0.05$ vs. blank.**

0.1 mg/ml scaffolds. Interestingly, while Gli1 expression remained elevated in the 0.1 mg/ml SAG scaffold for CM collected out to day 26 ($p < 0.05$), both the 0.01 and 0.001 mg/ml groups saw reduced Gli1 expression with time of CM collection, which resulted in 0.01 mg/ml at day 26 and 0.001mg/ml at days 8, 16 and 26 not being statistically different than blank scaffolds (Fig. 3B). These results indicate that the 0.1mg/ml SAG scaffold released a sufficient amount of SAG over a 26-day period to maintain activated Gli1 expression in bMSCs.

Localized delivery of SAG to the bone tunnels increased Gli1 activity and alkaline phosphatase activity: To determine the local effect of Hh agonist released from scaffold on nearby cells in an *in vivo* setting, we microdissected tissue within the medullary canal, including the surgically drilled tunnel (Fig. 4A), from cryosections using a needle and performed qPCR. There was an increasing trend in Gli1 expression in the 0.01 and 0.1 mg/ml scaffolds compared to the blank scaffolds at post-operative day 14 (Fig. 4B). To assess whether SAG release increased fibrocartilage and bone mineralization, we measured alkaline phosphatase (AP) activity in the medullary canal and bone tunnel. We found that the 0.1 mg/ml group had significantly greater AP activity compared to blank scaffold ($p < 0.05$, Fig. 4C).

Figure 4: Schematic representation of the TTT (A) including the area (red dotted line) used to calculate Gli1 gene expression (B) and AP activity (C).

DISCUSSION

In this study, we incorporated the small molecule Hh signaling agonist, SAG, into electrospun PCL scaffolds and found that these scaffolds could release SAG *in vitro* and *in vivo* while maintaining bioactivity. The SAG incorporation had a dose-dependent effect on fiber orientation (Fig. 1B) producing an increase in maximum stress but not modulus of the scaffold (Fig. 2). The *in vitro* release profile was dose dependent with CM from the 0.1 mg/ml concentration stimulating sustained, elevated expression of Gli1 in treated bMSCs (Fig. 3), whereas the other doses saw reductions in Gli1 expression to baseline levels by the end of the one-month release experiment. When the scaffolds were inserted within the bone tunnels of a TTT *in vivo* model, the 0.01 and 0.1 mg/ml groups resulted in an increasing trend in Gli1 expression (Fig. 4B). The SAG scaffolds also showed an increasing trend in AP activity, with the 0.1 mg/ml group having significantly greater AP activity than blank scaffolds (Fig. 4C), indicative of increased fibrocartilage and bone mineralization within the bone tunnel regions. This result is consistent with our previous work using systemic injections of a Hh agonist [5]. Future studies will apply the SAG-delivering scaffolds in our more clinically-relevant, yet lower throughput, ACLR model to improve the tendon-to-bone integration processes.

DEPTH-MAP IMAGE BASED INFLATION TEST FOR MECHANICAL CHARACTERIZATION OF SOFT MATTER

Rahul L. Maurya (1), Yash K. Shrivastava (2), Dr. Samarth S. Raut (1)

- (1) Department of Mechanical, Materials and Aerospace Engineering, Indian Institute of Technology Dharwad, Dharwad, Karnataka, India.
(2) Department of Information Technology, Manipal University Jaipur, Jaipur, Rajasthan, India.

INTRODUCTION

Mechanical characterization of soft tissue is very important for studying etiology and risk/factor of assessment. A typical biomechanical material model relates strain tensor (deformation) to the stress tensor (mechanical loading). Analysis of the deformation of 3D surface leads to strain assessment. Previously reported work have made valuable progress with certain assumption or simplifications with inputs ranging from medical images [1] [2] and experimental biaxial testing method [3]. Especially for thin membranes inflation tests are attractive experimental methods [4, 5]. Inflation tests have been applied to variety of soft tissues and polymers earlier however capturing the deformation as well as particle trajectory correctly has remained a challenge. Hence, here we report a method to estimate strain by combining established techniques in computer vision and computational mechanics with inputs about deformation captured in form of recently popular portable hardware for depth map and RGB images. Gelatin membrane samples were used in this prototype.

Non-contact method of strain assessment for mechanical characterization with reliable tracking of entire trajectory of the fiducial markers using depth map images provided by stereoscopic camera is presented here. It is especially suitable for curved samples as biaxial or uniaxial testing methods introduce errors due to flattening of the sample. Robust, flexible, and mathematically sound approach of Bezier surface technique is aptly implemented for strain tensor estimation.

METHODS

The setup for inflation testing here demonstrates the method to quantify the mechanical property of elastic/flexible material ranging from silicone rubber or nitrile sheets to Elastic 3D printed sheets to biological tissues like fetal membranes with adequate accuracy. The membrane

size can easily vary from 20 mm to 100 mm because of its modular design for the experimental test set-up. A 3D camera with resolution of (RGB + depth) to map the inflated surface by capturing the number of fiducial marks made on the surface of the quasistatically inflated membrane over the timestep of around 30 frames every second.

Figure 1: Illustration of the experimental setup, the depth map image, and the normal RGB image displayed on the computer.

Material preparation: To prepare the gelatin sheet/membrane we have taken the bovine (type b) gelatin powder. We mixed 2 tablespoons of water into 2 tablespoons of gelatin powder and allowed to bloom for 30 sec. After that it was heated in water bath for 4 minutes until it melted completely. Then precaution was taken to the air-bubble if any, and then carefully measured volume of this liquid gelatin gel was poured into Petri dish of 80 mm diameter and allowed it to solidify for 5 hours.

Inflation testing and position tracking: The required pressure chamber for inflation setup is designed for up to 10 bar capacity and fabricated by additive manufacturing to optimize the manufacturing cost and maintain the setup's modularity. Air is compressed using an air compressor (1.5 hp, 24L, 8 bar pressure). Proper precautions in design of set-up minimize the air leakage. Nine fiducial marks of approximate diameter of 2 mm each are created on the membranes such that those are located on corners, mid-points, and center of a rectangular region. The depth camera (Intel Realsense D435i) captures the position of the fiducial mark. Fiducial mark detection algorithm locates the markers in the image space and, at the same time, pressure is recorded by using electronic Pressure sensor (AMS-5818-0600_D) of inside the chamber is also taken on every time step by the NiDAQ to the computer (Figure 1). The membranes were pressurized up to 1 bar pressure gradually and de-pressurized; from this experiment, we recorded the position of each fiducial mark due to inflation over time. Bezier surface patch was defined using marker location. (Figure 2)

Figure 2: Schematic representation of strain evaluation process

RESULTS

From this point cloud data extracted from the depth map image and RGB images, using k-mean clustering algorithm we classified the trajectory of the individual 9 fiducial markers (refer Figure 3 a) located at corners, mid-point of edges, and center of a rectangular zone of a membrane. Here, we only consider first and last frame for simplicity.

Figure 3: Experimentally observed trajectories of fiducial markers (left, 3a) and visualization of gelatin sheet in reference (undeformed) and in current configuration (deformed) based on bi-quadratic Bezier surface interpolation (right 3b).

For coordinates in the reference configuration (i.e., undeformed state) and the current configuration (i.e., deformed state) we have fit the bi-quadratic Bezier surface (refer Figure 3b).

The deformation gradient tensor, \mathbf{F} , describes the deformation of an object. In the context of a Bezier curve, the partial derivative of the curve with respect to its parameter (u and v) (equation (1)), is used to calculate deformation gradient \mathbf{F} . The composite derivative (equation (2)) is then used to calculate the Lagrange strain tensor, \mathbf{E} (equation (3)), which describes the deformation of the object.

$$\frac{\partial}{\partial u} b^{m,n}(u, v) = m \sum_{j=0}^n \sum_{i=0}^{m-1} (b_{i+1,j} - b_{i,j}) B_i^{m-1}(u) B_j^n(v) \quad (1)$$

$$F_{ij} = \frac{dx(u,v)}{d\mathbf{x}(u,v)} \quad (2)$$

$$\mathbf{E} = \frac{1}{2} [\mathbf{F}^T \mathbf{F} - \mathbf{I}] \quad (3)$$

Where, b represents Bezier control points, u and v are parameters and $B_i^{m-1}(\cdot)$ is Bernstein polynomial. The results were compared with the manual calculations for the strain along two approximated orthogonal directions at the central point by fitting a second order curve and measuring the length of the curved 3D segment.

Figure 4: Lagrange strain spatial distribution

DISCUSSION

As seen in the plots above the strain distribution was more or less constant with minor errors reflecting along the peripheral region.. Possible reasons could be the positional error of the markers and curvature as the corner region that compromises marker shape as detected by the camera above. Especially with the more or less isotropic behavior of the material with all radially symmetric boundary conditions (at gripper) the membrane element is expected to be in equibiaxial stress state which would reflect similar values for E11 and E22 strain with the basis vector directions assumed to be along sides of the rectangular zone under consideration. Spatial variation of strain is also observed to be minimal and shear strain E12 is as expected for this specific geometry, loading, and material.

Here we have demonstrated the use of a fiducial mark detection algorithm to capture the deformation in the membrane by using a depth camera and 3D mapping of the membrane surface every instance, while inflation/deformation can tell us more about the fiber orientation and their basic crystallography. Using this device, we can characterize the mechanical properties of various flexible/elastic materials and biological tissues. We have performed this experiment to get the mechanical properties of gelatin tissue membrane and have verified with their standard material properties. Minor air bubble presence in gelatin sheets is ignored in this work. Also, it is targeted that more dense markers will be tracked in future during deformation for better resolution and accuracy for application to complex geometry and materials.

ACKNOWLEDGEMENTS

A LATTICE-BOLTZMANN FLUID-STRUCTURE INTERACTION FRAMEWORK FOR THE INERTIAL TRANSPORT OF BIOPARTICLES IN MICROFLUIDIC DEVICES

Alberto Mantegazza (1), Dario De Marinis (1), Marco D. de Tullio (1)

(1) Department of Mechanics, Mathematics and Management, Polytechnic University of Bari, Bari, Italy

INTRODUCTION

In the last two decades, significant advancements in the field of microfluidics allowed the development of diagnostic or therapeutic devices for bioparticle separation and focusing. In the context of multiphase flows in microchannels, inertial microfluidics has become a very attractive separation method because it does not require any external force to sort cells or bioparticles and has a high throughput. When the channel Reynolds number is in the range 10-100, the particle lateral migration is affected by competing forces: the shear-gradient lift force due to the curvature of the velocity profile and the wall-lift force resulting from the interaction between the particle and the microchannel walls. Reliable fluid-dynamic models are essential to effectively design such microfluidic devices for biomedical applications and to be able to sort cells according to the user needs. In this perspective, the Lattice-Boltzmann Immersed-Boundary (LB-IB) method has emerged as an interesting technique to treat the transport of rigid and deformable objects in a fluid flow [1, 2]. In the traditional LB method, the fluid pressure and density are linearly proportional. In the case of flow conditions typical of inertial microfluidics, in which a large pressure difference may be present between the inlet and outlet of the separation device, this means that fluid density would increase linearly in the streamwise direction. In this flow regime, this is a non-physical density increase that does not satisfy the fluid incompressibility condition.

With the goal of providing an accurate investigation of bioparticle transport in inertial flow regimes to design microfluidic cell-sorting devices, we aimed at developing a fluid-structure interaction (FSI) framework based on a fully-incompressible LB method for particle-resolved simulations.

METHODS

We developed an FSI framework in which the BGK-Lattice-Boltzmann (BGK-LB) method was used to solve the Navier-Stokes equations coupled with a spring-network surface-based model for structure dynamics by means of an Immersed-Boundary (IB) technique to describe the evolution of rigid and deformable bioparticles for $Re = 10 - 100$.

The fluid evolution was modeled on a three-dimensional computational lattice (D3Q19). Here, 19 distribution functions $f_i(\vec{x}, t)$ ($i = 0, \dots, 18$)

representing particles at position \vec{x} , time t , and flowing with velocity \vec{e}_i are transported using the forced Boltzmann equation:

$$f_i(\vec{x} + \vec{e}_i \Delta t, t + \Delta t) - f_i(\vec{x}, t) = -\frac{\Delta t}{\tau} [f_i(\vec{x}, t) - f_i^{eq}(\vec{x}, t)] + \Delta t \vec{F}_i \quad (1)$$

where τ is the relaxation time, which is related to the fluid kinematic viscosity according to $\nu = c_s^2 (\tau - \frac{\Delta t}{2})$, being $c_s^2 = 1/\sqrt{3}$ is the reticular speed of sound. To ensure the full incompressibility of the LB method and simulate flows driven by large pressure differences, an approximated equilibrium distribution function f_i^{eq} ($i = 0, \dots, 18$) was defined as [1]:

$$f_i^{eq}(\vec{x}, t) = \omega_i \left[\frac{1}{c_s^2 \rho_0} p + \frac{1}{c_s^2} (\vec{e}_i \cdot \vec{u}) + \frac{1}{2c_s^4} (\vec{e}_i \cdot \vec{u})^2 - \frac{1}{2c_s^2} \vec{u}^2 \right] \quad (2)$$

The forces generated by the presence of the body onto the fluid (\vec{f}_{lb}) were taken into account in the forcing term \vec{F}_i ($i = 0, \dots, 18$) [1]:

$$\vec{F}_i = \left(1 - \frac{1}{2\tau} \right) \omega_i \left[\frac{\vec{e}_i - \vec{u}}{c_s^2} + \frac{(\vec{e}_i \cdot \vec{u})}{c_s^4} \vec{e}_i \right] \cdot \vec{f}_{lb} \quad (3)$$

with weighting factors $\omega_0 = 1/3$, $\omega_{1-6} = 1/18$, and $\omega_{7-18} = 1/36$. Finally, we computed fluid pressure and velocity as the moments of the distribution functions: $p = c_s^2 \rho_0 \sum_i f_i$, $\vec{u} = \sum_i f_i \vec{e}_i + \frac{\Delta t}{2} \vec{f}_{lb}$.

Bioparticles were considered as a collection of Lagrangian inertial markers immersed in the Eulerian fluid lattice. The IB method was used to enforce the immersed structure boundary conditions onto the flow field. Following de Tullio *et al.* [3], a moving-least-squares reconstruction with a 27-point support domain was used to build a transfer function and make the Lagrangian mesh markers and Eulerian lattice nodes interact. The FSI time advancement was performed following a weak-coupling strategy. Given the fluid field at the time instant t , hydrodynamic stresses are evaluated on the Eulerian fluid lattice and transferred to the Lagrangian markers using the IB method. The internal stresses of the immersed body are evaluated by computing the elastic response modeled by a spring-network model [3].

The Newton equation of motion was solved using an implicit discretization

scheme to predict the immersed body position, velocity, and acceleration. Finally, the volume force \vec{f}_{lb} resulting from the immersed body kinematics was transferred back to the Eulerian fluid lattice nodes and used to compute the forcing term (Eq. 3) of the Boltzmann equation (Eq. 1).

RESULTS

Fluid dynamic and structural solver validation. To validate the LB method, we simulated the flow of an incompressible Newtonian fluid between two infinite parallel plates at different $Re = [1; 10; 100]$. A pressure inlet boundary condition was prescribed according to Poiseuille's theory, whereas a reference pressure was imposed at the outlet. No-slip condition was used at walls; periodicity was imposed on the third direction. A parabolic velocity profile was set as initial condition throughout the entire domain. Simulations were performed on an Eulerian grid of dimensions $(N_x, N_y, N_z) = (1, 216, 10000)$. Given the set of parameters $\tau = 1$, c_s^2 , and Re , the resulting maximum Mach numbers for current Eulerian grid were $Ma = [0.002; 0.02; 0.2]$. We reported CFD results at $Re = 100$ and $Ma = 0.2$, which is the worst-case scenario for the LB method (Fig. 1a). The velocity profile computed using the LB methods is fully developed in the streamwise direction and it is in excellent agreement with the analytical solution predicted by Poiseuille's theory at all longitudinal locations. The same result was obtained for the simulations at lower Re numbers. Despite the significant pressure difference imposed as boundary condition ($\Delta P/P_{out} = 10\%$), the fluid density remained constant over the length of the computational domain confirming that the equilibrium distribution function defined in Eq. 2 ensures fluid incompressibility.

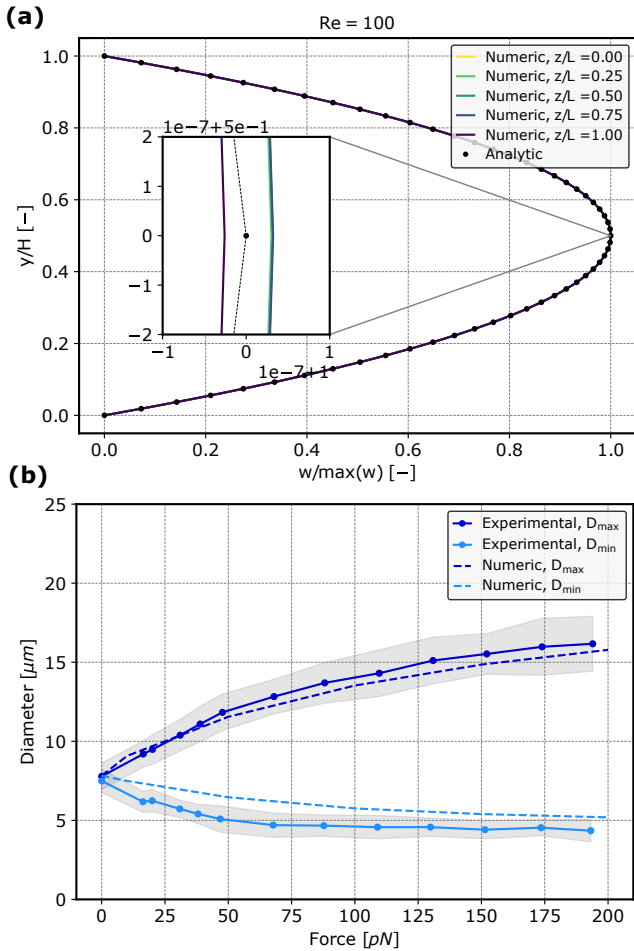

Figure 1: (a) Normalized velocity profile at different locations along the streamwise direction for $Re = 100$. Numerical results are compared to the analytical solution from Poiseuille's theory. (b) Minimum and maximum RBC diameter as a function of the stretching force compared to the experimental data reported in [4].

For the validation of the structural solver, we simulated the stretching of a red blood cell (RBC), when it is subjected to a tensile force. The model for the RBC membrane proposed by Fedosov *et al.* [4] was used in all computations. A triangular mesh with $N_v = 4932$ nodes was used to discretize the RBC surface. An external tensile force in the range $0 - 200$ pN was prescribed as boundary condition. The computations were independent of the viscous properties of the RBC membrane and the fluid because the RBC stretching was measured after convergence to the steady deformed configuration. Fig. 1b shows that the simulated RBC diameters agree very well with the optical tweezers stretching data [4].

Transport of bioparticles in a spiral microfluidic device. To show the capabilities of the proposed framework, we simulated the transport of two bioparticles in a spiral microfluidic device in the presence of inertia ($Re = 20$ and Dean number ≈ 5). A velocity inlet boundary condition was prescribed according to Poiseuille's theory, a reference pressure was imposed at the outlet, and no-slip wall condition was used elsewhere. The curved microchannel (hydraulic diameter $D_h = 33.3$) was treated as an obstacle using the Bouzidi interpolation condition. Simulations were performed on a grid of dimensions $(N_x, N_y, N_z) = (1500, 1600, 50)$. Particles with a diameter $D_p = 0.15D_h$ and a density $\rho_P = 1.1\rho_{fluid}$ were injected and tracked across the entire length of the device. The trajectories of the particles released at the same time instant and at two different transversal locations are displayed in Fig. 2. It is possible to appreciate the inertia-driven lateral migration of particle A that starting from the center of the microchannel, where it flows with a velocity higher than particle B, is eventually focused on the external side of the spiral.

Figure 2: Particle trajectory in the spiral microchannel.

DISCUSSION

In this study, we developed an FSI framework suitable for the inertial transport of bioparticles in microfluidic devices using a fully-incompressible LB method. The framework can be used to reliably predict the flow field in microchannels at $Re = 10 - 100$ and the deformation of soft bioparticles. Preliminary investigations on a spiral microfluidic device confirmed that the fully-incompressible LB-IB method is appropriate for the investigation of inertial microfluidic phenomena that can help to design microfluidic devices for cell-sorting applications.

COMPUTATIONAL AND EXPERIMENTAL BASED GUIDANCE FOR PERSONALIZED IMPLANT SELECTION AND ALIGNMENT IN REVERSE TOTAL SHOULDER ARTHROPLASTY

Colin R. Smith (1), Rony-Orijit Dey Hazra (1), Alex Brady (1), Matthew T. Provencher (1), Peter J. Millett (1), Scott Tashman (1)

INTRODUCTION

Rotator cuff arthropathy is common in the aging population and has debilitating effects on shoulder function. The most successful treatment for this combined muscle and joint pathology is Reverse Total Shoulder Arthroplasty (RTSA), which medializes the glenohumeral center of rotation to increase the deltoid moment arms to compensate for rotator cuff deficiency. Unfortunately, post-operative shoulder strength and range of motion (ROM) deficits can limit patients' ability to perform activities of daily living. Furthermore, scapular notching is a common complication caused by impingement between the humerus and inferior glenoid.

Technological advancements in virtual planning and patient specific instrumentation enable surgeons to precisely perform RTSA surgeries. However, personalized implant selection and alignment remains a critical challenge to maximize outcomes. The purpose of this study was to assess the predictive capacity of a patient-specific modeling framework to plan RTSA surgeries and investigate the influence of RTSA parameters on range of motion (ROM) and deltoid muscle function.

METHODS

Two shoulder cadavers were CT scanned after which RTSA was virtually planned (Arthrex VIP) and surgically performed. Passive adduction, abduction, scaption, and flexion ROM were measured using a KUKA robot for 9 configurations of glenosphere lateralization (0, 4 mm), inferiorization (0, 2.5 mm), and humeral spacer thickness (0, 6, 9 mm). Then an actuated cable system was used to load the deltoid to measure the force required to abduct from 30-50° for 8 configurations of

Figure 1: (top) The RTSA procedure was parameterized such that it could be performed virtually. Computational models were created for two specimens from CT scans to virtually assess the influence of RTSA on impingement (bottom left) and deltoid force (bottom right).

glenosphere lateralization (0, 4 mm) and humeral spacer thickness (0, 6 mm) and inclination angle (135, 155°). Computational models were constructed in OpenSim-JAM [1] for both specimens by segmenting the CT scans and identifying attachment points for nine deltoid paths.

Virtual RTSA surgeries were performed where 1000 different combinations of 6 glenosphere and 9 humerus parameters were randomly selected. Passive ROM simulations predicted the elevation angle where bone impingement occurred. Muscle driven simulations predicted the deltoid forces to abduct from 0° to 80° and corresponding glenosphere contact pressures and forces. To evaluate the predictive capacity of the model, the Pearson correlation coefficient (R) was computed between the simulation predictions and cadaver measurements of passive ROM for each RTSA configuration. The influence of RTSA parameters on the predicted ROM and peak deltoid force was ranked by computing the correlation (R) across all 1000 models.

RESULTS

The average errors in the predicted passive ROM were smallest in adduction (2°) and greatest in flexion (17°), with a strong correlation between the simulation predictions and experimental measurements ($R=0.97$). The peak predicted deltoid forces varied by more than 50 N across the 1000 virtual RTSA configurations and exhibited similar magnitude to the experiments and the same trend with increasing abduction angle (Fig 2).

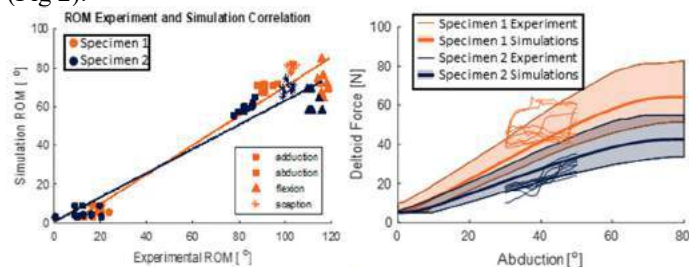

Figure 2: (left) Comparison of measured and predicted passive ROM. (right) The experimental measurements of deltoid force for 8 RTSA configurations generally remained within the 5-95 percentiles of the simulation predictions for 1000 RTSA configuration

In the simulation sensitivity analysis, glenosphere lateralization ($R=0.5$) and inferiorization ($R=0.1$), as well as humeral inclination ($R=0.5$) showed the strongest influence on passive abduction ROM.

The peak predicted deltoid force during abduction was strongly negatively correlated with glenosphere inferiorization ($R=-0.7$) and positively correlated with glenosphere lateralization ($R=0.2$), humeral spacer thickness ($R=0.2$), and inclination ($R=0.2$). The magnitude of the peak glenosphere contact force was also strongly negatively correlated with glenosphere inferiorization ($R=-0.4$).

Figure 3: Scatterplots of all 1000 virtual RTSA surgeries. (Left) Lateralizing the glenosphere increased passive abduction ROM. (Right) Inferiorizing the glenosphere decreased the peak deltoid force required to abduct the humerus.

Figure 4: The Pearson correlation coefficients averaged across both specimens representing the relative influence of the RTSA glenosphere (left) and humerus (right) parameters on the predicted passive abduction ROM and peak deltoid force.

DISCUSSION

The model predictions of impingement free ROM and deltoid force generally agreed with the cadaver experiments. In both the experiments and Monte Carlo simulations, the alignment and design of the RTSA implants had large influence on functional metrics, demonstrating that surgical planning and execution has important implications for patient outcomes. Glenosphere lateralization and inferiorization increased the ROM in nearly all directions, however inferiorization decreased the deltoid force while lateralization increased the deltoid force required to abduct the humerus. Humeral inclination increased the ROM in abduction and scaption but decreased the ROM in adduction and flexion as well as increased the deltoid force. These tradeoffs agree with the trends found in previous cadaver studies [2] and demonstrate the importance of including impingement and muscle function considerations in virtual planning for RTSA.

INTRODUCTION

Chiari malformation Type I (CMI) is characterized by cerebellar tonsillar descent and crowding of neural structures at foramen magnum [1, 2]. Imbalance is a symptom that affects nearly half of CMI patients and is thought to be caused by damage to neural tracts in the hindbrain [1, 2]. Paul et al. reported sensory loss related to the dorsal column in 19 of 71 CMI patients (~27%) through physical examination and 29 (~40%) of these patients reported loss of balance [1]. Milhorat et al. reported 189 of 364 CMI patients (~52%) experienced poor equilibrium [2]. Similar findings have also been reported by other researchers [3]. These studies suggest possible damage to the neural circuitry pertaining to balance, and postural controls.

The goal of this study is to examine the relationship between CMI imbalance and cardiac-induced strain on the vestibulospinal tract (VST) using displacement encoding with stimulated echoes magnetic resonance imaging (DENSE MRI). Reflexive postural adjustment of the head and body results from the vestibular system influence on skeletal muscular tone ensuring coordination between different muscle groups through the lateral and medial vestibulospinal tracts (lVST, mVST) [4]. We hypothesize that CMI subjects with imbalance have higher strain on VST than those without imbalance.

METHODS

Participants: 35 adult (5 males, 30 females) CMI subjects and 25 (8 males, 17 females) healthy adult controls were scanned at Emory University School of Medicine between 2017 and 2022 under a protocol approved by the institutional review board. All participants signed a written consent before enrollment in the study [5]. Symptomatology was collected by interviewing CMI subjects at the time of presurgical scan using approved questionnaires [5]. Based on self-reported symptoms regarding balance, CMI subjects were divided into two subsets, CMI with imbalance (n = 15, 2 males, 13 females), and CMI without imbalance (n = 20, 3 males, 17 females).

Image acquisition used in this study was described in our previous publications [5]. Briefly, sagittal T1 and T2 weighted images of the brain were acquired using a PrismaFit 3T MRI scanner (Siemens Healthcare, Erlangen, Germany) employing a 20-channel head coil. DENSE MRI scans were acquired in the midsagittal plane using a 2-dimensional (2D) spiral cine technique and peripheral pulse unit gating with spatial and temporal resolution. Pixel size was 0.9 x 0.9 mm, and the slice thickness was 8 mm.

Due to the proximity of lVST and mVST at vestibular nuclei and in the cervical spinal cord, we employed two regions of interest (ROI) boxes for both tracts in the midsagittal plane and referred to them as the vestibulospinal tract (VST) (Fig. 1). The rostral VST (rVST) box was placed at the start of the tract (~3–4 mm anterior to the posterior aspect of the pontomedullary junction to ensure ROI placement on tissue and not on the cerebrospinal fluid), and the caudal VST (cVST) was placed at the center of the spinal cord at the level of C1/C2.

Fig. 1: Location of the region of interest (blue and red boxes) on an anatomical MRI of a CMI patient at the midsagittal plane. The route of DCML was depicted with the dashed yellow line.

The tissue motion of rVST and cVST was traced over the cardiac cycle and the path was illustrated in Fig. 2. This displacement can be decomposed to rigid body motion and lengthening/strain that VST experiences over the cardiac cycle.

Fig. 2: Brain tissue motion path of rVST and cVST for one CMI subject (green box is starting point).

The 2D displacement field image was analyzed in the midsagittal plane. The local strain distribution along the line connecting the two ROI boxes was computed as it follows: a set of boxes along each line comprised of the average of 1 voxel on the line, and the two voxels adjacent to it (1x3) were determined. The coordinates of the ROI boxes, and the length of the line connecting them change throughout the cardiac cycle. The length of the line between the two boxes spaced seven voxels apart was calculated using equation (1) for each specific location along the line. Subsequently, the maximum lengthening and strain were computed using equations (2) and (3) respectively, to obtain strain distribution along the line. This definition of the lengthening and strain considers the tissue in tension only (no compression) as the undeformed configuration is unknown. Since the length of the lines among subjects was different, the one-to-one comparison of each calculated *localized* strain and the subsequent averaging were deemed impossible. As such as, averaging of the *localized* strains were made not based on the actual distance on the line but based on the relative distance from the caudal end. In particular, the relative distance was chosen in 5% increments from the caudal end, and the corresponding *localized* strain data were averaged for each increment (location) for each participant. Subsequently, the mean distributions were calculated based on the aligned *localized* strains. The average of a given increment was not computed for cases with missing subject data.

Statistical Analysis: were performed using MATLAB. Independent samples *t*-test was used to compare the maximum strain in controls, and CMI with and without imbalance. Comparisons with *p*-values of less than 0.05 were considered significant. Strain values were reported as mean \pm standard deviation.

EQUATIONS

$$d(t) = \sqrt{(X_{rVST} - X_{cVST})^2 + (Y_{rVST} - Y_{cVST})^2} \quad (1)$$

$$L = d_{max} - d_{min} \quad (2)$$

$$\epsilon_{max} = \left(\frac{L}{d_{min}}\right) * 100 \quad (3)$$

RESULTS

The local strain distribution values were typically 1–3% (Fig. 3). In general, the mean strain showed higher values caudally. The mean strain along VST in CMI ($1.97 \pm 0.64\%$) was not significantly different ($p = 0.128$) from that of the controls ($1.63 \pm 0.61\%$). The mean local strain along VST in CMI with imbalance ($1.97 \pm 0.71\%$) was not significantly different ($p = 0.996$) from that of CMI without imbalance ($1.97 \pm 0.60\%$).

DISCUSSION

We demonstrated that cardiac-induced strain distribution along the VST in CMI patients was not significantly higher than that of the controls. We also found no significant difference between the strain distribution along the VST in CMI patients with and without imbalance. The lack of statistically significant difference in the present study between strain in CMI subjects with and without imbalance could imply

that the magnitude of the observed cardiac-induced strain was too small to cause substantial damage to the tissue.

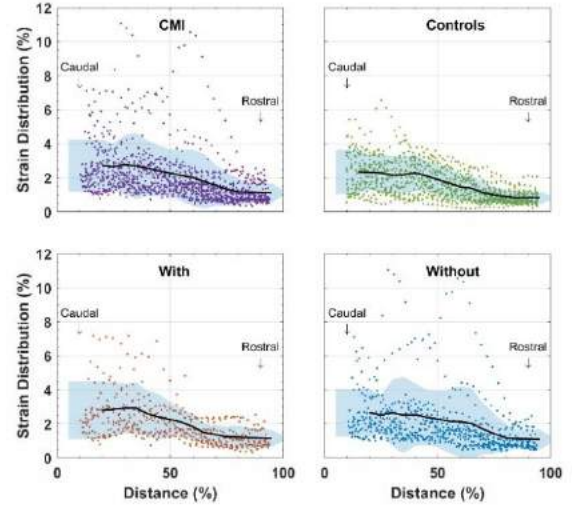

Fig. 3: Localized strain along VST of each participant for controls and CMI subjects with and without imbalance. Caudal and rostral ends are marked. The solid black lines and the shaded blue areas represent the mean and standard deviation, respectively.

We also computed strain along other neurological tracts/peduncles pertaining to balance such as superior and inferior cerebellar peduncles and found no significant difference between the strain in CMI subjects with imbalance as compared to those without. Investigating the relationship between symptom and activity-related (such as coughing or Valsalva maneuver) brain tissue strain may be necessary to explain CMI symptomatology. We believe that tissue strain analysis during a physiological activity is the future direction of this research.

This study has several limitations. First, only the first two-thirds of each cardiac cycle are reliable due to a reduction in signal-to-noise ratio caused by T1 decay [5]. Therefore, rVST and cVST positions at the end of the cycle do not match the start location (Fig. 2). Second, the assumption that DCML tract experiences similar strain as the VST due to their proximity may not be true for all subjects (Fig. 1). The reason for adopting such an assumption was that we did not expect an abrupt change in the displacement gradient within a few voxels, and, as such, we assumed that the DCML strain should be similar to that of the VST.

CONCLUSION

In summary, cardiac-induced strain distributions along VST were not significantly different between CMI and controls, neither between CMI with and without imbalance. As such, investigating activity-related strain may better explain the altered balance function in CMI subjects.

INTRODUCTION

Degenerative joint disease (DJD) affects more than 30 million adults in the United States. The disease causes the breakdown of articular cartilage which is responsible for bearing loads from body weight, and the loss of this cartilage can result in loss of the underlying bone and cause defects. The use of 3D printed biomaterials with therapeutic properties to mitigate diseased or damaged articular cartilage shows promise in developing novel materials for regenerative tissue engineering applications [1]. Mechanical properties and geometric factors such as porosity are important functional parameters of such engineered cartilage scaffolds [2]. Hyaluronic acid is a natural polysaccharide used as a hydrogel, which is a water-soluble polymer to create 3D structures. Cerium Oxide (CeO) nanoparticles are known as free radical scavenging species that can protect chemical bonds and biological entities by capturing reactive oxygen species (ROS). In this study we have fabricated 3-d printed scaffolds composed of varying polymers such as poly-vinyl-caprolactam (PVCL), methacrylated hyaluronic acid (MeHA), Pluronic F127, the photo-crosslinker Irgacure, (CeO), and varying concentrations of water. We also characterized these scaffolds using mechanical testing and FTIR spectroscopy.

METHODS

Hydrogels composed of varying polymers such as 5.63g poly-vinyl-caprolactam (PVCL), 5.75 g Methacrylated Hyaluronic Acid (MeHA) 3 mL Pluronic F127, 0.85 g of the photo crosslinker Irgacure, 18 μ L cerium oxide and varying concentrations of water were mixed in ice baths for 2 hours at 1100 rpm, replacing the ice every 30 minutes (Fig 1a). The Pluronic acid in samples required the produced solutions to be stored in the fridge or an ice bath when not in use. An Allevi 1 Bioprinter was used for the 3d printing. Each sample was printed using .6-layer height using a 4-layered lattice 3D file. The printer was auto calibrated before each print, and adjustments for temperature were done in increments of .5 degrees Celsius while adjustments for pressure were done in increments of 2 PSI. The samples were analyzed for their physical properties. pictures were taken at the time of printing and were compared to pictures at later time frames (Fig 1b). A Fourier

Transformed Infrared (FTIR) spectroscopy and microscopy was used to identify the chemical functional groups and analyze the distribution of the chemical composition throughout the sample (Fig 1c, d). The compositional make-up of the printed scaffolds is provided in Table 1. For mechanical characterization, the scaffolds were subjected to unconfined compression using bench-top mechanical testing set-up (Electroforce 3230). Scaffolds were compressed in orthogonal direction to the printing plane at a displacement rate of 1mm/s and an initial pre-load of 1 N was applied prior to testing to ensure uniform contact [3]. The contact areas of the porous scaffolds were calculated using image processing in FIJI. Data from the compression tests at 7% strain, were used to calculate elastic modulus by calculating the slope of the stress-strain curve in a linear region of the curve (Fig 1e) [4].

RESULTS

Our results show that samples such as MPV2010 (100 μ L H₂O) and MPV 2010 (300 μ L H₂O) took longer to dry (about 5 days) compared to those that lacked water such as MPV2010 (no H₂O). The inclusion of water also required lower pressure, 35 PSI as compared to 41 PSI for MPV 2010, for printing. Scaffolds such as MPV2010 (100 μ L H₂O) required higher printhead temperatures compared to samples such as MPV2010 (without water). We also observed that consecutive prints can result in thinner prints even when using the same settings. Pluronic F127 being thermosensitive, crosslinks the solution to a solid at higher temperatures. Thus, when not in use sample solutions were kept in a cooler filled with ice. FTIR measurements also showed that there is a more uniform distribution of material in samples containing water than in those without (Fig 1c, d). Compression modulus of the scaffolds varied within the range of 1-9 MPa across different specimens, with altered composition and cross-linking. We observed significant changes in the elastic modulus of the scaffolds subjected to different crosslinking intensities (10,15 and 20%) across HA scaffolds with different Cerium oxide content (Fig 1 f). Further, we found that the addition of CeO significantly increased the elastic modulus of the MPV 2010 scaffolds (Fig 1 g). Also, the addition of water can influence the mechanical properties of these scaffolds.

M2520	2.5	1	20%-20 s	86.84
M3010	3	1	10%-20 s	67.72
M3015	3	1	15%-20 s	58.62
M3020	3	1	20%-20 s	76.38
MPV2010 (no H ₂ O & CeO)	0	1	10%-10 s	57.23
MPV2010 (no H ₂ O)	2	3	10%-10 s	64.45
MPV2010 (100µL H ₂ O)	2	3	10%-10 s	52.06
MPV2010 (300µL H ₂ O)	2	3	10%-10 s	52.69

DISCUSSION

Our results showed that the inclusion of water decreased the required pressure for a successful print and increased the printhead temperature. This is important for integrating cells, as the increased temperature approaches human body temperature it will foster proliferation-friendly environments. The material from scaffolds containing water is more evenly distributed which also alters their mechanical properties. These scaffolds are also environmentally sensitive and show altered responses under temperature change. Current efforts are aimed investigating wait times required for printing samples to ensure consistency of prints and utilizing varying quantities of CeO or MeHA to investigate their influence on print settings and exploring methods of drying samples that contain water. We would like to test for consistency of mechanical properties in each group over a larger sample population and compare the bulk mechanical properties with micro scale properties using an Atomic Force Microscope.

ACKNOWLEDGEMENTS

The authors would like to thank NSF and EMBRIO for funding the research efforts and Jazzmin Owens for helping with scaffold fabrication.

NO STRINGS ATTACHED: PREDICTING TRICUSPID VALVE COAPTATION WITHOUT *IN VIVO* CHORDAL GEOMETRY

INTRODUCTION

Tricuspid valve leakage is a significant contributor to morbidity and mortality. That is, when the tricuspid valve does not seal completely, retrograde leakage through the valve reduces ventricular efficiency and induces volume-overload and cardiac remodeling. Together, reduced forward flow with adverse remodeling of the right ventricle leads to exercise intolerance and, when untreated, to heart failure and ultimately death. Methods to treat the tricuspid valves are plentiful and include surgical approaches and – recently – also transcatheter approaches. However, regardless of invasiveness, all current methods are suboptimal with recurrence rates of leakage at least as high as 15-30%, some worse [1]. Reasons for the ineffectiveness are multi-fold. Here we focus on the complexity of the valve apparatus which makes standardization of surgeries and medical devices difficult. Among those complexities are large inter-subject variations in valve geometry. For example, only about 54% of patients actually have a three-leaflet valve, while all other patients have either 2, 4, or even 5 leaflets [2]. We submit that a patient-specific approach to treating the tricuspid valve may overcome some of today's methods' ineffectiveness. Toward this end, we and others have tried to develop patient-specific models of the tricuspid valve with which patient-specific preclinical planning may be possible. Unfortunately, this is an entirely non-trivial challenge. For example, patient-specific data from routine clinical examinations is limited to 3D echocardiography without detailed information on tissue properties and – very importantly – information about the complex subvalvular apparatus, which is invisible to 3D echocardiography. In our current work, we are adapting the work by Sacks' group on the mitral valve to the tricuspid valve. Specifically, we are implementing a modeling approach in which we can replace the (unknown) subvalvular chordal apparatus with a virtual pressure field that we inform through a mapping procedure between 3D echocardiography-derived images of the valve at end-systole and end-diastole. Here, we describe our preliminary findings.

METHODS

To predict tricuspid valve coaptation in the absence of the true, *in-vivo* chordal geometry, we use a hyperelastic shape-matching framework [3]. That is, we build a material-point correspondence between the valve geometries at end-diastole (ED) and end-systole (ES) without explicitly modeling the chordae tendineae.

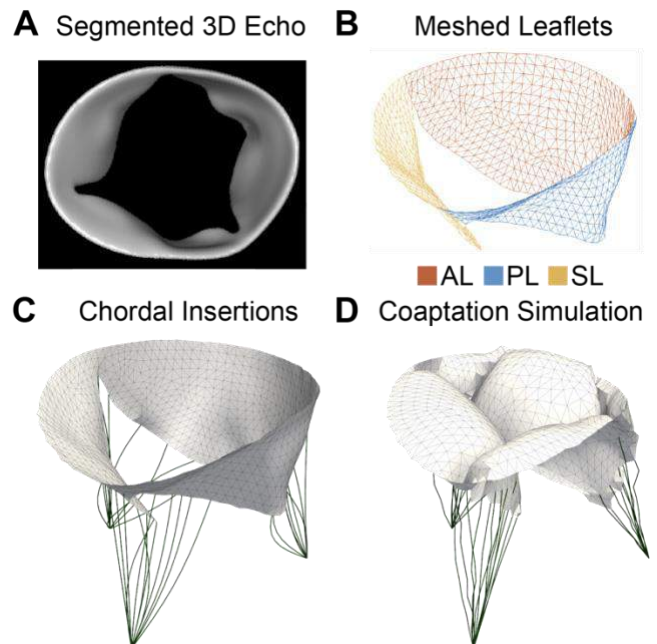

Figure 1: “Synthetic” imaging-based valve modeling pipeline

Figure 3: (A) We successfully simulate valve coaptation without explicitly modeling the chordae tendineae. (B) The error in displacements is minimal at the leaflet centers

“Synthetic” Imaging-based Tricuspid Valve Model

We first create a “synthetic” imaging-derived finite element model of the human tricuspid valve. Specifically, from 3D ultrasound data, we segment the tricuspid valve leaflet surfaces using MATLAB (v2021b, MathWorks, Natick, MA) at ED and ES, see **Figure 1A**. Next, we fit spline surfaces to our segmentation at ED and create a finite element mesh in Cubit (Coreform, Orem, UT), see **Figure 1B**. We then define papillary muscle heads from which chordae tendineae originate and insert into the ventricular surface of the leaflets based on existing literature, see **Figure 1C**. Furthermore, we manually adjust chordal insertion sites and lengths to ensure leaflet coaptation that matches the segmentation at ES, similar to our previous work [4]. Next, we assign ultrasound-derived displacements to the annulus and a literature-derived transvalvular pressure to the leaflet surfaces. Finally, we quasi-statically load the valve in Abaqus/Explicit (Dassault Systèmes, Providence, RI) to simulate leaflet coaptation, see **Figure 1D**. As a result, we create a “synthetic” finite element model with which we establish our shape-matching framework.

Hyperelastic Shape-Matching Framework

To begin the shape-matching process, we consider the coapted “synthetic” valve to be our target ES geometry. That is, we morph the segmented ED geometry to match this shape. To this end, we first remesh the ES geometry in MeshLab (ISTI, Pisa, Italy) to smooth out any discontinuities, see **Figure 2A**. Next, we sample the space surrounding the ES geometry and identify the shortest distance to the leaflet surface for each sample point, see **Figure 2B**. This distance map, or shape field, allows us to penalize any mismatch between the ED and ES geometries, as detailed below.

To simulate leaflet coaptation, we delicately balance a downward force in place of chordal tension, annular displacements, and a generic transvalvular pressure. Furthermore, we ensure shape accuracy through penalization from the shape field. That is, we penalize a shape mismatch by applying an incremental pressure load to the ED surface that is proportional to its distance from the target ES surface. Moreover, we

generate an analytical expression for this shape field by encoding its components through a 3D Discrete Cosine Transform, similar to Rego et al. Furthermore, we implement this in Abaqus/Explicit through the VDLOAD subroutine.

RESULTS

We use the hyperelastic shape-matching scheme to successfully morph the ED geometry to that of the ES state, see **Figure 3A**. Specifically, we establish initial contact of the leaflets by balancing annular displacements, the chordal-mimicking force, and generic transvalvular pressures. We then activate our shape field to ensure a close match in geometries. Specifically, we observe an average nodal error of 0.39 ± 0.455 mm between the target and simulated shape, see **Figure 3B**.

DISCUSSION

In conclusion, we successfully adapted a method first proposed by Rego et al, for the tricuspid valve. That is, we are able to identify a virtual pressure field that replaces the chordal apparatus of the tricuspid valve. We do so, through a mapping between 3D echocardiography-derived geometries of the tricuspid valve at end-diastole and end-systole. This pipeline will allow us to conduct patient-specific simulations of the tricuspid valve that are built solely on 3D echocardiography data even in the absence of imaging-based data on the subvalvular chordal apparatus. Naturally, this approach is prone to several potential errors and inaccuracies. Our next step will be to conduct the procedure on a virtual 3D echocardiography image that we create using the Texas TriValve 1.0, a high-fidelity model that we have previously developed, published, and made openly available. Knowing its true deformation throughout the cardiac cycle, we will have the means to quantify the errors we accrue using the above-described approach. If successful, we will expand our preliminary study to actual patient data and evaluate its usefulness in preprocedural planning. Specifically, we aim to predict the outcomes of clinical procedures based on pre-operative images and compare them to post-operative images of the same procedure. We hope that through this work, we will aid surgeons and interventionalists in improving clinical outcomes and providing patients with improved health and quality of life.

A COMPUTATIONAL FRAMEWORK FOR SURGICAL PLANNING OF PULMONARY ARTERY STENOSIS REPAIR IN TETRALOGY OF FALLOT PATIENTS

INTRODUCTION

Tetralogy of Fallot (ToF) is a congenital heart defect present in 1 of every 3600 births [1]. A characteristic feature of ToF is stenosis of the pulmonary arteries, leading to obstruction of the right ventricular outflow tract. This defect can be repaired surgically through the incision and patching of the pulmonary arteries. However, due to differences in pulmonary artery anatomy, treatment and surgical strategies may vary between patients [2]. Additionally, vessel patches can be made out of multiple synthetic and biological materials [3].

In recent years, methods such as finite element analysis have been used to evaluate the local mechanical environment within regions of the cardiovascular system. Mechanical parameters are known to influence remodelling of the vessel over-time [4] and may have important implications for long-term clinical outcomes within this patient population. In previous work conducted by our group [5], a computational framework to simulate the surgical repair of pulmonary artery stenosis has been developed. This framework was also used to compare the mechanical consequences of using different patch materials in different repair locations (Table 1). This same framework, which is described below, will also be employed in the present work.

Table 1: Summary of Patch Materials and Repair Locations

Patch Materials	Surgical Repair Locations
<ul style="list-style-type: none">• Dacron• PTFE• Porcine Xenopericardium• Human Pericardium	<ul style="list-style-type: none">• INF+MPA (Infundibulum and Main Pulmonary Artery)• MPA (Main Pulmonary Artery)• MPA+LPA (Main Pulmonary Artery and Left Pulmonary Artery)

METHODS

Research Ethics Board approval was received at the Hospital for Sick Children, Toronto, Canada (REB #1000026285). Patient-specific computational meshes were then generated from MRA imaging for three post-operative patients using manual segmentation methods in SimVascular (www.simvascular.org) [6].

The virtual surgery methodology that was developed aimed to computationally replicate the stenosis repair procedure. This was accomplished in three main steps:

1. Cardiopulmonary Bypass Simulation (Depressurization)

Firstly, a zero-pressure geometry was generated to replicate the changes that occur to the vessel as a result of intraoperative cardiopulmonary bypass conditions. This simulation step was developed using the methods proposed by Raghavan et al [7], and was performed using ANSYS APDL (ANSYS Inc, Somerset) and MATLAB (MathWorks, Natick, MA).

2. Virtual Patch Creation

An incision and patch were then defined within MATLAB. A patch mesh was generated and exported to Autodesk MeshMixer (Autodesk Inc., San Rafael, CA) where it was post-processed and combined with the zero-pressure geometry.

3. Return of Blood Flow Simulation (Pressurization)

Finally, the return of blood flow was simulated for the patched geometry by applying a uniform pressure of 6000 Pa (45 mmHg) to the walls of the vessel using ANSYS Mechanical.

RESULTS

Following virtual surgery, the mechanical environment within the repaired vessels was assessed. The average Von Mises stress was compared between patch locations as well as between the patch materials (Figure 1) both visually and using Friedman statistical tests with Dunn post-hoc analysis. It was shown ($p < .001$) that significant differences existed in average stress between models featuring different patch materials. It was also observed that lower levels of average Von Mises stress were seen in models featuring synthetic patch materials (Dacron and PTFE) than in biological patch materials (porcine xenopericardium and human pericardium).

Figure 1: Average Von Mises stress for three patients with stenosis repair occurring at three different locations with four patch materials.

Using the methodology proposed above, it was also possible to visualize the stress distribution within the patched vessels (Figure 2). Regions of high stress are observed at the suture line, between the two materials.

Figure 2: Resulting stress distributions for Patient 3 in a single patch location (INF+MPA) following virtual surgery.

DISCUSSION

The mechanical consequences of pulmonary artery patching have previously been studied using virtual surgery and computational simulation. However, these studies have been limited by factors such as

the use of idealized vessels [3] or the investigation of a single patch location and material [8]. The methods proposed here allowed for the comparison of four patch materials across multiple stenosis locations for multiple patient geometries. It was observed that relative patch material performance, in terms of average stress, was the same across the locations and patient geometries included. This suggests that certain materials may be better suited for patch repair from a mechanical perspective, however, the long-term clinical consequences of these mechanical differences should be assessed in larger, longitudinal studies.

The goal of the present work is to continue to develop our understanding of the relationship between patch parameters and mechanical indices through the inclusion of additional patients. A larger patient cohort will allow us to investigate the influence of patient-specific geometric parameters on patch mechanical performance. Computational methods, such as those presented in this work, may aid in the generation of patient-tailored surgical planning tools in which different repair options can be compared.

INTRODUCTION

Chiari Malformation Type 1 (CMI) is a disorder anatomically characterized by descent of the cerebellar tonsils greater than 5 mm below the foramen magnum (FM) [1] causing pressure on the spinal cord. CMI patients experience signs and symptoms such as severe headaches, neck pain, unsteady gait, poor hand coordination, numbness and tingling of the hands and feet, dizziness, difficulty swallowing, sometimes accompanied by gagging, choking, and vomiting, and speech problems, such as hoarseness. However, some patients meeting the anatomic criteria of CMI have minimal to no symptoms while some others have typical CMI symptoms without meeting the anatomic criteria.

Because of altered brain morphology, CMI patients have more resistance to cerebrospinal fluid (CSF) motion compared to healthy subjects [2]. To quantify the CMI patients' resistance to CSF, a hydrodynamic property called *longitudinal impedance* (LI) is defined as the ratio of pressure harmonic to flow harmonic at the same frequency. To obtain the *integrated longitudinal impedance* (ILI), which represents the overall CSF resistance, the resulting LI is integrated from 1 to 8 Hz. Also, CMI patients have increased tissue motion in the cerebellum and brainstem [3].

In the present study, we examined the interaction of CSF motion and brainstem/cerebellum tissue displacement to understand the possible correlation between these factors.

METHODS

The MRI exams were acquired at Emory University under an IRB-approved research protocol. Thirty-two CMI patients (x male, x female) and eighteen healthy subjects (x female, x male) were analyzed by

determining ILI and displacement in the brainstem and cerebellum. All patients had the cerebellar tonsillar position (CTP) greater than 5mm.

To calculate ILI, axial T2 weighted images were used with axial slice thickness 0.9 mm and pixel spacing 0.85 mm to segment the subarachnoid space into a 3D model of CSF space that extends from the FM to an axial plane 60 mm caudal to the FM (near C3 or C4).

ANSYS ICEM CFD was used to generate the computational mesh for the CSF space. Depending on the shape and size of the flow geometry, A time-dependent velocity inlet boundary condition based on the subject-specific MRI flow measurements was specified at the inlet and a zero-pressure boundary condition was assumed at the flow outlet. No slip (zero velocity) boundary conditions were specified at the walls. The commercial finite volume solver *Ansys Fluent* was used to run computational fluid dynamics (CFD) simulations of CSF motion. ILI was calculated using an internally-developed MATLAB program.

To quantify brain tissue motion, another internally-developed MATLAB program was employed (DENSEPro) which utilized DENSE phase images to compute the average displacement of the brain tissue over the cardiac cycle [4]. A 30 mm² circular region of interest (ROI) was automatically identified in sections with the greatest amount of displacement or principal strains to obtain a more homogeneous representation of maximum displacement and principal strain in each brain region. The decision to use 30 mm² was based on the previous findings, which showed that DENSE MRI requires approximately 80 averaged voxels to provide a reliable displacement measurement [4]. The average of the peak displacements within each circular area for all brain regions was used to determine the maximum displacement in each circular area (Figure 1).

Statistical analysis were performed using Excel. The linear regression analysis was used to examine the correlation between ILI and maximum displacement at the cerebellum and brainstem.

Figure 1: Two-dimensional Eulerian displacement maps of the brainstem and the cerebellum of a CMI subject [4]

RESULTS

Figures 2 and 3 depict maximum displacement at the brainstem and cerebellum versus ILI for CMI and healthy subjects. These figures show a significant correlation between the ILI and displacement at the cerebellum in CMI subjects. The result of the regression test shows a significant correlation between ILI and maximum displacement at the cerebellum of CMI subjects, $r=0.75$, $p=6.77 \times 10^{-7}$. However, the results of the regression test show that no correlation exist between the ILI and maximum displacement at the cerebellum for healthy subjects, as well as maximum displacement at the brainstem for both CMI and healthy subjects.

Figure 2. ILI versus maximum tissue displacement at the cerebellum for Chiari subjects and healthy controls.

Figure 3. ILI versus maximum tissue displacement at the brainstem for Chiari subjects and healthy controls.

DISCUSSION

The present study examines the effect of two different parameters, including CSF flow resistance and cardiac-induced brain tissue motion for thirty-two CMI patients and eighteen healthy controls. Subjects with CMI have tonsillar herniation which often results in an increase in resistance to CSF motion between the cranium and spinal canal. The magnitude of ILI provides a quantitative measure of this resistance to CSF flow. ILI and brain tissue motion have both been shown to be elevated for CMI subjects [2, 3]. Thus, we postulated that there was a connection between resistance and tissue motion. However, the results of this study demonstrates that this postulation is only true for the correlation between ILI and cardiac induced brain tissue motion for CMI patients in the cerebellum and not in the brainstem. Since, patients with Chiari malformation, have CTP greater than 5 mm below the FM, the tonsils of the cerebellum in CMI patients herniate to the spinal canal and leading to an increase in the CSF flow resistance. On the other hand, since the cerebellar tonsils are in direct contact with CSF flow in the spinal canal, their displacement increases. Therefore, CMI patients show strong correlation between CSF flow resistance and displacement at the cerebellum. This phenomenon can explain the elevated cerebellum displacement in CMI patients compared to healthy subjects. Also, no correlation was found between ILI in both cerebellum and brainstem displacements of healthy controls.

As the resistance to CSF flow in spinal canal and maximum displacement at the cerebellum are significantly correlated in CMI patients, we explored how this relationship might change at higher displacement values. Therefore, we performed regression tests for the ILI and maximum displacement at the cerebellum for the values greater than 150 μm , 200 μm , and 250 μm to find out the correlation of these parametes at higher motion. The results showed that at higher values of displacements, the relationship between ILI and displacement at the cerebellum is stronger (Table 1).

Table 1. Correlation between ILI and maximum displacement at the cerebellum for CMI cases

	p-value	r
Maximum displacement at the cerebellum		
Total CMI cases	6.77E-07	0.75
Greater than 150 μm	9.94E-06	0.77
Greater than 200 μm	4.73E-04	0.82
Greater than 250 μm	1.16E-03	0.86

Elevated brain tissue motion has been associated with elevated brain tissue strain [3, 4] and may imply nerve damage. Thus, understanding the underlying biomechanics present in cardiac induced brain tissue motion/strain could help further understand how various clinical symptoms arise. While ILI clearly plays a role in the unsteady pressure environment within the spinal canal, the relationship between ILI and tissue motion requires further study.

INTRODUCTION

Pelvic organ prolapse is a condition that results from a loss of support to the pelvic organs. As many as 10% of women will seek surgical repair of this condition in their lifetime [1]. Repair with polypropylene mesh provides the greatest likelihood of a long-term, successful repair. However, these devices have been associated with unacceptable complication rates. Our work has shown that devices with a higher stiffness are associated with a more pronounced host response compared to those with a lower stiffness, suggesting that this response is, in part, driven by mechanical interactions between the device and the host.

Pelvic organ prolapse mesh devices are manufactured from thin, knitted polypropylene filaments. The differences in mechanical behavior across devices largely result from different knit patterns. Our recent data show significant regional variation in the host response, which indicates that mesh-host mechanical interactions must be studied at the level of individual pores if not filaments [2].

Simulating textiles such as polypropylene mesh at the level of filaments is challenging because they undergo large deformations with significant filament-filament interactions (contact and sliding). Recent developments in finite element modeling have now made it possible to simulate these interactions for devices undergoing large deformation. This study aims to utilize Incremental Potential Contact (IPC) implemented in the finite element solver PolyFEM to determine if the force-displacement relationship of a polypropylene mesh undergoing a ballburst test can be predicted from a simulation that includes local filament interactions with large deformations [3].

METHODS

The geometry of Restorelle™, a popular prolapse repair mesh, was captured using a SkyScan 1272 microCT system at 80kV, 125μA, 6.15μm pixel size, 180° rotation, and no filter. The images were thresholded to create a rough 3D geometry (3DSlicer, slicer.org) where individual filaments could be easily visualized, however the exported mesh fused adjacent filaments at areas of contact. To account for this, the exported mesh was imported into Blender (blender.org; v.3.3.1), where a series of circles with the same diameter as the filaments were manually fit to the geometry in 3D space and lofted to create a smoothed geometry of individual filaments within a single pore. An array modifier was then used to create multiple pores from this geometry, thereby resulting in a complete representation of Restorelle's geometry. Individual filaments were discretized into 104,906 tetrahedral elements using Houdini (sideFX, Inc.; v. 19.5) and a custom-written plugin to interface with the meshing software fletwild [4]. A triangular surface mesh (3,960 triangles) obtained from a CAD model of the ballhead that was used in the experiment provided the ballhead geometry. The simulations were performed in PolyFEM, a finite element solver that incorporates an incremental potential contact implementation for robust and accurate high order elastodynamic FE simulations that do not suffer from intersections or inverted Jacobians [3,5,6]. Boundary conditions were assigned to match the experiment with the deformable mesh device fixed around its circumference and the ballhead displaced as a rigid body along the vertical direction (methods depicted in Figure 1). A Neo-Hookean material model was selected for polypropylene. Since the material stiffness of polypropylene can vary depending on

the specific blend, Young's moduli of 0.896, 1.1, 1.3, and 1.55 GPa were assigned based on the range of values reported in the literature [7]. A Poisson's ratio of 0.425 was used for each simulation. The contact force on the ballhead was plotted versus the displacement for each simulation and compared among themselves and to experimental results. The experimental results were previously published and are represented by a force-displacement curve from N= 4 samples.

Figure 1: Workflow diagram where 1) is an image of Restorelle, 2) is a shadow projection of the Restorelle during microCT, 3) is the segmentation, 4) is the experimental setup of a ball burst test and 5) is the simulation of a ball burst test

RESULTS

The resulting simulations all demonstrated a nonlinear force-displacement response that was consistent with the experimental data. In addition, all simulations were intersection-free and there were no issues with element inversion. As expected, the predicted force-displacement relationship demonstrated stiffening behaviour with increases in Young's moduli. The predicted curve for a Young's modulus of 1.1 GPa provided the best match to the experimental data (Figure 2).

Figure 2: Resulting force-displacement curves compared with experimental data (mean±SD, n=4)

The greatest differences between the simulated and experimental data for the other curves exist primarily at larger displacements; however it is notable that all curves show similar differences in the low displacement behavior with respect to the experimental data (Figure 2). As expected for a ballburst test, stress concentrations appear near the tip of the ballhead and along mesh filaments with local variation within the filaments (Figure 3). The solving times for the simulations was in the range of 41.45 to 56.99 hours with stiffer simulations solving faster (Machine 1: AMD Ryzen 9 5950X, 16 cores at 4.9GHz, 2667 MT/s, 128 GB Machine 2: Intel Core i9-10980XE, 18 cores at 3.0 GHz, 3200 MT/s, 256 GB; no GPU acceleration used).

Figure 3: Simulated von Mises stresses in the mesh device as viewed from two perspectives

DISCUSSION

This study demonstrates the feasibility of simulating filament-level mechanical interactions for a textile, namely a pelvic organ prolapse repair device, undergoing large deformations. By validating this approach for a known experimental result, further research comparing mesh devices and modeling their interactions with tissue can be pursued. It should be noted that we have used a hyperelastic neohookean representation of material behavior in this study. While the resulting stresses of a neohookean material for large deformations was likely providing a reasonable approximation of plastic deformation, this methodology cannot be used to make predictions about the plastic behavior in this material. Future work will aim to improve the material model to account for systematic discrepancies between the simulation and experiment (i.e. forces at low displacements). It is possible that the latter may be related to the coefficient of friction, which was not considered in this study but will be in the future. In addition, we are planning to perform mechanical testing of individual filaments that can be isolated from these devices to determine if the measured Young's modulus matches that predicted here (i.e. 1.1 GPa).

INTRODUCTION

Anterior cruciate ligament (ACL) reconstruction is the 6th most common orthopedic procedure performed in the United States (1,2). ACL injury leads to altered knee joint function, significantly increasing the risk of developing knee osteoarthritis. There is substantial evidence to suggest that muscle weakness contributes to adverse outcomes after ACL injury/reconstruction (3). Despite efforts to improve rehabilitation methods, current strategies often fail to restore pre-injury muscle strength in ACL-injured limbs. Our team has identified that estrogen-related receptor gamma (ERR γ) is a crucial regulator of paracrine angiogenesis in skeletal muscle (4). Selective over-expression of ERR γ in skeletal muscle (Err-gamma transgenic mice, TG) activates a robust paracrine angiogenic gene program involving myofibrillar induction and secretion of a battery of angiogenic factors resulting in promotion of muscle vascularization (4). The goal of this study was to determine if ERR γ -driven muscle angiogenesis can mitigate muscle atrophy after ACL injury by comparing TG mice to age-matched wild-type (WT) littermate control mice using a mechanically induced ACL injury model.

METHODS

Animals: 12 week old male and female TG and WT mice obtained from Dr. Narkar's laboratory were used for this study. The mechanically induced ACL rupture was conducted by our collaborators, Dr's Santangelo and Sikes at Colorado State University, who have specialized equipment for and prior experience with this injury model. The ACL rupture was performed on the right leg, and the left leg was used as non-injured control. The mice were euthanized four weeks after injury. The muscle tissues were harvested and the gastrocnemius muscle (GM) mass was flash-frozen in liquid nitrogen-cooled 2-methylbutane, and cryo-sectioned. The myofiber cross-sectional area (CSA) was measured based on the H&E staining on the GM muscle of TG and WT mice. **Cell Isolation and Myogenic Differentiation Assay:** Muscle progenitor cells (MPCs) from TG and WT mice were isolated using a modified preplate technique (5) and myogenic differentiation was performed by replacing the proliferation medium with fusion medium (DMEM with 2% FBS). The MPCs were isolated from TG and WT control mice and the diameters of myotubes were measured based on desmin staining after myogenic differentiation. H&E staining was performed on 10 μ m cryosections from GM according to the

manufacturer's instructions. Immunohistochemical staining and muscle force: It has been reported that ACL injury promotes muscle fibrosis (8). To assess fibrosis, the number of PDGFR α (fibrogenic cell marker) + cells were counted in the skeletal muscle samples. Muscle sections were fixed with 4% paraformaldehyde. PDGFR α and desmin staining were performed as previously described (6). To assess muscle performance, we measured the isometric torque of the anterior crural muscles in TG and WT mice as previously described (7). The number of PDGFR α + cells and the diameter of myotubes were counted and measured using ImageJ software. Statistical analysis: All results are presented as mean \pm standard deviation (SD). Means from ACL injured and non-injured of WT and TG mice were compared using Student's t-test, with a significance value of $p < 0.05$.

RESULTS

Muscle-specific ERR γ activation mitigated muscle fiber atrophy after ACL rupture. As expected, mean muscle fiber size was reduced in gastrocnemius muscles (GM) from the ACL-injured limbs of WT mice compared to the contralateral, uninjured limb (Fig. 1A and Fig. 1B left plot, $p < 0.01$). Conversely, there was significant difference in the average size of muscle fibers between ACL-injured and control limbs for the TG mice (Fig. 1B right plot, $P > 0.05$). We also observed that the muscle fibers in TG mice were significantly smaller than WT muscle fibers (Fig. 1B right, $P < 0.01$), due to a greater percentage of slow-twitch muscle fibers in muscles from the TG mice. Desmin staining demonstrated significantly decreased myotube diameter in the MPCs isolated from WT mice after ACL injury (Fig. 1C, D, $p < 0.01$). However, this ACL injury-induced myotube atrophy was not observed in TG MPCs after ACL injury (Fig. 1C, D). Taken together, these results indicated that ERR γ overexpression in the muscle prevented muscle fiber atrophy after ACL rupture. Muscle-specific ERR γ activation ameliorated muscle function loss after ACL rupture. Muscle torque testing revealed that muscle strength was significantly decreased in the ACL injured limbs in both male and female WT mice compared with non-injured limbs (Fig. 2A, male, 2B, female, 2C, $p < 0.01$). Strikingly, after ACL injury, the hindlimb muscles in TG mice were resilient to atrophy, as muscle function was similar in the ACL-injured and control limbs (Fig. 2. A, B and D). Muscle-specific ERR γ activation prevented fibrogenic cell expansion within skeletal muscle after ACL rupture. The number of PDGFR α + cells was significantly higher in the WT muscle

compared to TG muscle after ACL injury (Fig. 3A and B, $p<0.05$). In summary, those results demonstrated that muscle-specific ERR γ activation mitigated muscle atrophy and appears to reduce or prevent muscle fibrosis after ACL injury.

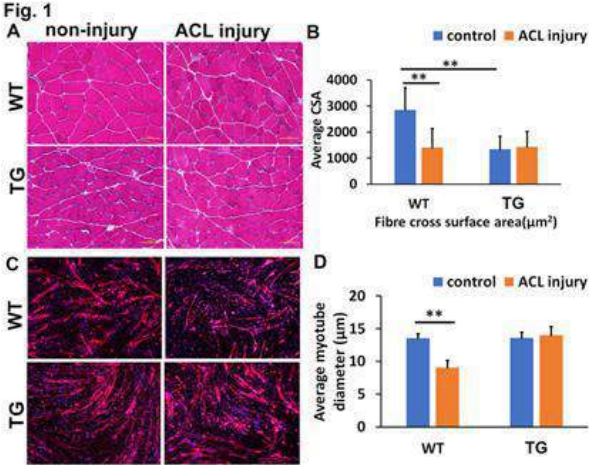

Figure 2:

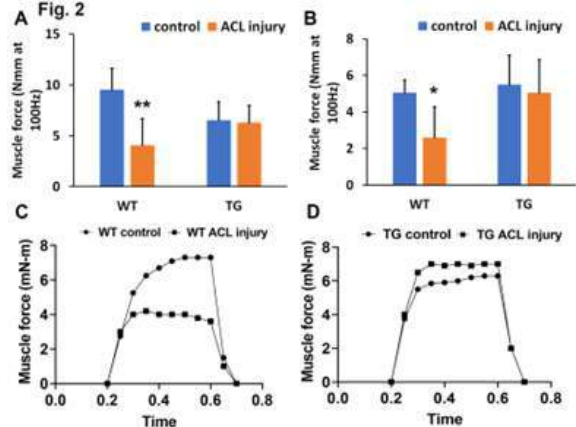

Figure 3:

DISCUSSION

Skeletal muscle is adversely affected by the ACL injury and recovery (even after reconstruction surgery) is often limited by muscle weakness. In the murine ACL injury model, muscle weakness is correlated with a reduction in angiogenesis and accumulation of fibrosis. It has been reported that ERR γ expression in the skeletal muscle directly correlates with vascular density, and ERR γ is highly expressed in well-vascularized muscle beds (4). This evaluated whether ERR γ overexpression can prevent muscle weakness after ACL injury, and if so whether this preventive effect would be potentially linked to increased muscle angiogenesis. We observed that the TG mice with muscle specific ERR γ activation have the capacity to mitigate muscle atrophy, as evidenced by the maintenance of muscle fiber size and muscle function after ACL injury. It is known that exercise induces muscle angiogenesis, and regular physical activity has been considered a therapeutic modality for preventing aging-related muscle wasting. Although exercise is the primary method for alleviating muscle weakness, many patients cannot achieve the exercise intensity that is necessary to prevent or reverse muscle atrophy. ERR γ belongs to the nuclear receptor superfamily, which are excellent ‘druggable’ targets with unique ligand-binding pockets that facilitate selective and specific drug design. Thus, future development of pharmaceuticals targeting ERR γ could provide a safe and effective therapy for improving outcomes after ACL injury and potentially other musculoskeletal disorders.

INTRODUCTION

Residual stress distributions are a common and characteristic trademark of soft biological tissues, especially in the cardiovascular system [1]. Residual stresses have been shown to have a potential protective effect in healthy tissue, however this beneficial effect can be hindered in disease [2]. As a way to estimate the residual stress distribution, the opening angle experiment has historically been the golden standard in soft tissues of the cardiovascular system, including the left ventricle (LV) [1][3]. Furthermore, while the effect of opening angle has been investigated on the *in vivo* stress state for arteries and the myocardium [4], how the existence of residual stresses affects material parameters estimation has not been studied yet. In this study, we considered how the opening angle affects parameters estimation in the case of a uniaxial tensile test on ring-shaped samples [5]. We have developed an inverse finite element (FE) approach to investigate the relationship between the opening angle and material parameters in the LV, associated with uniaxial mechanical testing.

METHODS

We developed an inverse FE parameter estimation protocol that is briefly outlined here. All FE analysis in this study have been performed in FEBio 3.0, following a modified approach to what previously described in [6]. All material parameters estimations have been performed by pairing FEBio 3.0 with Matlab R2022a.

1) *Development of a reference model for an opening angle equal to 96°.* A FE model of the stress-free configuration of a representative LV was created (**Fig. 1**). This specific model had a value of the opening angle of 96°. To generate the geometry of the model we used a solid arc tool for the LV tissue, the pins were modeled as rigid bodies, and all solid elements were meshed using hex8 elements. We used a sliding node-on-facet contact model between the pin surface and the tissue during the

simulated mechanical test. A defined strain energy density was employed to describe the myocardium, as follows

$$W = c(\exp k(I_1(\mathbf{C}) - 3) - 1) + U(K, J). \quad (1)$$

Here $I_1(\mathbf{C})$ is the first invariant of right Cauchy-Green tensor $\mathbf{C} = \mathbf{F}^T \mathbf{F}$ and $J = \det \mathbf{F}$. The material parameters used were the same as in the continuum model (i.e., $c = 50$ Pa and $k = 2$). The value of bulk modulus K was 1000 Pa to simulate a semi-incompressible material.

Figure 1: Stress free ring model used for simulations. The tissue is shown in orange and pins are purple and yellow.

2) *Calculation of a pseudo-experimental force-deflection curve.* Using this geometry and material specifications, we created a reference force-displacement dataset for a value of the opening angle of 96°, as follows. First, we applied a deformation to “close” the model based on the closed geometry calculated using a continuum mechanics analytical approach (to ensure an equilibrated condition) [4]. During this step the pins were

fixed. At this simulation point, we identified the elements that where part of the symmetry plane after the opening angle closure. For the specific reference system considered here, this plane can be identified by all points having the x-coordinate equal to zero. Second, a displacement of 2 mm was applied to one of the pins to simulate the mechanical test. We calculated the pseudo-experimental force during the test as the summation of the product of the x-stress by the surface area for all elements part of the symmetry plane. We also calculated the corresponding deflection as the average x-displacement of all elements part of the symmetry plane. This resulted in the force deflection curve shown in Fig. 2.

Figure 2: Force distribution during the ring test.

3) *Development of FE models for a set of opening angle values.* Following the same procedure described in point 1, we created 3 more FE models corresponding to opening angles equal to 30°, 60°, 120°. These models where then employed as numerical models to be compared to the pseudo experimental dataset created in point 2. For each model we calculated the numerical force-deflection curve, starting with a set of initial material parameters.

4) *Inverse parameter estimation by interfacing FEBio and MATLAB.* We used MATLAB to perform the parameters optimization. We developed a custom code to interface FEBio and MATLAB and we used the function 'fminsearch' to optimize the material parameters as a function of the opening angle. The error used in the optimization process was the root mean square difference between the pseudo-experimental force-deflection curve and the numerically calculated one for each value of the opening angle. The output was the optimized values for the parameters c and k for which the force displacement plot best-described the pseudo-experimental results.

RESULTS

Table 1 represents the estimated values of c and k for different opening angles that best-fitted the pseudo-experimental dataset. In Fig. 3 (a) and (b) we show the material parameters c and k as a function of the opening angle, respectively. In these results we also include the values we used as reference, i.e., opening angle equal to 96°.

Opening angle	c (Pa)	k
96	50	2
30	92.370	1.917
60	68.503	2.003
120	33.938	2.587

Table 1: Best-fitting values for the material parameters c [Pa] and k , calculated for different values of the opening angle

As a validation we have performed the material parameter estimation for this model as well, which returned the original values. Our parametric study seems to suggest there is as strong inverse linear correlation between the opening angle and the estimated value of c ($R^2 = 0.9925$). Whereas, we could not identify a clear correlation between the opening angle and the material parameter k . moving forward we will explore the possibility of a non-linear correlation, by performing more parametric analysis.

Figure 3. Material parameters c (a) and k (b) as a function of the opening angle. Also shown, the linear correlation as well as the corresponding values of R^2 .

DISCUSSION

We developed an inverse FE parameter estimation protocol to investigate the relationship between material descriptors and residual stress distribution magnitude. We have also performed a parametric study employing a pseudo-experimental reference force-deflection curve. What we found is that the value of the opening angle affects significantly the material parameter estimation. Indeed, we have observed a strong inverse linear correlation between the opening angle and the value of c . In future, we will use the protocol shown here to model experimentally collected datasets.

CARTILAGE CONTACT PRESSURES DURING WALKING ARE RELATED TO T2 RELAXATION TIMES IN PATIENTS WITH KNEE OSTEOARTHRITIS

**Benjamin D. Bernarding (1), Austin J. Carcia (1), Adam J. Bradshaw (1), Johnny Huard (1),

INTRODUCTION

Osteoarthritis (OA) is a leading cause of disability in the aging population and is associated with progressively worsening cartilage degeneration, pain, and loss of joint function [1,2]. The loading environment experienced by knee articular cartilage is an important factor in maintaining tissue homeostasis and also plays an important role in the initiation and progression of OA. In this study, we investigated relationships between simulated cartilage contact pressures during walking and MRI measures of cartilage degeneration in patients with mild-severe knee OA.

METHODS

Twenty-one patients with mild to severe tibiofemoral OA (65 ± 8 years, BMI 26 ± 5.1 kg/m², Kellgren-Lawrence Grade II-IV, 11 female) were included in this study. Data was acquired as part of an ongoing IRB-approved clinical trial (NCT04210986). For each subject, the most symptomatic knee was scanned on a 3T MRI system (SkyraFit, Siemens Healthineers USA). A double echo in steady state (DESS) sequence was used for cartilage segmentation and a multi-echo spin echo (MESE) sequence was used to calculate cartilage T2 relaxation times (6 echoes, range 16-96 ms). The patellar, femoral, and tibial cartilage were manually segmented from the DESS images using Mimics (Materialize) and registered to T2 relaxation time images generated using MapIt software. The average T2 relaxation times were calculated for the medial and lateral tibial cartilage, distal portions of the medial and lateral femoral cartilage, trochlear groove of the femoral cartilage, and patellar cartilage. At the same visit, motion capture and ground reaction forces were measured as participants walked at 1 m/s on

an instrumented treadmill (Bertec). A lower extremity musculoskeletal model with a detailed knee joint including explicit representations of fourteen ligaments as well as tibiofemoral and patellofemoral articular contact was scaled to each subject based on segment lengths calculated from a static motion capture trial [3]. Muscle driven simulations of walking were performed using the COMAK simulation routine to predict cartilage contact pressures using the open-source OpenSim-JAM framework [4]. Inverse dynamics was used to calculate the knee flexion and adduction moments. The predicted contact pressure maps on the medial and lateral tibial plateaus and femoral condyles, and also between the trochlear groove and patella, were averaged spatially and temporally over the stance phase. Spearman correlation coefficients were calculated between the average T2 relaxation times and average stance phase contact pressures for the tibiofemoral cartilage and patellofemoral cartilage areas, as well as overall joint adduction and flexion moments.

RESULTS

In regions of tibiofemoral contact, the mean cartilage contact pressure on the medial tibial plateau throughout the stance phase of walking was negatively correlated with the medial tibial cartilage T2 values ($\rho = -0.47$, $p = 0.03$, Figure 1), while the lateral plateau did not show a significant correlation ($\rho = 0.12$, $p = 0.60$). Similar correlations were observed for maximum pressures. Medial femoral T2 values were significantly positively correlated with mean lateral contact pressures ($\rho = 0.44$, $p = 0.04$). The knee flexion and adduction

moments were not significantly correlated with the medial or lateral tibial or femoral T2 values.

In regions of patellofemoral contact, the mean and maximum patellofemoral contact pressures were significantly positively correlated with mean patellar T2 relaxation times ($\rho = 0.47$, $p = 0.04$ and $\rho = 0.57$, $p < 0.01$ respectively). A correlation plot for the mean patellofemoral contact pressure is provided in Figure 2. There were no significant relationships between contact pressures and femoral T2 values, nor between patellar or femoral cartilage T2 values and knee flexion and adduction moments.

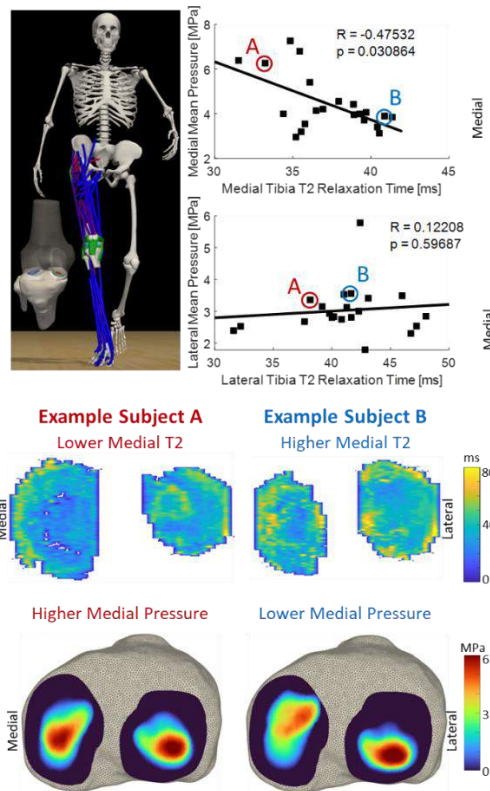

Figure 1: Cartilage contact pressures were estimated using a lower extremity musculoskeletal model with muscle-driven simulations of walking. Predicted contact pressures were negatively correlated with T2 relaxation times for the medial tibia. Representative T2 maps and contact pressure maps are shown.

Figure 2: Patellar cartilage contact pressures were significantly positively correlated with T2 relaxation times.

DISCUSSION

OA patients with more severe cartilage degeneration on the medial tibial plateau, as indicated by higher T2 values, demonstrated gait mechanics resulting in lower medial tibial cartilage contact pressures. Conversely, patients with more severe cartilage degeneration on the patella demonstrated higher contact pressures. These differences may reflect different regional pain responses or the limited ability of patients to unload the patellofemoral cartilage on a fixed speed treadmill. Relationships were less pronounced between articular contact pressures and femoral cartilage T2 relaxation, which could be related to more spatially distributed loading patterns across the femoral cartilage surface during movement. There has been mixed information in the literature regarding patterns of cartilage contact pressure and cartilage thickness and T2 relaxation times, though most have been limited to regions of tibiofemoral contact [5,6]. Further work is necessary to investigate these connections in more detail across the joint.

Importantly, the knee flexion and adduction moments exhibited no correlations with cartilage T2 relaxation times. Together, these results demonstrate the important role for musculoskeletal simulations that predict cartilage loading patterns across the joint in OA research.

We plan to incorporate the patient-specific cartilage geometries into the musculoskeletal model for whole-joint modeling of patterns of cartilage loading and degeneration over time. A further longitudinal analysis on the sub-population with early OA at collected follow-up timepoints will be needed to discern whether the unloading of the medial compartment observed in the present study is a cause of cartilage degeneration or instead a local pain response. Additionally, it will be important to examine the role of cartilage thinning in relationships between contact patterns and T2 relaxometry measures.

Overall, significant relationships between articular contact pressure patterns during walking and cartilage composition were observed in individuals with knee OA. Measures of cartilage quality and joint loading provide complimentary information that may be useful in monitoring disease progression and efficacy of disease-modifying interventions.

INTRODUCTION

Glaucoma is a leading cause of blindness globally and the major risk factor is elevated intraocular pressure (IOP). The fluid mechanics of the drainage of aqueous humour from the eye determine the IOP, lowering of which is the sole therapeutic target for glaucoma treatment. Therefore, accurate measurements of aqueous humour (AH) dynamics are critical for the development of improved treatments to inhibit progression of sight loss in glaucoma patients.

AH is actively pumped from the ciliary processes into the space behind the iris, then flows through the pupil into the anterior chamber (AC). From there, AH drains across specialized ‘outflow tissues’ with a hydrodynamic resistance, thereby generating the IOP. An increase in the resistance, or equivalently a decrease in the conductance, C (known as outflow facility), is responsible for the IOP elevation in glaucoma.

Due to the financial and ethical difficulties associated with human or non-human primate models, the mouse model is a key tool for glaucoma research. Optimized experimental methods for perfusion of *ex vivo* enucleated eyes to accurately measure C are well established [1]. However, detailed methods for *in vivo* measurements vary widely, and reported values of C *in vivo* vary across a wide range. As an example, two studies that both used the same perfusion method and C57BL/6J mice reported 5.8 [4.7, 7.0] nl/min/mmHg [3] and 19.5 [17.4, 21.6] nl/min/mmHg [4], a difference more than 300%, which is way beyond what would be expected due to random sampling or small differences. There is thus an urgent need for a precise and repeatable method to measure C in mice *in vivo*.

We posit that a major source of variation is the time-dependent changes to aqueous humour dynamics that occur under anaesthesia. Here, we propose a new approach to address this issue and carry out a series of experiments to evaluate how it affects the measurement precision. In order to evaluate repeatability, we compare values measured by two different researchers in two different institutions.

METHODS

The intraocular pressure is determined by a mass balance on AH known as the Goldmann equation, which can be written in the form

$$S\{t\} = \frac{Q_{in}\{t\} - Q_u\{t\}}{C\{t\}} + P_{ev}\{t\} \quad (1)$$

where the braces indicate potential dependence on time due to the effects of anaesthesia. $S\{t\}$ represents the spontaneous intraocular pressure, $Q_{in}\{t\}$ is (AH) inflow, $Q_u\{t\}$ pressure-independent outflow, $P_{ev}\{t\}$ is episcleral venous pressure and $C\{t\}$ is outflow facility. It is assumed that Q_{in} , Q_u and C do not to change with pressure, $S\{t\}$.

In a perfusion, the AC is cannulated and an additional flow rate $Q\{t\}$ is introduced to the anterior chamber, which in turn changes the pressure from $S\{t\}$ to $P\{t\}$, hence

$$P\{t\} = \frac{Q\{t\} + Q_{in}\{t\} - Q_u\{t\}}{C\{t\}} + P_{ev}\{t\} \quad (2)$$

Subtracting Equation (1) from Equation (2) and rearranging yields

$$Q\{t\} = C\{t\}(P\{t\} - S\{t\}) \quad (3)$$

The term $S\{t\}$ can be interpreted as the IOP that would exist in the same animal under anaesthesia in the absence of perfusion. Although $S\{t\}$ cannot be directly measured, it can be accurately inferred via repeated measurements of $Q\{t\}$ at a single pressure S_0 , interlaced between measurements at different $P\{t\}$ values. $C\{t\}$ can be estimated at each time point or by regression under the assumptions that $C \neq f\{t\}$. This approach ‘corrects’ the estimated pressure-drop driving outflow by accounting for time-dependent changes. Our ‘Corrected method’ compares to the ‘Typical method’, which implicitly treats $S\{t\}$ as constant.

We carried out multiple studies with humidity controlled iPerfusion systems [2], and isoflurane anaesthetized C57BL/6J mice. For the purpose of comparison, we consider a fold increase in Precision of the Corrected Method based on the 95% margin of error (ME) for relevant parameters:

$$\text{Precision Increase} = \frac{\text{Typical method ME}}{\text{Corrected method ME}} \quad (4)$$

Statistics were carried out using the log-transform of C which has previously demonstrated to be appropriate [1]. Results are converted back into the linear domain and reported as mean [95% confidence interval].

RESULTS

We first considered both methods with data from N=16 independent eyes perfused by MM at Imperial College, to evaluate the effect on Precision. The average facility was 6.9 [5.9, 8.1] nl/min/mmHg with the Typical method vs 5.9 [5.4, 6.6] nl/min/mmHg with the Corrected method, a 1.8-fold increase in Precision (Eq. 4).

We then compared the measured C in contralateral eyes of N=9 different mice, which has been shown in *ex vivo* models to be similar. For the Typical method, we found a percent difference between the two eyes of 7 [-19,41]%, compared to 0 [-12, 15]% for the Corrected method (Figure 1). This corresponds to a 2.2-fold increase in Precision.

Figure 1: Cello plots [1] comparing the relative difference in C between untreated contralateral eyes for the Typical and Corrected approaches. Each data point represents an animal and error bars indicate 95% confidence intervals. The distributions show the estimated log-normal distribution, with the wide central line indicating the geometric mean. The dark band indicates the 95% confidence interval on the mean and the thin white lines indicate the range covered by the mean $\pm 2SD$.

To further evaluate the value of the approach, we then measured the effect of Netarsudil, a compound known to increase outflow facility. We treated one eye of N=9 mice with Netarsudil solution, with the untreated contralateral perfused with acting as a control. The Typical method predicted an increase of 61 [-4,172]% which is only borderline statistically different from zero at a significance level of 0.05 ($p=0.07$, paired t -test). By contrast, the Corrected method predicted an increase of 36 [13,64]% ($p=0.005$, paired t -test). This significant improvement corresponds to a 3.5-fold increase in Precision (Figure 2).

Figure 2: Cello plots [1] comparing the relative difference in C between Netarsudil and untreated contralateral eyes for the Typical and Corrected approaches. See Figure 1 for a description of the statistics visualized.

Finally, to demonstrate repeatability, the average facility in N=16 independent eyes was measured on different perfusion systems at Columbia University by NT. Using the Corrected method, we found an average C of 5.9 [4.6,7.5] nl/min/mmHg (compared to 5.9 [5.4, 6.6] nl/min/mmHg from MM at Imperial).

DISCUSSION

We described and demonstrated a new ‘Corrected’ method for improved measurements of *in vivo* outflow facility in mice. Across a range of experiments, we found that for the same experimental data, the proposed method increased precision by ~2 fold or more, effectively halving the uncertainty on the measurements. For a given sample size, this would provide more confidence on results, or equivalently would allow fewer animals to be used to achieve the same statistical power.

We carried out similar measurements on the same mouse strain at two institutions in order to identify if the measured values were repeatable, which was the case. This adds further confidence to the value of the method.

In addition to this improved analysis method, our measurements used a humidity chamber to inhibit evaporation from the eye, which has been demonstrated to be a source of over-estimation of facility in *in situ* postmortem perfusions [2].

Finally, it is interesting to note that the current values of facility are similar to, but marginally higher than those found in the same strain using *ex vivo* and postmortem perfusions (4.3 nl/min/mmHg & ~4.2 nl/min/mmHg respectively [2]).

In conclusion, our new method seems to effectively account for time-dependent changes in AH dynamics, thereby increasing the precision of *in vivo* measurements of C in mice.

INTRODUCTION

Collagen hydrogels have been used for many applications from tissue engineering to cell culture. The robustness of the collagen protein as well as the diversity of uses within tissues allows for many applications within cell culture. Hyaluronic acid (HA) is another common glycosaminoglycan that resides within many tissues. Current hydrogel cell cultures commonly use collagen as the base protein, and some studies have been conducted showing the stability of Col-HA gels at varying HA concentrations [2]. Increasing HA concentration has been found to lower gel stability, but little work has been done to show how varying HA molecular weight (MW) affects the gel mechanical properties, such as storage modulus (G') and loss modulus (G'') [3]. Many cells, such as macrophage cells, respond to changes within the mechanical environment of their ECM by their adhesion proteins, such as adherons or integrins [4]. Thus, studies involving the characterization of cell behavior in 3D gel matrices must consider the gel culture's physical stiffness and stability and how it will affect the cells. Macrophage cells specifically have been demonstrated to exhibit differing phenotypes, generally called M1 and M2 activation. These activations correspond with inflammatory and anti-inflammatory responses respectively. Previous work has shown that HA MW within the extracellular matrix (ECM) can influence the phenotyping of the macrophage cells, however, in this work, the effect of HA MW on the *mechanical* properties of the hydrogel was not considered [5]. Gel stiffness is a key variable for cell culture as macrophages have been seen to adjust behavior through means of mechanotransduction between the macrophage integrins and the ECM [4]. The goal of this work is to characterize the effects of collagen concentration and HA MW on the mechanical properties of the hydrogel, with eventual application on macrophage activation and behavior in this 3D cell culture. The creation of this gel will also lend itself to the future study of macrophage interaction with pathogenic bacteria, such as *Borrelia Burgdorferi*.

METHODS

Collagen-Hyaluronic Acid Gel Synthesis

To form the various samples needed for the characterization, PureCol® type I bovine collagen (Advanced Biomatrix, Carlsbad, CA) dissolved in acid at a concentration of 3 mg/mL was added to six individual sample wells in a 12-sample well plate. To get the desired final concentrations of 1.8 mg/mL, 2.1 mg/mL, and 2.4 mg/mL, the following volumes in Table 1 were used. Once all necessary portions were added, the gels were stirred and allowed to gel in an incubator at 37°C for 35 minutes until completely gelled for a total sample volume of approximately 2 mL per gel.

Table 1: The volumes volume and mass of the components used for the formation of pure collagen and Col-HA gels

Component:	1.8 mg/mL	2.1 mg/mL	2.4 mg/mL	2.1 mg/mL-20k	2.1 mg/mL-500k	2.1 mg/mL-15M
Collagen (μL)	1200	1400	1600	1400	1400	1400
10x PBS (μL)	450	250	100	250	250	250
MEM (μL)	150	150	150	150	150	150
0.1M NaOH (μL)	170	200	230	200	200	200
NaHy (mg)	-	-	-	4.2	4.2	4.2

For the Col-HA co-gels, a similar process was used at a constant collagen concentration of 2.1 mg/mL. Sodium hyaluronate (NaHy) (Lifecore Biomedical LLC, Chaska, MN) at molecular weights of 20 kDa, 500 kDa, and 15,000 kDa was added to each sample. The total solution was mixed in centrifuge tubes and pipetted into six individual samples in the well plates for each MW. These samples were allowed to gel in the same conditions as previously described.

Rheological Characterization

The gel properties were measured on the Anton Paar MCR 72 rheometer (Anton Paar GmbH, Graz, AT) using a 25 mm parallel plate. Both measuring surfaces had fine-grit sandpaper adhered to them to reduce any possibility of slippage, as demonstrated in previous studies [5]. The rheometer was calibrated with the sandpaper to eliminate any

introduced error. An amplitude sweep from 0.1 to 100% strain was conducted on several test samples to determine the linear viscoelastic range (LVE). Once this was determined, the samples were measured by a frequency sweep at 1% strain, ranging from 0.5 rad/s to 10 rad/s, which was in the LVE and was demonstrated in other collagen gel rheology work [6]. The resulting G' and G'' graphs were analyzed to find the mean values for both properties. The resulting values were analyzed by ANOVA and Tukey-HSD t-test for statistical significance as well as linear regression to determine if a linear trend was present.

RESULTS

Figure 1: A representative chart with the resulting G' and G'' plots for all six replicates of the 1.8 mg/mL collagen sample.

Figure 1 shows an example of the data collected from a single hydrogel sample using the frequency sweep from 0.5 rad/s to 10 rad/s on the rheometer. Given that G' is greater than G'' for the gel, it can be classified as a viscoelastic solid, which is expected given the polymerization of the collagen within the system.

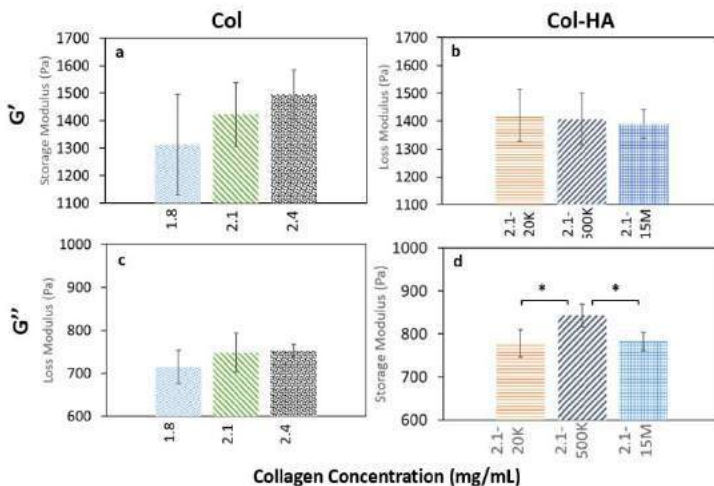

Figure 2: (a) The mean G' values for the 3 collagen concentrations. (b) The mean G' values for the Col-HA co-gels concentrations. (c) The mean G'' values for the 3 collagen concentrations. (d) The mean G'' for the Col-HA co-gels. (n=6 for each group, error bars represent 1 standard deviation). * represents statistical significance with $p < 0.05$ using the Tukey-HSD test.

Figure 2(a) displays the mean values that were determined from the frequency sweep for the storage moduli. While an increasing trend in G' was observed with increasing collagen concentration, no statistically significant differences were found using ANOVA and the Tukey-HSD t-test. Linear regression of the results at different concentrations yielded

an R^2 value of 0.985. This result offers the potential of a linear relationship between collagen concentration and G' . From Figure 2(b), no significant differences were found correlating the MW of HA with storage modulus, although a slight downward trend is observed and had an R^2 of 0.83.

Both the loss modulus results pictured in figure 2(c) and figure 2(d) were much lower in magnitude than the storage moduli. No significant change was found from the t-tests for the collagen concentration samples. For the Col-HA samples, the large spike in G'' for the 500 kDa sample resulted in statistically significant differences when compared to both the 20 kDa and 15,000 kDa samples, with p-values of 0.004 and 0.005 respectively. The large spike in G'' at 500k MW is unexpected and can be further studied.

DISCUSSION

The linear trend with G' increasing is expected as there will be more collagen within the system to polymerize into a stiffer gel. As the collagen polymerizes at 37°C, the greater concentration allows for more available molecules to be added to the actively growing chain. The effects of collagen concentration on the final MW of the collagen itself is unknown; however, it is expected that higher MW of both HA and Col within the gel should increase both G' and G'' . Previous work has shown that in a polymer matrix, increasing MW of the system aids in the construction of a denser polymer network, which will increase G' [7]. However, for the purposes of our Col-HA gel network, it acts more as a bimodal or polydisperse MW distribution, so direct changes in the MW of one of the components will have less direct effect. Any high MW chains that are dissolved in the liquid portion of the hydrogel will also act as a thickener for the system, increasing the G'' and viscosity.

For the purposes of the cell culture gels, relatively low concentrations of the biopolymer matrix are needed. Once cell culture in these gels begins and the cell behavior is studied, the desired gel G' can be fine-tuned using this linear correlation. As the initial data shows, the increase in HA molecular weight does not greatly affect the G' of the system, although it did have an impact on the loss modulus. In the findings here, there is no statistically significant difference between G' at the varying MWs, however, there is a slight decrease overall as MW increases. The initial interpretation is that the collagen network provides the solid structure and is thus less affected by changes in the MW of the HA. The HA is likely contained in the liquid portion of the gel since it does not polymerize itself unless crosslinked. Thus, it will increase the viscosity of the liquid and raise G'' . Why this trend does not correspond with the 15,000 kDa sample warrants further study. As the MW of the HA does not give an observed change in the G' this offers more confidence in future studies of macrophage activation within the gels. Any changes within the macrophage phenotyping would likely not be due to gel stiffness changes and more reasonably could be associated with the HA MW.

PRE-OPERATIVE FUNCTIONAL CHARACTERIZATION OF AORTIC NECK IN ABDOMINAL AORTIC ANEURYSMS AND ITS ASSOCIATION WITH TYPE I ENDOLEAK FOLLOWING EVAR PROCEDURE

INTRODUCTION

Endovascular aneurysm repair (EVAR) has become the primary procedure for the management of abdominal aortic aneurysms (AAA). While less invasive when compared to an open repair, EVAR procedures are associated with negative outcomes and complications that may lead to re-intervention or death [1,2]. Endoleaks are common complications of EVAR procedure. Type I endoleaks occur when a proper sealing between the stent and the artery is not achieved at the aneurysm neck (type Ia) or at the iliac arteries (type Ib) and have been linked to negative clinical outcomes. The pre-operative characterization of AAAs from CT images has been the focus of many studies aimed at predicting the presence of type I endoleaks and poor outcomes [3,4]. These studies mainly looked at the assessment of morphological features of the aneurysm neck to define risk factors associated with post EVAR type I endoleaks. Diameter, length, angulation and conicity are examples of morphological features of the neck that have been extensively investigated and associated with the development of type Ia endoleaks. Anatomical neck features that represent guidelines listed in the recommended instructions for use (IFU) of stent manufacturers are part of current clinical practice. These anatomical features, however, ignore the characterization of the aortic tissue and its suitability for a successful sealing. For this reason, many EVAR procedures still result in negative outcomes despite being performed under IFU, with studies reporting conflicting results when looking at the effect of adherence to IFU on overall negative outcome and mortality [5-7], clearly highlighting the shortcomings of a purely anatomical evaluation.

In the context of AAAs, aortic hemodynamics and aortic wall deformability are known to have an important role in understanding the progression of arterial disease as well as providing an insight into regions of structural weakening in the aorta [8-11].

This retrospective study proposes a non-invasive functional characterization of the aortic neck tissue from pre-operative ECG-gated multiphase CT images by means of a combined in-vivo strain and

hemodynamic analysis and explores the association between the functional characterization and the post-EVAR outcomes for a population of AAAs.

METHODS

The study focused on population of sixteen AAA patients (n=16) enrolled to participate in a CHREB-approved protocol consisting of pre-operative multiphase CT imaging, post-operative follow-up imaging as well as follow up imaging at 12 months or more.

The aortic wall and lumen were segmented and reconstructed from CT images. In-vivo strain analysis was performed with the in-house ViTAATM software by means of a surface mesh of the aortic wall used as 3-D feature-tracking model to measure nodal displacements on successive images throughout the cardiac cycle. The in-vivo strain was obtained from the nodal displacements, therefore no assumption on constitutive model was needed [9,12].

Computational Fluid Dynamic (CFD) simulations were performed on patient-specific geometries of the aortic lumen to obtain a hemodynamic assessment in terms of Time Averaged Wall Shear Stress (TAWSS).

Finally, the presence and amount of intraluminal thrombus (ILT) for each patient was determined by measuring the ILT thickness as the distance between the aortic wall and lumen geometries.

The aortic neck was isolated by defining a region 15 mm below the lower renal artery along iso-length chords defined on the wall surface (*Figure 1*). The functional characterization of the aortic neck was achieved by combining the three obtained variables into one surrogate index of Regional Aortic Weakness (RAW) designed to simultaneously capture areas of disturbed blood flow (low TAWSS), elevated strain and thick ILT [11,13].

Statistical analysis was performed by using a two-sample t-test to investigate associations between neck properties and post-operative outcome (significance for p-value < 0.05).

RESULTS

The AAA study population ($n = 16$, age 72 ± 6 years, 93.75% males) had a mean maximum aortic diameter of 51.6 ± 9.3 mm.

Two patients in the study (12.5%) developed type I endoleak shortly after EVAR procedure as assessed during post-operative imaging, with one patient needing immediate endoleak treatment. The anatomy of the aortic neck was assessed pre-operatively in terms of neck conicity (expressed as difference between the distal diameter and the proximal diameter of the neck), angulation and diameter. The patients who developed a type I endoleak presented significantly higher conicity when compared to the patients that did not develop a type I endoleak (18.22 ± 8.99 mm versus 1.68 ± 2.52 mm, $p = 0.001$), while both neck diameter and angulation did not show significant difference for the two groups (26.74 ± 1.22 mm versus 24.23 ± 2.82 mm, $29.62 \pm 7.37^\circ$ versus $29.23 \pm 11.50^\circ$).

From the pre-operative functional characterization of the aortic neck, the patients who developed a type I endoleak presented significantly higher median RAW index at the neck region when compared to the other cases (4.83 ± 0.16 versus 4.15 ± 0.69 , $p = 0.01$).

During post-operative follow-up imaging the presence of early type II endoleaks was also reported for six patients (37.5%). The early type II endoleaks eventually resolved resulting in no additional treatment and aneurysmal sac reduction. Interestingly this sub-group presented a neck region with significantly higher median TAWSS (1.01 ± 0.36 versus 0.71 ± 0.16 , $p = 0.05$) and lower median RAW index (2.84 ± 0.69 versus 4.00 ± 0.42 , $p = 0.004$) when compared to the group of patients that did not develop an early type II endoleak.

Figure 1: example of two AAA geometries in the study population showing the aortic wall (transparent), aortic lumen and renal arteries. The isolated aneurysm neck is also shown with the distribution for the RAW index for a case of high RAW (right) and a case of low RAW (left).

DISCUSSION

The present study proposes a combined CFD and in-vivo strain analysis approach to achieve the functional characterization of the aortic neck for a population of AAA patients selected to receive EVAR. Despite the procedure being performed following IFU, a type I endoleak was found in two patients during post-operative follow-up imaging. While the conicity of the aortic neck was significantly higher for the

two mentioned cases, it was within threshold according to IFU. Additional anatomical analysis of the aortic neck did not show significant differences for the two analyzed groups (i.e. presence versus absence of type I endoleak). However, after performing the functional characterization of the aortic neck using the RAW index, significant differences were found between the two groups. Patients developing type I endoleak showed higher RAW index at the neck region as indicative of a weaker aortic tissue unlikely to provide a suitable landing zone to achieve correct sealing (Figure 1).

Six patients in the study population showed evidence of early type II endoleak during post-operative imaging. Type II endoleaks may be due to the retrograde flow from collateral aortic branches. Interestingly, the group of patients who developed an early type II endoleak presented lower RAW index and higher TAWSS at the neck region. This finding suggests that a good neck region characterized by unaltered flow conditions could provide an ideal sealing therefore resulting in a reduced pressure in the aneurysm that drives the retrograde flow from collateral branches. For the cases under analysis the early type II endoleak eventually resolved without the need for re-intervention and sac reduction was achieved, supporting the idea that endoseal had been achieved. This association between excellent landing zone seal related to high tissue strength and Type II endoleak has not been previously reported.

Despite being limited to a small patient cohort, the functional assessment of the aneurysm neck provided a useful insight into post-operative complications for patients who received EVAR procedure under IFU. Present results show the potential of the proposed approach to support clinical decisions and improve the management of AAAs.

SENSITIVITY OF FINITE ELEMENT MODELS TO RELATIONSHIP BETWEEN T₂ RELAXATION AND MODULUS IN ARTICULAR CARTILAGE

Alexander A. Donabedian (1), Deva D. Chan (1)

(1) Weldon School of Biomedical Engineering, Purdue University, West Lafayette, Indiana, United States

INTRODUCTION

Osteoarthritis (OA) is one of the leading causes of disability in later adult life and consumes 1-2.5% of the gross national product in the USA¹. Degeneration of cartilage in the knee is a hallmark sign of OA and its progression varies greatly between patients. Although finite element (FE) modeling can be tailored to individual patients, critical barriers still hinder FE-based, specific-patient care for the highly heterogeneous disease.

Previous FE models identify regions of high strain or failure within tissue to predict potential areas at risk for degeneration and OA progression.² However, because the mechanical characterization of cartilage and other joint tissues is not often performed within those specific patients, material properties found in the literature are implemented for these tissues. Although several noninvasive techniques exist to characterize tissue ultrastructure, constitutive models used in FE analysis are often simplified due to the complex and heterogeneous material properties of tissues, potentially affecting the predictive ability of patient-specific models.

Recently, we proposed using quantitative magnetic resonance imaging (MRI) to implement elastic heterogeneity in an FE model of articular cartilage using data from the Osteoarthritis Initiative (OAI).³ A linear correlation between T₂ relaxation times and elasticity was found by Nissi et al.⁴ Based on this relationship, our T₂-refined FE model estimated a higher maximum first principal stress and shear strain where high T₂ values were located compared to a model with homogeneous material properties. The regional MRI Osteoarthritis Knee Score (MOAKS) of each patient, dependent on the size of cartilage loss, showed a significant correlation to the number of elements exceeding a threshold of 0.5MPa.

Although we found that a T₂-refined FE model held promise for prediction of regions of future cartilage degeneration, the linear correlation between T₂ relaxation times and material properties is based on a single study with limited human data. Additionally, the correlation

developed by Nissi et al, may not hold for patients outside their study. Therefore, the objective of this work is to determine the degree to which our T₂-refined FE models are sensitive to the assumed relationship between T₂ relaxation times and modulus in articular cartilage.

METHODS

Models of articular cartilage were created using publicly available data from the OAI.³ Three subjects, one classified as having minimal OA (Kellgren-Lawrence (KL) grade = 2) whereas the others showed no sign of OA (KL = 0), were used. Segmented images from the OAI were used to define subject-specific cartilage and menisci regions of interest, which were meshed into hexahedral elements, as in a previous study.⁵

Material properties were assigned to each element using a voxel-to-element mapping based on the T₂ map of each subject.³ T₂ relaxation times negatively correlate to the elastic properties of human tissue and the linear relationship is defined in Eq. (1).⁴ This correlation determined the elastic values in each element within the model. An expected dynamic modulus and span of T₂ relaxation times in human cartilage were used as the inputs to the simulation. A baseline simulation of each subject implemented a dynamic modulus of 1-8 MPa and T₂ relaxation times of 15-75 ms.³

$$E_D = \left(\frac{-3.5}{3} \times 10^5 \right) T_2 + 9.75 \times 10^6 \quad (1)$$

Average motion and loading from a walking gait cycle were applied to the model and the estimated measures of stress and strain were evaluated using FE analysis from FEBio Studio version 2.0.

The sensitivity between the inputs and predicted outputs was analyzed by incrementally changing the maximum and minimum elastic values in the model until a 10% variation from the baseline parameters was reached. These adjustments were first manipulated to change the slope relationship between T₂ relaxation times and the dynamic modulus. Then, the dynamic modulus was shifted while maintaining the

same slope correlation to T_2 values. The maximum first principal stress and shear strain were recorded in each simulation and plotted against its deviation from the baseline predicted outputs.

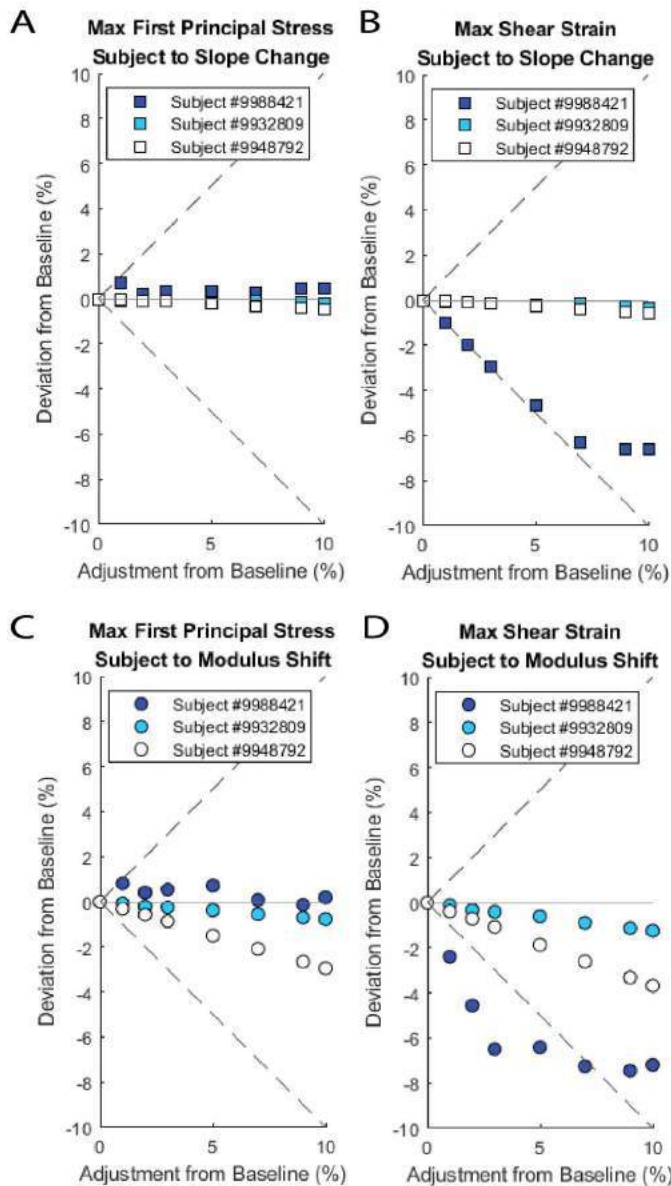

Figure 1: Percent changes in maximum first principal stress and shear strain due to a slope change (A, B) and dynamic modulus shift (C, D)

RESULTS

T_2 relaxation times were used to create elastically heterogeneous, subject-specific models of the knee. The model's sensitivity to changes in the T_2 to modulus relationship was evaluated by altering the slope and intercept from 0 to 10% of the previously published correlation.³ Deviations in the predicted maximum shear strain and first principal stress from the baseline study are shown in Figure 1. A dashed line is presented to visualize a one-to-one ratio between a change in parameters to the model outputs. The estimated maximum first principal stress does not show a sensitivity to a change between the input relationships. All subjects showed a less than $\pm 1\%$ deviation from the baseline outputs

due to a slope change between T_2 values and the dynamic modulus. Similarly, all subjects showed a less than $\pm 3\%$ change in max first principal stress due to a dynamic modulus shift.

The predicted maximum shear strain in each parametric adjustment shows a larger variability. The maximum shear strain differs by less than -1% in two subjects due to the slope relationship change; however, the third subject shows a one-to-one correlation until a -7% deviation is reached. This subject also shows up to a -8% difference from the baseline simulation due to a dynamic modulus shift whereas the others show a linear correlation with varying magnitudes.

DISCUSSION

In this study, a sensitivity analysis was performed on T_2 -refined FE models of articular cartilage. The maximum first principal stress and shear strains were recorded due to incremental parametric adjustments from a baseline simulation. The maximum first principal stress in each test did not deviate far from the initial simulation since the applied load stayed consistent between tests. The elastic values substituted into the constitutive equations resulted in larger changes in max shear strains across the subjects with varying degrees in magnitude. This work informs us that the estimated results are impacted by various aspects of the model in addition to the input relationships.

For the three subjects, a FE model of articular cartilage was created with customized geometry and material properties. Nodes were fixed on the proximal and distal surfaces of the femoral and tibial cartilage respectively to best emulate biological boundary conditions. A rigid body was applied to simulate loads experienced during an average walking cycle as well as constraints to mimic a walking motion. To our knowledge, a method to uniformly constrain articular cartilage models across different subjects does not exist. Therefore, the initial position of the rigid body was manually placed which enabled the model to converge to a solution. Consequently, the initial position of each subject-specific model varied slightly. This manual positioning alongside differing geometries could have induced differences in the model's sensitivity across the patients.

The range of elastic parameters that enabled the simulation to run to completion limited our study. Reducing the dynamic modulus below 1MPa and implementing the large loads experienced while walking produced deformations that were not feasible to estimate in a reasonable amount of time.

In future studies, we may develop a new method to constrain our model that is consistent across any type of geometry. Further research also aims to define a subject-specific relationship between T_2 relaxation times and material properties as well as other quantitative MRI techniques such as diffusion tensor imaging. Work pairing MRI with cartilage morphology enables more advanced subject-specific FE models aimed to accurately represent cartilage degeneration.

MULTISCALE SIMULATIONS SHOW ROLE OF DIFFUSE DAMAGE IN ANOMALOUS FIBER REALIGNMENT

INTRODUCTION

Neck and back pain impacts 30-50% percent of the population in their lifetime and costs an estimated 30 billion dollars per year [1]. One source of this pain is the highly innervated Facet Capsular Ligament (FCL). The FCL is primarily made from type I Collagen, and reorientation of the collagen fibers has been linked to neuron activation i.e., pain. Collagen fiber alignment varies by spinal region with patches of aligned fibers in the cervical region [2].

Experiments have shown that under some loading conditions, fibers in one region of the ligament rapidly reorient away from the mean fiber orientations in a process called Anomalous Realignment (AR). These AR events have been shown to coincide with the initiation points of observable macroscale rupture. Although significant efforts have gone into the detection and measurement of AR in rat and human FCLs, the micromechanical cause of AR remains unknown [3, 4].

This work explores three hypotheses for the cause of AR in the FCL. Namely, AR is caused by 1) material inhomogeneity caused by the aligned collagen patches in the cervical FCL, 2) localized material instabilities, 3) diffuse damage. We employ a concurrent multiscale method that affords monitoring the fiber micromechanics while constructing tissue scale models directly from biological imaging data.

METHODS

Multiscale Finite Element Method. We will briefly outline the concurrent multiscale procedure that we use and has been implemented in MuMFiM (www.github.com/SCOREC/mumfim). For a complete treatment we refer the reader to [5]. Our two-scale method is based on the FE2 method originally developed by Feyel and others for modeling composite materials.

On the macroscale we seek to solve the static equilibrium equation using an updated-Lagrangian finite element method. This requires a constitutive response function for the Cauchy stress and 4th-order tangent material stiffness tensor. Rather than providing an analytical response function, the constitutive response is computed from a second finite element solution of a representative volume element (RVE) made up from discrete fibers. This

decomposition is shown in figure 1. RVEs must be large enough to have behavior of the continuum scale. A guideline for RVE sizes for 3D fiber networks is provided in [6]. This coupling methodology requires there is a strong scale separation meaning that the physical size of the RVE must be at least an order of magnitude smaller than the size of the macroscale mesh elements.

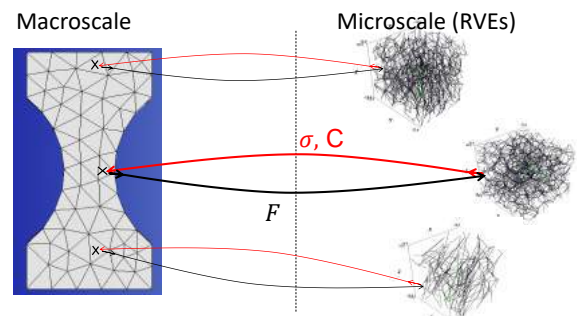

Figure 1: Graphical representation of hierarchical coupling methodology. The black lines represent the transfer of the deformation gradient F to the microscale RVEs. Red lines represent the transfer of the Cauchy stress and tangent material stiffness to the macroscale. This coupling occurs at every macroscale integration point.

Network Generation. To generate the networks, a Delaunay triangulation is created from seed points which are distributed in a uniform random distribution in a domain with an edge length L_g . Fibers are modeled by truss elements placed along the edges of the Delaunay triangulation. For the aligned cases, an isochoric affine deformation is applied (rotations and deformations). Any fibers with a length, l_f , which is less than $1/100$ of the mean segment length, l_c , are removed by merging the two fiber end nodes into a single node that is placed at the mean nodal location weighted by the connectivity. The resulting network is trimmed to a final size with edge lengths L .

For these networks density is quantified as the total fiber length per

volume $\rho = l_{\text{tot}}/V$. This is related to the volume fraction as $\phi = \rho A_f$. Fiber properties and volume fraction follow [7] are selected such that the macroscale stress/strain curve matches a 2mg/mL collagen.

To quantify the level of alignment in the loading direction, the second Legendre polynomial, $P_2 = \frac{1}{2} \langle 3\cos^2(\theta) - 1 \rangle$ is used. This yields a measure that ranges from $-1/2$ for all fibers oriented orthogonal to the loading direction to 1 where all fibers are perfectly aligned in the loading direction.

To promote instabilities, we also produce a diluted network. Construction of diluted networks proceeds similarly to the base networks, however fibers are randomly selected for deletion until the desired mean fiber connectivity is obtained. To aid in the numerical solution of these unstable networks, we do not delete any fibers that have nodes that have a connectivity which is less than or equal to a threshold. In this paper, we use a threshold connectivity of 6 and a mean connectivity of 7.5. The initial number of seed points is varied to ensure that the density remains constant between the dilute and undilute cases.

Diffuse Damage. Based on the load-displacement curves of Rat FCLs we expect that the initial ligament damage is primarily of the diffuse type. To model diffuse damage, we reduce the fiber stiffness to 10% of the original stiffness when the homogenized RVE stress surpasses a threshold value. In this paper, the threshold stress is chosen such that damage starts to develop at $\sim 10\%$ strain. We expect this value is artificially low, however it provides a reasonable trade off for computational cost in these exploratory models.

Macroscale Model. The macroscale model is constructed using the geometry of the cervical FCL sample reported in [2]. The finite element discretization has 63,821 linear tetrahedron elements. At each integration point of the macroscale mesh, a network orientation is selected based on an orientation field. The orientation field is constructed from a Gaussian random field with a correlation length of 0.35 mm as reported in [2]. To obtain a set of orientations that is uniformly distributed along the unit circle, we use inverse transform sampling to obtain a uniform distribution and map the result to angles between 0 and 2π . The orientation field is constant through the ligament thickness which is small and roughly approximates the plane stress condition.

To match the bone attachment, of the FCL, the left and right surfaces shown in figure 2 are fixed and displacement boundary conditions are applied in the loading direction. The top and bottom surfaces have traction free boundary conditions.

Anomalous Realignment. Anomalous realignment is detected using the vector correlation method and thresholds defined in [3]. This method is designed to work on 2D image data. To obtain an “image” from our model that is comparable to the experimental data, we first take a slice of the top surface of the model and use the “ResampleToImage” filter in Paraview with 100 by 100 pixels which provides approximately one pixel per mesh element.

RESULTS

Table 1 summarizes each test condition which corresponds to our original hypotheses for the cause of anomalous realignment. Here we see that AR is detected when diffuse damage is present. However, it is not detected when there is both diffuse damage and patches of oriented fibers.

Table 1: Summary detection of anomalous realignment with various test cases.

network with patches of aligned collagen (H1)	network with reduced connectivity (H2)	network with failure (H3)	AR
X			N
	X		N
		X	Y
	X	X	Y
X		X	N

The white lines in figure 2 enclose the domains where AR is detected for a model with diffuse damage undergoing $\sim 13\%$. These lines are superimposed onto P_2 field of the ligament at the same strain, plotted on the undeformed configuration. The regions of detected AR correspond to a localization band where fibers are more aligned in the loading direction than in the surrounding material.

Figure 2: Plot of the P_2 field for a FCL undergoing $\sim 13\%$ strain with diffuse damage. The white lines enclose the regions where AR was detected.

DISCUSSION

This work applies a novel computational approach to understanding the micromechanical causes of AR in the FCL. We see that material inhomogeneity in the form of aligned patches of collagen fibers, and increased microstructural instabilities produced from diluted networks do not allow AR to develop in the FCL. However, when diffuse damage is included in the model AR is detected at similar levels to those observed in experiments. This matches well with experimental observation that AR location is predictive of the locations of visible ligament rupture.

Most interestingly, we also see that when our model contains both patches of aligned collagen fibers and diffuse damage, we no longer see AR develop at the levels of strains that were analyzed. We suspect that the inhomogeneity is delaying the onset of AR and we are continuing to investigate this phenomenon.

When AR does develop, we see that the location visibly correlates to a localization band in the P_2 field where the fibers become more strongly aligned in the loading direction. This is the result of diffuse damage causing a softer region in the material where fibers must reorient into the loading direction to carry the applied load.

INTRODUCTION

Osteoarthritis (OA) is a disease in which there is an irreversible loss of articular cartilage that affects approximately 240 million people worldwide [1]. The TGF- β 1 inhibitor, losartan, can improve cartilage repair by promoting hyaline rather than fibrous cartilage tissue regeneration [2]. However, there are concerns about side effects associated with oral administration and short retention within the joint following intra-articular injections. To facilitate local and sustained intra-articular losartan delivery, we modified the peptide composition of our previously published PA nanofibers [3] to achieve an injectable nanofiber formulation that can bind and slowly release losartan. The aims of this study are to characterize the release kinetics of losartan from two different PA nanofiber compositions followed by testing pro-regenerative bioactivity on chondrocytes. We hypothesize that the PA nanofiber chemistry can be modified to achieve sustained release of losartan over a two-week period and promote chondrocyte proliferation and chondrogenesis *in vitro*.

METHODS

A total of eight nanofiber formulations were prepared by combining four different losartan potassium doses (0, 0.5, 5, and 50 mg/mL) and two PA molecules with opposite charge. First, we tested the impact of electrostatic interactions on nanostructure morphology and release kinetics of the negatively charged losartan molecule from either a positively (K) or negatively (E) charged PA nanofiber over the time course of 2 weeks.

Subsequently, the various losartan nanofibers were co-cultured in 0.4- μ m semipermeable transwell over the ATDC5 chondrocyte cell line in a 24-well plate. Total of 12 groups were divided by losartan dose (0, 0.5, 5, and 50 mg/mL) and presence/absence of positively charged K or negatively charged E nanofibers. Cell proliferation was evaluated longitudinally at 24 hours, 5 days, and 14 days after losartan nanofiber

treatment using the non-destructive PrestoBlue assay. To access the regenerative potential of these nanofibers in an OA pathology, ATDC5 chondrocytes were primed with interleukin (IL) -1 β (10 ng/ml) for 24 hours [4]. The glycosaminoglycans (GAG) assay was used to evaluate proteoglycan production following treatment with the nanofibers. Gene expressions of chondrocyte-related markers (*Il6*, *Mmp13*, *collagen X*, *collagen II*, *aggrecan (acan)*, and *Tgf- β 1*) were evaluated 14 days after treatment using quantitative real-time PCR.

All plots and statistical comparisons were made using GraphPad Prism version 9.4.0 (GraphPad Software, La Jolla, CA, USA) with statistical significance again set at $p < 0.05$.

RESULTS

In TEM imaging, we observed similar fiber length distributions (~200-2000 nm) for K-PA and E-PA nanofibers both with and without losartan (**Figure 1A-D**). Both nanofibers offered a sustained release profile but that negatively charged E-PA nanofibers released losartan at approximately twice as fast as the positively charged K-PA nanofibers (**Figure 1E**).

Figure 1: Structure and release profile of losartan sustained release nanofibers.

No cytotoxicity was observed in any of the treatment groups (**Figure 2**). We found that both positively and negatively charged PA nanofibers significantly increased cell numbers at all time points compared to no nanofibers at each losartan dose.

Figure 2: Nanofibers promote cell proliferation in a losartan-independent fashion.

We first confirmed that, in our hands, 24 hours of IL-1 β (10 ng/mL) leads to reduced GAG production (**Figure 3A**). Subsequently, significant increase in GAG production was observed with the positively charged K-PA nanofibers alone or when dosed with low (0.5 mg/mL) or moderate (5 mg/mL) losartan compared to controls without losartan or nanofibers (**Figure 3B**).

Figure 3: Positively charged nanofibers with low doses of losartan promote GAG production.

The positively charged K-PA nanofibers themselves significantly suppressed *il6* expression, and this stayed low, but not significantly different with the addition of losartan (**Figure 4A**). Conversely, K-PA nanofibers did not significantly change *mmp13* expression, but increasing doses of losartan resulted in a dose dependent decrease in expression of both the metalloproteinase (*mmp13*) and hypertrophy (*col10a1*) marker (**Figure 4B-C**). A pro-regenerative response was stimulated by the addition of K-PA nanofibers, as evident by the significantly increased expression of *col2a1* and *acan* (**Figure 4D-E**). Bioactivity of the losartan as a TGF β antagonist was further confirmed by showing a dose-dependent decrease in *tgfb1* expression with increasing losartan delivery (**Figure 4F**).

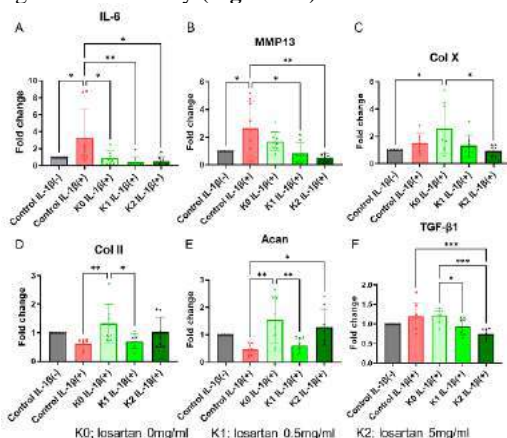

Figure 4: Positively charged nanofibers have pro-regenerative impact on OA-induced chondrocytes.

DISCUSSION

The results of this study showed that slower sustained release of losartan was achieved with our designed PA nanofibers, especially in the positively charged K-PA nanofibers. This result suggests that in addition to hydrophobic encapsulation, positively charged nanofibers supported an electrostatic interaction with the negatively charged losartan that enhanced the binding affinity between the peptide amphiphile molecules and the drug.

The results of this study also showed that PA nanofibers, of either charge, significantly increased chondrocyte proliferation. Self-assembled PA nanofibers have been reported to maintain chondrocyte morphology and promote cell division by encapsulating chondrocytes [5]. As for ECM production, the results of this study showed that positively charged K-PA nanofibers without losartan and with low (0.5 mg/mL) to moderate (5 mg/mL) losartan significantly increased GAG production for OA cells. This result may suggest that positively charged K-PA nanofibers may provide more effective ECM production ability due to their electrical complementarity with GAGs, considering the characteristics of negatively charged GAGs [6].

Positively charged K-PA nanofibers with low (0.5 mg/mL) to moderate (5 mg/mL) doses of losartan also significantly suppressed *il6* and *mmp13* expression. Interestingly, positively charged K-PA nanofibers without losartan did not suppress the expression of *mmp13*, whereas it significantly increased the expression of *col10a1*, a marker of hypertrophic chondrocytes. The results suggested that low doses of losartan, but not PA nanofibers, had an effective inhibitory effect on hypertrophic differentiation and inflammation of chondrocytes in the OA cell model. In addition, our study showed *tgfb1* was significantly inhibited by the positively charged K-PA nanofibers with low (0.5 mg/mL) to moderate (5 mg/mL) doses of losartan.

Taken together the results of this study suggest that the positively charged K-PA nanofibers bound with moderate (5 mg/mL) losartan can have a pro-regenerative phenotype in OA-activated chondrocytes by inhibiting *tgfb1* expression. This therapeutic strategy for articular cartilage repair using losartan sustained release PA nanofibers may provide a safer and more efficient treatment compared to oral administration or intra-articular injection of losartan.

INTRODUCTION

Osteoarthritis (OA) is a debilitating disease of synovial joints, including degeneration and loss of articular cartilage, that impacts nearly 20% of people in the US alone and affects quality of life through pain, functional limitations, lost earnings, anxiety, and depression. Mechanical stimuli are essential for chondrocytes (the cells within cartilage) to maintain healthy cartilage. Chondrocytes express chemicals (e.g. cytokines, growth factors, collagenases, and aggrecanases) in response to pathological loading, i.e. overloading (e.g. trauma) and reduced loading (e.g. immobilization) [1]. These biochemical species promote production or degradation of structural constituents, e.g. collagen and proteoglycan. Existing investigations on effects of mechanical loading on cartilage—including both *in vitro* experiments with human cartilage and *in vivo* animal models—fall short of true human physiological relevance [2]. Additionally, current mathematical models of signaling pathways lack mechanical effects while biomechanical models lack the chemical effects [3]. In particular, the concept of homeostatic adaptation, wherein tissues/cells receive pathological loading for prolonged periods of time, is understudied and poorly understood.

Leveraging our coupled chemo-mechano-biological framework for cartilage [4], we investigate interactions among intra-tissue mechanics and cell-driven mass/volume changes mediated by cytokines and chemical species. In this study, we: (1) implement our framework in 3-D, nonlinear finite elements using FEBio (U. of Utah, USA), (2) elucidate homeostatic adaptation to pathological stimuli during immobilizing, (3) simulate cartilage undergoing injury, immobilization, and treatments (with/without active growth factors). Specifically, we simulate applications of suramin, recently proposed as a treatment for OA and cartilage degeneration [5].

METHODS

Constitutive model. We utilize our established constitutive model of cartilage to predict tissue and intra-tissue mechanics under deformation [6].

Anisotropic growth. We employ anisotropic, through-thickness volume growth (TVG) to model degeneration and thinning of cartilage [7].

Mechanical stimuli - homeostasis and adaptation. We consider that pathological levels of mechanical stimuli cause perturbations to tissue-homeostasis. They drive a signaling pathways biochemical model using a stimulus function $f_S(\sigma_i(\tau), \sigma_{i,hom}^L(\tau), \sigma_{i,hom}^H(\tau))$ that is a function of mechanical stimuli ($\sigma_i(\tau)$) and salient homeostatic thresholds ($\sigma_{i,hom}^L(\tau), \sigma_{i,hom}^H(\tau)$) with L/H representing immobilizing/overloading, and $i \in \{sh, 1\}$ representing maximum shear and first principal stresses, respectively. The function f_S is well-shaped (see Fig. 1(a)) and adapts with time (τ) (see Fig. 1(b)) to reflect adaptation of homeostatic thresholds.

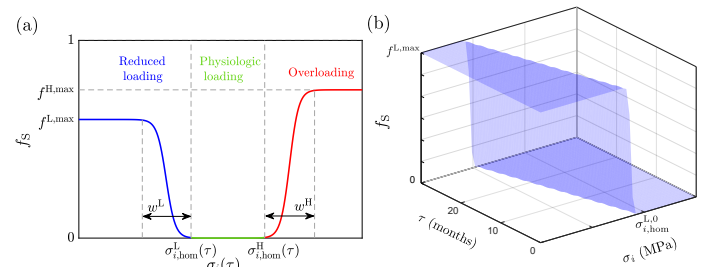

Figure 1: The mechanical stimuli function (a) ranges from reduced loading to overloading region, and (b) adapts pathological stimuli.

We define a piecewise continuous stimulus function f_S as,

$$f_S = \begin{cases} f_S^{L,max}, & \text{if } \sigma_i(\tau) < \sigma_{i,hom}^L(\tau) - w^L \\ f_S^L, & \text{if } \sigma_{i,hom}^L(\tau) - w^L \leq \sigma_i(\tau) < \sigma_{i,hom}^L(\tau) \\ 0, & \text{if } \sigma_{i,hom}^L(\tau) \leq \sigma_i(\tau) < \sigma_{i,hom}^H(\tau) \\ f_S^H, & \text{if } \sigma_{i,hom}^H(\tau) \leq \sigma_i(\tau) < \sigma_{i,hom}^H(\tau) + w^H \\ f_S^{H,max}, & \text{if } \sigma_i(\tau) \geq \sigma_{i,hom}^H(\tau) + w^H \end{cases}, \quad (1)$$

where f_S^L, f_S^H are sigmoidal functions, w^L, w^H control the width of sigmoidal transition regions, $f_S^{L,max}, f_S^{H,max} \in (0, 1]$ are constants. During

normal physiological loading, the tissue is in homeostasis and $f_s = 0$.

The (lower) homeostatic threshold $\sigma_{i,\text{hom}}^L(\tau)$ adapts during immobilizing ($\sigma_i(\tau) \leq \sigma_{i,\text{hom}}^L(\tau)$) as,

$$\sigma_{i,\text{hom}}^L(\tau) = \begin{cases} \sigma_{i,\text{hom}}^L(\tau = 0), & \text{if } \tau \leq \tau_{\text{del}}^L \\ \left(\int_{\tau-\tau^L}^{\tau} \sigma_i(\tau) d\tau \right) / \tau^L, & \text{if } \tau > \tau_{\text{del}}^L \end{cases}, \quad (2)$$

where τ_{del}^L represents a time-delay for homeostatic adaptation to begin and τ^L is a temporal averaging period for adaptation of homeostatic thresholds.

Biochemical signaling pathways. During pathological loading, the stimulus function is activated ($f_s > 0$) and drives the conversion of latent pro-inflammatory cytokines $\hat{c}_{\ell p}$ and latent growth factors $\hat{c}_{\ell \beta}$ to active forms \hat{c}_p and \hat{c}_β , respectively. Activated cytokines, in turn, upregulate collagenases \hat{c}_{ca} and aggrecanases \hat{c}_{ag} that degrade collagen \hat{m}_{co} and proteoglycan \hat{m}_{pg} , respectively. TIMPs \hat{c}_i inhibit collagenases and aggrecanases naturally, and suramin \hat{c}_{sm} prevents their uptake by cells in many tissues, cf. [5]. With the evolution of \hat{m}_{co} and \hat{m}_{pg} , cartilage thickness and intra-tissue stresses changes, and thus, the mechanical stimuli evolve.

Numerical studies. We implement our chemo-mechano-biological framework in FEBio. We exercise our model considering a single, linear hexahedral element representing cartilage, and apply boundary conditions simulating unconfined compression. We complete three studies: (i) homeostatic adaptation during joint immobilization, (ii) treatment with suramin during immobilizing following injury, and (iii) treatment with suramin and growth factors during immobilizing following injury. We predict the chemo-mechano-biological evolution of cartilage over 24 months.

RESULTS

(i) Homeostatic adaptation during joint immobilization. We performed simulations varying $\tau^L = 5, 10$, and 15 months to fit experimental data on cartilage thinning during immobilization over 24 months [8], see Fig. 2. Before immobilizing ($\tau < 0$), cartilage is in homeostasis, i.e. the evolution of all constituents is in equilibrium and $f_s = 0$. At $\tau = 0$, we begin immobilizing such that the current maximum shear stress is less than the lower homeostatic threshold, i.e. $\sigma_{sh} \leq \sigma_{sh,\text{hom}}^L$ and thus f_s increases. Adaptation of homeostatic thresholds to pathological loading follows depending on time averaging period τ^L following (2), see Fig. 2(a). The upper threshold $\sigma_{sh,\text{hom}}^H$ for physiologic loading remains fixed. As the lower homeostatic threshold $\sigma_{sh,\text{hom}}^L$ adapts towards the current maximum shear stress σ_{sh} , f_s approaches zero, see Fig. 2(b). Active growth factors and pro-inflammatory cytokines increase when f_s is elevated in the beginning, but goes back to zero once f_s returns to zero, see Fig. 2(c). With $\tau^L = 15$ months, numerical results for the evolution of cartilage thickness fit experimental data obtained *in vivo*, see Fig. 2(d).

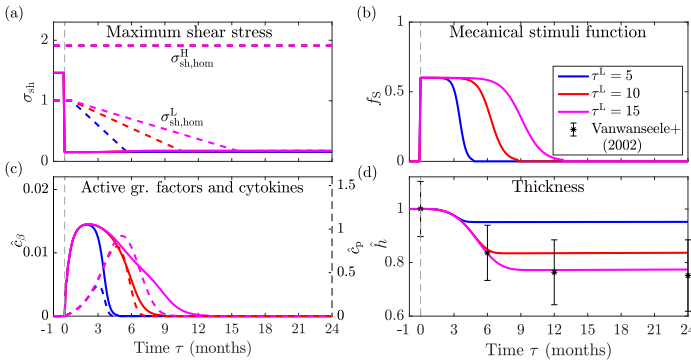

Figure 2: Evolution of intra-tissue mechanics as cartilage evolves during immobilizing with varying time averaging τ^L : (a) maximum shear stress (solid and dashed lines represent current stress and homeostatic thresholds resp.), (b) mechanical stimuli function, (c) activated biochemical species (solid and dash lines represent active growth factors and pro-inflammatory cytokines, resp.), and (d) cartilage thickness.

(ii) Treatment with suramin during immobilizing following injury. We performed simulations of healthy cartilage experiencing a high-impact injury at $\tau = 0$ month, followed by immobilizing for six months. Post injury,

cartilage receives treatments with suramin for 6, 12, 18, and 24 months. Cartilage loses functional collagen and living chondrocytes due to injury. The loss of chondrocytes causes latent growth factors to drop initially, but then increase thereafter due to activation of growth factors during immobilizing, and finally reach equilibrium as immobilizing ends after six months. Cartilage thickness recovers modestly to 77% and 78% if suramin is applied for six and 24 months, respectively (results not shown).

(iii) Treatment with suramin and growth factors during immobilizing following injury. We repeated the simulations in study (ii) but with different applications of active growth factors, i.e. maintaining constant level of $\hat{c}_\beta^{\text{const}} = 0.01, 0.02$, and 0.03 . After 24 months, cartilage thickness is 87% with $\hat{c}_\beta^{\text{const}} = 0.03$ compared to 77% without growth factors (Fig. 3(a)). With the application of active growth factors, chondrocytes promote production of structural constituents and proliferation. Total type II collagen recovery is 32% (Fig. 3(b)) and living chondrocytes are almost fully recovered during highest concentration of applied active growth factors and suramin (Fig. 3(c)). Latent growth factors also see a seven-fold increase with treatment versus without active growth factors (Fig. 3(d)).

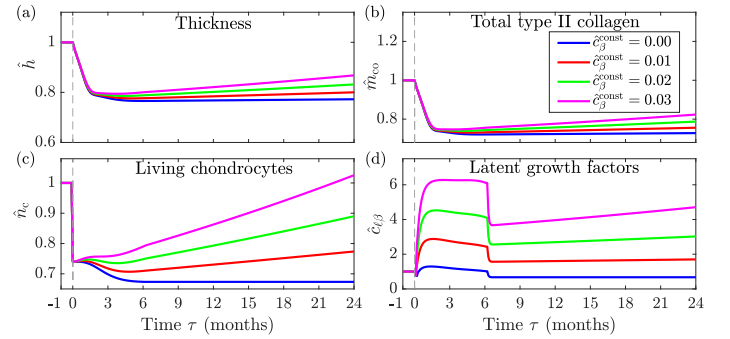

Figure 3: Cartilage evolving in injury and recovery with suramin for different dose of active growth factors. (a) Thickness, (b) Total type II collagen, (c) Living chondrocytes, and (d) Latent growth factors.

DISCUSSION

We implemented our chemo-mechano-biological framework for cartilage, including complex chemical and mechanobiological mechanisms resulting from pathological mechanical loading, into FEBio to facilitate 3-D finite element simulations. Our simulations illustrate the novel features of adaptation to pathological mechanical stimuli using two parameters, a time delay and a time averaging period, and successfully fit thinning of cartilage measured experimentally [8]. Our predictions show that the use of suramin alone to treat OA or thinning of cartilage after injury and immobilization may be ineffective. However, additional predictions indicate that the use of growth factors in addition to suramin may provide significant recovery of cartilage thickness after injury.

Limitations and outlook. We considered only a subset of known signaling pathways [9]. In studies (ii) and (iii), we considered growth factors as a combination of numerous growth factors in cartilage, although some may result undesired changes to homeostasis. We aim to leverage our chemo-mechano-biological framework in FEBio for patient-specific analyses, enabling advanced understanding of pathological changes due to biomechanical factors, improved clinical diagnostics and therapies, and new methods for non-invasive diagnosis and pre-/post-operative decisions.

A NEURAL NETWORK-FINITE ELEMENT APPROACH FOR MULTIBODY CONTACT IN SOFT BIOLOGICAL MATERIALS

Christian L. Goodbrake (1), Michael S. Sacks (1)

(1) Willerson Center for Cardiovascular Modeling and Simulation, Oden Institute, University of Texas, Austin, Austin, TX, USA

INTRODUCTION

Simulations of biological mechanical evaluation and system function such as micro-indentation of cells and heart valve closure often rely on accurate simulation of highly nonlinear elasticity with multi-body contact. Additionally, for simulations over time, such as the simulation of an entire cardiac cycle, or simulating disease progression, these contact problems must be solved many times on the same domain with varying boundary conditions. The computational expense of these simulations is a severe bottle neck of digital twin models, since these simulations must be solved as subroutines in a larger, more complicated model. We present a novel technique for the rapid simulation of friction-free contact between soft bodies, represented using Non-Uniform Rational B-Splines (NURBS). This method, which we call the neural network finite element (NNFE) method, utilizes neural networks to learn the equilibrium configurations of multi-body systems under a chosen family of boundary conditions by directly minimizing the system's potential energy. Because this technique learns solutions directly from the system's energy functional rather than pre-computed solutions, it does not rely on previously known solutions to generate results.

Contact was incorporated through a variationally consistent energy penalty, which exactly enforces contact in the limiting case. We demonstrate that this approach generates a neural network capable of rapidly and accurately predicting the equilibrium configurations of systems of several deformable bodies in contact. Once trained, this network accepts specific problem data, such as boundary conditions, body force fields, or the relative positioning of the bodies, as input, and produces equilibrium configurations corresponding to that problem data as outputs. Additionally, the time required to compute these solutions is front loaded into the training of the network, so the trained network produces solutions in the time required to compute a single forward pass through the network, typically on the order of milliseconds. Furthermore, by representing bodies using NURBS

functions, we can ensure solutions of any degree of desired smoothness a priori while accurately capturing any complex geometry present in our own system.

METHODS

Building on our previous work on neural network finite element approaches in soft tissue modeling in [1], we seek to train a neural network to predict equilibrium solutions to a parameterized family of nonlinear elasticity problems involving multi body contact. Summarizing our previous method, we construct a neural network whose inputs are these parameters, and whose outputs are the degrees of freedom of a finite element discretization of our PDE problem. This network therefore assigns a finite element solution to each set of parameters. However, before training, the output of this network are nonsense, with no relation to the PDE, or the input parameters. We therefore use features of solutions to this partial differential equation to train the network.

We do this by sampling from the parameterized family of PDE problems, creating a set of training protocols. The neural network is then applied to these parameters, producing a set of trial configurations. The total potential energy of these configurations is computed, and through automatic differentiation, the gradient of this energy with respect to the neural network's weights and biases computed. This gradient is then used to minimize this total energy by adjusting the network's weights and biases, training the network to predict solutions with minimal potential energy, the defining feature of stable equilibria.

By itself, merely computing the potential energy of a multi body system by summing the energies of each individual body will not enforce contact between these bodies, resulting in predictions involving interpenetration. We incorporate contact by defining a surface-surface interaction energy between bodies. For each pair of bodies, Ω^i and Ω^j , we define a contact energy contribution Π_c :

$$\Pi_c = \frac{k}{2} \int_{\partial \Omega^i} \langle -g^{(j)} \rangle^2 dA + \frac{k}{2} \int_{\partial \Omega^j} \langle -g^{(i)} \rangle^2 dA$$

where $g^{(i)}$ is the signed distance from the boundary of body Ω^i , and $g^{(j)}$ similarly, the angled brackets being the Macaulay bracket, replacing negative arguments with 0, and k an appropriate constant controlling the strength of the contact force. This energy vanishes when the bodies do not interpenetrate each other, and increases as the depth of penetration increases. Thus this energy imbues each body with an expelling force, ejecting other bodies from its interior, this force increasing as k increases. In the limit as k approaches infinity, the equilibrium solutions of this weakened problem will approach the contact constrained problem exactly. Such an energy contribution is added for each pair of bodies to the total energy, and our network is trained as before. Computing this energy in a differentiable and just-in-time compilable way required writing custom python NURBS code in Google's JAX framework. This software was written carefully to avoid dynamic memory allocations or indefinite loop, so that it could be just-in-time compiled to make training feasible.

RESULTS

We applied this approach to several test contact problems involving rigid indentation, where geometric parameters of the indenter are taken as inputs to the network, and the control points and weights of the NURBS discretized domain as the output. The first of these involved rigid spherical indenters, with the radius and the depth of indentation being the geometric parameters trained over (Figure 1).

Figure 1: Validation solution (blue wire frame) compared with NNFE prediction (red vertices). NNFE solutions required .0023 to .0026 seconds to compute. The spherical indenter is not shown so as not to obstruct the view of the indentation.

Secondly, we modified this problem by changing the indenter geometry to a cone rather than a sphere, and trained over the tip angle, and depth of indentation. Because our initial NURBS discretization does not allow sharp features, the contact in the very near proximity of the indenter tip is not captured. However, by inserting knots into the knot vectors at the point of contact, NURBS allows for the capture of sharp features (Figure 2). Training a network on this new discretization produces sharp deformations at the point of contact.

Finally, we construct a toy problem involving a rectangular flap impinging on a rigid wall, which serves as a stand-in for heart valve leaflet contact. The solutions to these problems feature large displacements and rotations, features that cause difficulties in traditional finite element implementations, since displacements and rotations do not generate strain energy.

In these simulations, the difference between the NNFE predictions and the ground truth solutions were very small. However, the primary advantage is the minimal run time, as reported in Figure 1.

Figure 2: Repeated knots for at the center allow for the localization of sharp features caused by a conical indenter. (Here displacement magnitude is shown, with blue corresponding to 0 and red to the maximum indentation depth .

DISCUSSION

We see that the trained network is capable of rapidly predicting equilibrium solutions of the family of problems used to train the network, in a fraction of the time that a conventional solution methodology requires. Therefore, in the many query setting, or in the low-computational power setting, these neural network models can produce accurate results where traditional solution methods would be infeasible due to their high computational time and power demands.

This allows these NNFE models to be incorporated into, for instance, digital twin models, where they are run several times as a subroutine. Conventional finite element techniques would be infeasible in this setting, because the time they require is two to three orders of magnitude greater than that required by the NNFE predictions. Because these models are incorporated into digital twins as subroutines, they will be run many times, and as such, the runtime of traditional FE techniques accumulates to an unacceptable level.

These NNFE predictions are also useful for inverse problems where many forward solutions must be computed. These inverse problems require the computation of a solution and its gradient with respect to a set of parameters, but the primary computational cost is dramatically concentrated in the forward solve, because the gradient can be computed with a single linear solve using the adjoint method. Therefore, these NNFE models can be used to solve these inverse models much more quickly than the traditional FE models.

Further, in a clinical setting, where patient specific data is necessary to produce accurate simulation results, these trained NNFE models can reduce the computational demands of these models to the point where these simulations can be run in the office during a patient consultation. The hardware required to run the NNFE simulations is significantly more common than that for traditional FE simulations, allowing these trained NNFE models to be deployed in a clinical setting, where high performance computing resources are not available, allowing high fidelity patient specific simulation of heart valve function to be used in real time.

EFFECT OF STANDARDS-BASED GRADING ON THE COURSE GRADE DISTRIBUTION IN A BIOMECHANICS COURSE

INTRODUCTION

The standard midterm and final exam evaluation model creates a high-stakes environment on a few exams that is detrimental to poor test-takers and learners that require more time to master the material. My Basic Biomechanics course had relied on three (3) midterm exams over 3 broad topic areas and a comprehensive final exam. A poor grade on the first exam often 1) limited the final grade in the course, and 2) seemed to discourage learners from continuing to learn/master the material. The only opportunity for re-testing was on the comprehensive final—a separate grade. I believed an alternative form of evaluation may improve outcomes and implemented standards-based grading.

Overview of Standards-Based Grading and Pros/Cons:

Standards-based grading [1,2] is assessing mastery for each learning objective (LO) in a course, with multiple opportunities to demonstrate that mastery. Competency or mastery is demonstrated on exam problems for each LO. There are more exams, so there are more opportunities to demonstrate competency. Students do not get exam grades, but earn points for successfully demonstrating competency in the LOs.

The advocates for standard base grading believe it creates a more equitable learning environment and students are given clear learning targets and rubrics so that they can then use those to master the content in the course. In addition, students are not penalized for early shortcomings or failure as long as they have sufficient chances to study and demonstrate competency. Theoretically standards-based grading encourages and facilitates a deeper learning of the content.

There are detractors for standards-based grading, because it does place essentially based the course grade almost solely on exam problems for the LOs, as assessments of competency. Homework, or what I prefer to call practice, for the LOs is typically not included in the grade.

However, because of the greater number of exams, and the mindset that exams are opportunities to earn points, the test-pressure and anxiety is likely reduced for most students. Some educators also have concerns that giving multiple opportunities to show competency creates a mindset that students should expect to get a do-over.

Standards-Based Grading at KU and my Biomechanics Course:

Let me give you some context about the use of standards-based grading at the University of Kansas in science and engineering. The department of physics began using standards-based grading several years ago in the calculus-based physics courses and has since expanded its use. The goal was to reduce the drop, withdraw, and failure rates in the courses, and physics did see improvement. A few people in engineering, including myself, heard about his approach and adopted it.

My prior course and exam structure only allowed for one additional opportunity on some learning objectives on the final exam. That was an additional (not replacement) grade, so it did not eliminate earlier poor scores. So, in hopes of reducing the D's and F's in the course, I implemented standards-based grading in Fall 2019.

METHODS

Implementation of Standards-Based Grading:

I based the structure of standards-based grading heavily on prior work in physics. Students were given with nearly twice as many opportunities to demonstrate mastery than points required to earn the maximum score for an LO (one point for each problem successfully completed). The approach includes seven (7) exams during the semester, plus an optional final exam with two questions per learning objective. The course has nine (9) learning objectives related to biomechanics concepts including knowledge of anatomy, tissue and cell properties, and analysis approaches including statics, single joint dynamics, inverse dynamics, tissue mechanics and cellular mechanics.

The Table 1 indicates how many opportunities the students had to show competency in each learning objective on individual exams and in total. The last two rows are most important, comparing the total number of opportunities per objective to the total points required to obtain the highest score (called the S-score) for each objective.

Table 1: Learning Objective Problem Distribution by Exam.

Number of Questions from each Learning Objective per Exam									
Exam	Objective								
	1	2	3	4	5	6	7	8	9
Exam 1	3	3							
Exam 2	1	1	2	1					
Exam 3		1	1	1	2	2			
Exam 4	1		1	1	1	1	2	1	
Exam 5	1	1		1	1	1	1	2	
Exam 6	1	1	1	1	1	1	2	2	3
Exam 7	1	1	1	1	1	1	1	1	3
Final Exam	2	2	2	2	2	2	2	2	2
Total	10	10	8	8	8	8	8	8	8
Points for S-score=5	6	6	5	5	5	5	5	5	4

Note that students had to earn the majority of available points to get the maximum S-score in all objectives, except LO9, for which there was the least amount of time for mastery. The maximum S-score was 5, and the minimum S-score was 1. The LO points were related to S-score through Table 2. The geometric average of the S-scores, s_i , determined the overall course score, S , per Equation 1. Note that there are 10 scores in the geometric average and for my course, the 10th “objective” was attendance and submission of an in-class activity. This course does have required active in-class student work on relevant example problems.

Table 2: Converting Learning Objective Points to S-scores

Category	Grade (S_i)				
	5	4	3	2	1
Objective 1 # of Correct Problems (Points)	6	5	4	3	<3
Objective 2 # of Correct Problems (Points)	6	5	4	3	<3
Objective 3 # of Correct Problems (Points)	5	4	3	2	<2
Objective 4 # of Correct Problems (Points)	5	4	3	2	<2
Objective 5 # of Correct Problems (Points)	5	4	3	2	<2
Objective 6 # of Correct Problems (Points)	5	4	3	2	<2
Objective 7 # of Correct Problems (Points)	5	4	3	2	<2
Objective 8 # of Correct Problems (Points)	5	4	3	2	<2
Objective 9 # of Correct Problems (Points)	4	3	2	1	<1
In-Class Activities not submitted*	0-2	3	4	5	>5

$$S = (s_1 \times s_2 \times s_3 \times s_4 \times s_5 \times s_6 \times s_7 \times s_8 \times s_9 \times s_{10})^{1/10} \quad (1)$$

The course grade was determined from the overall course score, S , using cutoff scores in Table 3.

Table 3: Course Grade Assigned from the Course Score, S .

Score	Course Grade
$S \geq 4.6$	A
$3.9 \leq S < 4.6$	B
$2.6 \leq S < 3.9$	C
$1.6 \leq S < 2.6$	D
$S < 1.6$	F

These grade cut-off scores were previously developed by the physics instructors, and I did not alter them. Some, perhaps non-standard approaches in this course with standards-based grading was the opportunity for partial credit (partial LO points for substantially correct work) and the opportunity for extra credit points that could be applied/distributed to any combination LOs prior to the final exam.

The Analysis of Standards-Based Grading:

To determine the effect of standards-based grading on student performance, the course grades for my last three offerings of the course in the traditional exam scheme were compared to the grades with objective base grading (Fall 2019, 2021, 2022). Because Fall 2020 had hybrid course delivery, exams were online, and academic misconduct was apparent, that semester was excluded.

RESULTS

In terms of student perception, they generally indicate preference for the standards-based grading approach, though it is harder for them to predict or understand their grade (standing) early in the course. I generally tell students they are doing OK if they are earning about half of the available points for the LOs. Each semester, some students earned a grade of A without taking the final exam.

As noted earlier, the hope was that the standards-based grading would reduce the D's in the F's in the course. What the data actually show is that standards-based grading increased the A's in the course and decreased the B's (and perhaps slightly decreased C's). The D+F rate was unchanged (Table 4). The sample size is obviously small (3 data points before and after standards-based grading), and the differences are not statistically significant.

Table 4: Average Percentage of Letter Grades Before and After Implementation of Standards-Based Grading.

	Traditional	Standards-Based
A's =	34.4%	42.4%
B's =	32.3%	25.8%
C's =	25.8%	24.2%
D's & F's =	7.5%	7.6%

DISCUSSION

I noted that low-performing students did not complete extra credit assignments. I hypothesize that low-performing students may lack time (or bandwidth) to improve their competency/mastery, whether because they are trying to balance education and work or simply because they are struggling in multiple courses.

From the instructor perspective, there are some challenges with the standards-based grading approach. Standards-based grading requires more exams and more exam problems. Also, for this course, the end of the semester has 3 exams (last LO exam #6, comprehensive exam #7, and the final exam) in quick succession (each about one week apart). Exams can be written in advance, but grading and returning of exams must still be done quickly. The grading of each LO exam problem is more efficient, since the outcome/score for each exam problem is binary (or has few levels) in terms of score. However, providing constructive feedback can still be time-consuming.

So, is standards-based grading effective? Not necessarily in the way I expected, but it does appear to help and motivate some students to improve their understanding of course materials, their performance on exam problems, and, thus, their grades. Is standards-based grading worth the effort? Because the student learning appears to be positively affected, the current plan is to continue this approach in the basic biomechanics course.

INTRODUCTION

Viscoelasticity describes materials that exhibit both elastic and time-dependent viscous behaviors in response to stress, resulting in stress relaxation and viscous creep under load. While it is well established that matrix stiffness is influential for tissue form and function, matrix viscoelasticity has recently emerged as a key driver in tissue spatiotemporal organization[1]. Furthermore, as cells are the sensors and effectors of mechanical response, it is important to understand how these properties change at cellular length-scales within engineered 3D tissues. Measurements at these scales relevant to cells cannot currently be predicted using bulk mechanical testing methods or sub-cellular optical spectroscopy techniques[2],[3]. To address these limitations, we extend the use of our previously described thermoresponsive hydrogel microdroplet stiffness sensors [2] to measure viscoelastic parameters. These mechanosensors swell at hypothermic temperatures to exert local stresses, and by characterizing, measuring, and modelling expansion time dynamics, we demonstrate the ability to make highly local measurements of tissue viscoelasticity.

METHODS

Fluorescent microspherical hydrogel droplets are fabricated in Poly-n-isopropylacrylamide (NiPAAm) in an oil-water emulsion as previously described, producing sensors 10-50um in diameter that compact at temperatures above 32°C, and can be coated with Type I collagen to allow incorporation into engineered tumor spheroid models [2], [4]. Rapidly cooling the microtissues below 32 °C causes the sensors to expand at a rate commensurate with tissue viscosity.

Since conventional measurements of viscoelasticity require application of a known stress to a deforming tissue, we first needed to measure the stresses generated by the sensors during expansion. Sensors were embedded in polyacrylamide gels of known mechanical properties in their collapsed state. Sensor expansion in these gels, in combination with finite element modelling allowed us to measure stress as a function

of sensor size and actuation stroke length (Fig. 1A, B). This information was then used to simulate sensor expansion in Kelvin-Voigt models of viscoelasticity, for which the two parameters E and τ are parametrically swept (Fig. 1C, D). Matching these characteristic expansion profile libraries to experimental measurements allowed us to obtain two-parameter measurements of tissue viscoelasticity.

Tumor models with randomly distributed embedded sensors were generated by passive confinement in micro-pocket devices[5], using three differentially invasive breast cancer cell lines: non-invasive T47D cells, invasive MDAMB-231 cells, and engineered MCF7 cells that can overexpress Src upon induction, and invade on demand.

Figure 1: A - Sensors imaged under epifluorescence in their compacted and expanded states (Scale bar 50um). B - Stress-sensor stroke length relation. C - Modelled sensor expansion profile independently controlled by E and η/τ in Kelvin-Voigt model.

RESULTS

We first confirmed that in linear elastic materials such as polyacrylamide gels, expansion completed within seconds of the applied temperature change (data not shown). We then compared measurements in live and fixed T47D tissues, and showed that as expected, viscoelastic characteristics of the tissues were dissipated on fixation, which behaved more elastically and exhibited substantial stiffening due to protein cross linking (Fig. 2).

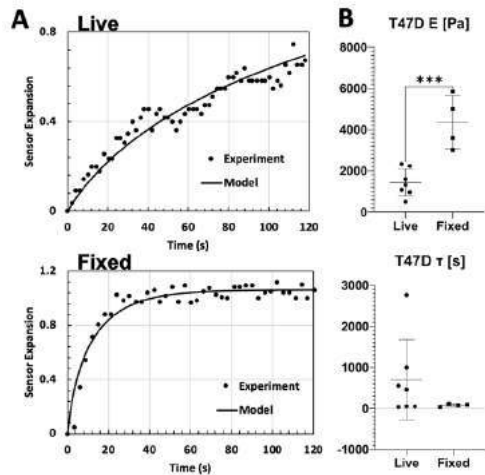

Figure 2: A - Example fitting of model to experimental data for T47D spheroids in live and fixed conditions. B - Young's modulus (E) and time constants (τ) in live and fixed T47D spheroids

We then evaluated viscoelasticity within tumor models of differentially invasive cell lines. Both non-invasive T47D and invasive MDAMB-231 spheroids exhibit similar local stiffnesses, but the time constants of sensor expansion are consistently lower in the invasive tissue, even in regions of similar stiffness (Figure 3), suggesting that internal local fluidity is a characteristic of quiescent tumors.

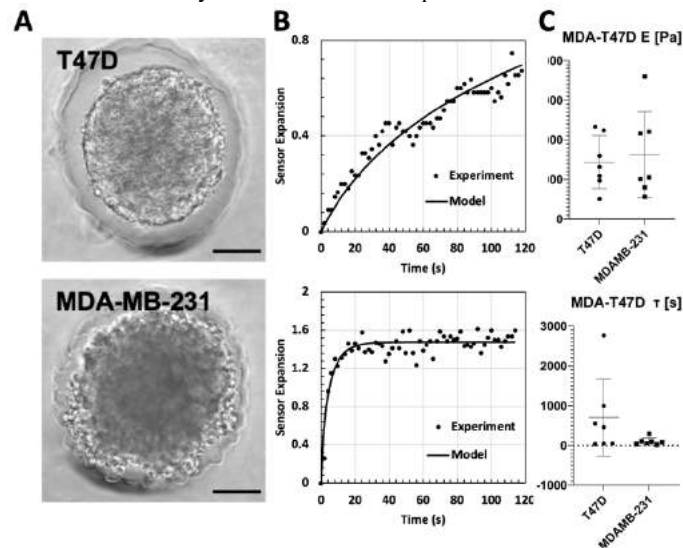

Figure 3: A - Representative images of T47D and MDAMB-231 spheroids. B - Corresponding sensor expansion profiles. C - Young's modulus (E) and time constants (τ) of sensors actuated in invasive (MDAMB-231) and non-invasive (T47D) spheroids.

Because comparisons between the MDAMB-231 and T47D models may capture more than invasive potential, we engineered an MCF7 cell line to overexpress Src upon induction with doxycycline. Consistently, inducing a tissue to invade reduced local viscous properties, while maintaining similar elastic properties (Figure 4).

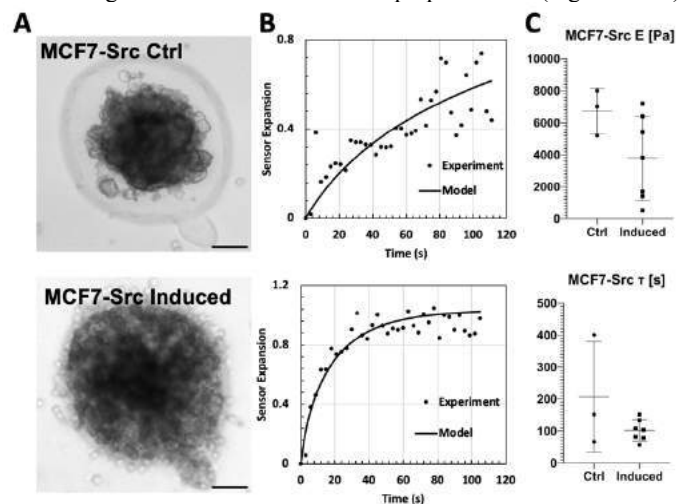

Figure 4: Figure 3: Young's modulus (E) and time constants (τ) of sensors actuated in inducibly invasive MCF7 spheroids.

DISCUSSION

These cell-sized mechanosensors demonstrate that spheroids with different invasive potentials showed highly distinctive internal viscoelastic characteristics, where invasive spheroids (MDAMB-231 and MCF7-Src) display rapid strain responses to stress, compared to non-invasive spheroids (T47D and MCF7-Ctrl) which have more varied viscoelastic responses including a much slower, more viscous deformation profile. These findings are consistent with recent literature evidence demonstrating that individual invasive cancer cells exhibit significantly less viscous behaviors to normal healthy cells [6] and in response to a passive viscous surrounding matrix, non-invasive tissues exhibit high levels of invasion[1]. Ultimately, changes in tissue viscoelasticity affects how those cells perceive their mechanical environment over time and thus, the ability of these sensors to quantify the viscoelastic properties as experienced by cells permits investigation of how mechanics and cell behavior interact.

EFFECT OF AORTIC CURVATURE ON BIOPROSTHETIC AORTIC VALVE PERFORMANCE

INTRODUCTION

Aortic stenosis (AS) is the most common valvular heart disease in developed countries and is a major cause of heart failure¹. A treatment approach for AS can be accomplished by replacement of the diseased valve with a bioprosthetic transcatheter aortic valve or surgical aortic valve. The performance and durability of these bioprosthetic valves have been related to postoperative mean transvalvular pressure gradient (ΔP).

Echocardiography (ECHO) and catheterization (CATH) modalities are used to measure ΔP non-invasively and invasively, respectively, leading to differences in measurements. These discrepancies are a result of the different measurement locations for each modality in the pressure recovery zone. ECHO measurements do not account for pressure recovery unlike CATH measurements. Several attempts have been made (clinically, computationally, and experimentally) to quantify pressure recovery and to understand its effect on postoperative ΔP measurements. Attempts have also been made to modify the simplified Bernoulli equation to account for pressure recovery as a function ascending aorta size².

Despite the aforementioned efforts, pressure recovery assessment of physiological diameter, shape, and three-dimensional curvature of the ascending aorta and aortic arch is still lacking. In this study, we aim to assess PR in physiological 3D aortic arches to determine their effects on valve performance.

METHODS

A 23mm SAPIEN 3 Ultra (Edwards Lifesciences, Irvine, CA) was hemodynamically assessed in a pulse duplicating left heart flow loop simulator under various combinations of cardiac conditions (**Table 1**)

Table 1. Cardiac Conditions.

Blood Pressure (mmHg)	Cardiac Output (L/min)	Heart Rate (bpm)
120/80, 140/80	3, 5	60, 80

The aortic chambers used had identical root dimensions but with 3 different aortic arch geometries; with 2 distinct physiological 3D aortic arches that will be referred to throughout this abstract as “Curvature 1” and “Curvature 2” and with a straight downstream tube (without aortic arch). All the models had the same aortic root dimensions (same annulus size, sinus dimensions, and sinotubular junction (STJ) dimensions). The aortic arch geometry was based on the work by Boufi et al³. A schematic of all the models is shown in **Figure 1**.

Figure 1. Schematics of the 3 aortic models: (A – C) Curvature 1 model, (D – F) Curvature 2 model and (G) straight model.

All pressure measurements were taken with Millar Pressure Catheters (Millar, Houston, TX) and with a Validyne pressure sensor (Validyne Engineering, Northridge, CA) set to monitor the aortic pressure constantly. The measurements were made incrementally along the aortic model with an interval of 0.2cm from the ventricular pressure port to the valve leaflet tips and 0.5cm from the leaflet tips to the end of the model. In all the models, the position of 0cm corresponds to the most

upstream measurement taken at the same axial position as the ventricular pressure port. Peak flow for each measurement occurred when flow was maximum (peak systole), this time point was used to select the instantaneous pressure for each axial position. The peak ΔP , defined as the difference between the ventricular pressure measurement (0cm) and each subsequent axial position, was calculated for all models at each cardiac condition.

RESULTS

The pressure as a function of axial distance at the different cardiac conditions is plotted in **Figure 2A** and **2B** for the models with aortic arches. Results from the pressure measurements are plotted starting from upstream of the valve and ending downstream of the valve after the aortic arch. As the valve opens, pressure decreases until it reaches the vena contracta (VC), where it is at its minimum. After passing the VC, pressure gradually rises until the start of the aortic arch. This rise in pressure marks the beginning of PR. At the arch, pressure begins decreasing until the middle of the arch. After passing the middle of the arch, the pressure starts increasing gradually marking the beginning of a second PR zone. The pressure follows a general trend for both models, where PR zones occur after the valve and at the aortic arch. This trend is independent of the cardiac condition, but the measured pressures do change with different conditions. At a pressure of 140/80mmHg, an upward shift of the pressure curve is observed for both models. There is less pressure loss after the aortic valve and aortic arch for the 3L/min condition for both models. At a heart rate of 80bpm the resulting pressure curve has a slight downward shift compared to the default 120/80mmHg and 60bpm condition for Curvature 1 model, whereas no shift in the curve is present in Curvature 2 model.

The pressure as a function of axial distance at the different cardiac conditions is plotted in **Figure 2C** for the straight model. Results from the pressure measurements are plotted starting from the upstream of the valve and end downstream of the valve. The straight model pressure curves follow the general trend where only one PR zone occurs after the aortic valve. The trend in the straight model is also independent of the cardiac condition, but the measured pressures do change with the different conditions.

DISCUSSION

In this study, we evaluated PR in three different aortic models which had the same aortic root dimensions but different aortic arch geometries. The models with aortic arches had two distinct PR zones, the first after the VC and the second after the main curvature of the aortic arch, whereas in the straight model, only a single PR zone was present after the VC.

The PR phenomenon has been well described in literature: as the blood leaves the aortic valve towards the STJ and ascending aorta, a decrease in blood velocity and kinetic energy occurs. As a result, pressure starts recovering and potential energy increases. When the blood flow reaches the aortic arch, a change in the velocity profile of the fluid occurs. The faster moving fluid in the aorta is pushed towards the outer wall of the aortic arch due to its higher inertia⁴. In addition, as the fluid passes through the bend, centrifugal forces cause a difference in pressure at the inner and outer bend, causing the formation of a recirculation zone containing Dean vortices⁵. These vortices cause the kinetic energy of the fluid to change, resulting in an energy loss downstream which is represented by a pressure loss.

The general trend of pressure recovery in all the models was independent of the cardiac condition used. Instead, the individual pressure measurements at each axial position that make up the pressure curve depended on the cardiac condition. At a pressure of 140/80mmHg, the same changes in energy are occurring in the 3 distinct aortic models,

but the overall pressure of the system has increased. At a lower cardiac output of 3L/min, lower pressure drops occurred at the aortic valve and aortic arch. This is due to a reduction of kinetic energy from lowering the cardiac output, which is dependent on velocity. As a result of this lower kinetic energy, there is less energy loss due to viscous losses, turbulent losses, and flow separation losses. An increase in heart rate to 80bpm appeared to have little effect on the resulting pressure measurements. The work of Rozenman et al.⁶ shows that an increase in heart rate up to a certain level (150bpm) leads to a decrease in pressure gradient. The magnitude of this decrease depends on cardiac output and aortic valve area.

In this study, we illustrated the differences in PR between distinct aortic curvatures and a straight aorta. This highlights the potential inconsistencies in invasive pressure drop measurements, especially when there is no guideline for optimal commercial catheter placement. Patient specific studies are warranted in order to investigate the impact of catheter position for an accurate assessment of valve performance, and the effect of aortic arch size and angle on valve performance.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a standard therapeutic approach for patients with severe aortic stenosis (AS). A major postoperative concern with this procedure is the risk of stroke. In fact, the Placement of Aortic Transcatheter Valves (PARTNER) II Trial, reports the incidence of ischemic stroke as 5.5% at a two-year clinical end point¹. Atherosclerosis of the aortic arch has been identified as a significant predictor of stroke. Results of the Rotterdam Study² have shown a strong association between aortic stiffness and atherosclerosis. Veulemans et al.³ has shown an increased rate of stroke in patients with horizontal aortas greater than 51°. It may be possible that aortic geometry influences the development of stroke in patients who have undergone TAVR.

The aim of this study is to assess how aortic arch geometry influences the hemodynamic parameters that are associated with the development of stroke after aortic valve replacement. We hypothesize that stroke after TAVR is more likely to occur in patients with certain geometric and hemodynamic properties in the aortic arch.

METHODS

Contrast-enhanced computed tomography (CT) images of patients who did and did not (control group) have a stroke after TAVR were obtained from Mayo Clinic under an IRB approved protocol. Patient selection criteria was based on age and sex. The CT images were imported into Mimics Research 23.0 (Materialise, Belgium) and segmented to generate patient-specific 3D digital models of the aorta with the brachiocephalic artery (BCA), left common carotid artery (LCCA), left subclavian artery (LSCA), and calcium. The aortic root (aortic annulus to sinotubular junction (STJ)) was removed from the models in order to isolate the effect of the aortic geometry in our analysis. Geometrical measurements of the aorta and main branching arteries were performed using 3-Matic 15.0 (Materialise, Belgium).

All simulations were calculated using STAR-CCM+ (Siemens, Inc., Germany). Large eddy simulations (LES), which has the capability to resolve the wall regions that contain a wide range of scales of flow motion from both temporal and spatial domains, was adopted in our study. It can directly resolve the large scales of turbulence everywhere in the computational domain and model those small-scale motions in the near-wall region. The wall-adapting local-eddy viscosity (WALE) sub-grid scale model was used to account for the effects of small eddies on the resolved flow. The all y^+ treatment method is used to resolve the flow within the near-wall region. This method combines the high y^+ wall treatment for coarse meshes and the low wall y^+ treatment for fine meshes, which gives similar results to the low y^+ treatment as $y^+ \leq 1$ and to the high y^+ treatment for $y^+ \geq 30$. In addition, it is also designed to produce reasonable results within the buffer layer (i.e., $1 < y^+ < 30$) for intermediate meshes. The working fluid has a density of 1060 kg/m³ and a kinematic viscosity of 3.5cSt. In this study, 25 prism layers with a growth ratio of 1.3 were generated in the near-wall region and the first layer thickness is 2e-6m. The maximum wall y^+ value was around 0.0684, which provides sufficient resolution for LES results.

The boundary conditions (e.g., flow and pressure data) adopted in this study were obtained from the literature published by H.J. Kim⁴. Briefly, those data were derived from a lumped parameter heart model and 3-element Windkessel models which was used with the curved aortic model along with a typical straight one under pulsatile physiological conditions. The cardiac output was 3.4 L/min, the heart rate was 88 beats per minute. **Figure 1** illustrates the boundary conditions applied in the computational study for the control model. The hemodynamic parameters of interest were helicity and the volume averaged velocities during peak systole.

RESULTS

The geometry measurements of the aorta, main branching arteries, and calcium for the control and stroke patients are shown in **Table 1**.

The percent total calcium volume (with respect to the total model volume) was higher in the stroke patients than in the control patients. The ostium areas of the LSCAs and LCCAs were similar between the control and stroke patients, but the ostium area of the BCAs was higher in the stroke patients than those of the control. Interestingly, we observed an attachment of the LCCA to the BCA superior in position to the BCA ostium, only in the stroke patients. The STJ area was similar amongst all the patients.

Table 1. Geometry measurements of the control and stroke patients.

Geometric Parameters	Control 1	Control 2	Control 3	Stroke 1	Stroke 2	Stroke 3
Percent total Calcium Volume (%)	0.21	0.25	0.00	1.19	0.94	0.24
STJ Area (mm ²)	662.23	532.67	684.13	508.16	438.51	734.81
Descending Area (mm ²)	434.69	432.88	724.27	227.93	306.21	537.71
Brachiocephalic Ostium Area (mm ²)	160.56	157.8	230.99	409.22	312.87	592.15
Left Subclavian Ostium Area (mm ²)	61.10	96.94	141.78	70.11	73.48	108.91
left Common Carotid Ostium Area (mm ²)	158.33	123.81	241.01	191.73	119.89	200.63

The volume averaged velocities during peak systole for the control and stroke patients are shown in **Figure 2**. Velocity was not found to be a factor of difference between control and stroke patients.

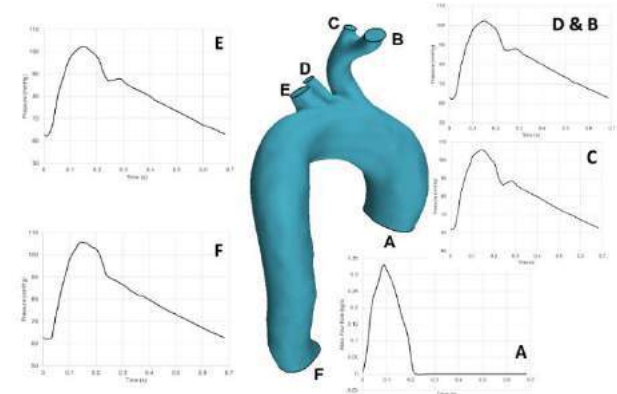

Figure 1. Inlet and outlet boundary conditions, where (A) is the inlet located at the STJ, (B, C) are the BCA outlets, (D) is the LCCA outlet, (E) is the LSCA outlet, and (F) is the descending aorta outlet.

Helicity for a complete cardiac cycle for the control and stroke patients is shown in **Figure 3**. Positive and negative helicity was present during systole before returning to about zero during diastole for all the patients. Helicity was mainly positive for Stroke 1, Control 1 and Control 2. Fluctuations in helicity were present in Stroke 2 but not in any other patient.

DISCUSSION

In this study we have investigated the effect of aortic arch geometry on local flow hemodynamics to better understand and predict stroke after TAVR using LES. A non-uniform trend of hemodynamic parameters (velocity and vorticity) was observed amongst the patient population. However, geometrical measurements showed marked differences in BCA ostium area and the percent total calcium.

Figure 2. Volume averaged velocities during peak systole for the control and stroke patients.

Deployment of a TAV requires the use of a catheter. While guiding the device into position and expanding it, there is the possibility for the TAV, catheter, and accessory guidewires to interact with the aortic wall and native valve leaflets. This interaction may cause dislodgment and embolization of calcium into the branching arteries. A 2-vessel branching pattern, where the LCCA originated from the BCA otherwise known as a bovine arch, was observed in only the stroke patients. This aortic arch variant has been well documented and is quite common. We have observed that the stroke patients, all of whom have this variant in this study, also have increased BCA ostium areas compared to the control patients. Given this increase in area, we believe it makes embolization of calcium from TAVR procedure far easier than if the artery ostium area were smaller.

It has been reported that lower levels of helicity are associated with vascular stiffness⁵. Results of the Rotterdam Study have shown a strong relationship between aortic stiffness and atherosclerosis². Increased levels of atherosclerosis in the aortic arch are associated with an elevated risk of stroke. Mukherjee et al.⁶ has shown that helical flows may be an important factor for facilitating transport of embolic particles.

Figure 3. Helicity for a complete cardiac cycle for the control and stroke patients.

In this study we have demonstrated the feasibility of using LES to predict TAVR related stroke. We have observed a trend in the stroke patients where an aortic arch variant is present. Further investigations using a larger patient cohort are warranted to better understand its role and prevalence in this study.

WAVY MICROCHANNELS SUPPRESSED PERSISTENT CELL MIGRATION

Ze-Hao Lin and Pen-Hsiu Grace Chao

Department of Biomedical Engineering
National Taiwan University
Taipei, Taiwan

INTRODUCTION

Extracellular matrices (ECM) with collagen and elastin are often organized in parallel and wavy bundles in dense connective tissues. The wavy architecture varies as a function of location within the tissue microenvironment, with amplitude ranging from 1-15 μm and wavelength from 20-50 μm [1-3]. Reduced fiber curvature surrounding tumor stroma is associated with tumor cell invasion and poor prognosis [4, 5]. Studies propose that the straight fibers increase cancer cell metastasis, however, the underlying mechanism behind cell migration in wavy structure is still unclear.

Persistent cell migration requires defined front-rear polarity which is mediated by the cytoskeleton and focal adhesion [6, 7]. Microtubule and its post-translational modification/stabilization are major regulators of polarity formation and migration [8, 9]. We have previously reported that wavy morphology changes nuclear structure and phenotype [10, 11]. In this study, we investigate the role of wavy structure in MSC migration and the underlying mechanisms.

METHODS

Microfabrication Microchannels with agarose side walls and fibronectin-coated PDMS substrate were generated by micromolding [12]. All channels were 15 μm wide with 10 μm -tall side walls. The wavy pattern was composed of arcs with the inner radius of 7.5 μm at 60 μm wavelength.

Cell Culture Mesenchymal stem cells (MSCs) were seeded at a density of 4,000 cells/ cm^2 in the microchannels for 4 hours before the start of live imaging. Actin cytoskeleton was labeled with SPY555-Actin (Spirochrome) and nuclei were labeled with SPY505-DNA (Spirochrome). Cells were treated with DMSO or 2 μM tubacin (Cayman) for 3 hours prior to live imaging.

Imaging and Analysis For live-cell imaging, cells were imaged every 10 minutes for 5 hours in a stage-top incubator on an inverted

fluorescence microscope using a 20x objective (Tokai-Hit and Nikon). For fixed samples, filamentous actin was labeled with Alexa Fluor 568 phalloidin (Invitrogen) and nuclei were labeled with DAPI (Sigma). Microtubule network was labeled by total α -tubulin and acetylated α -tubulin (Sigma and Abcam), and imaged using confocal microscopy (Leica SP8). Cell migration was tracked by monitoring the centroid location of nuclei using a custom Matlab program. Migration speed was defined as the total length of migration path normalized by time. Migration persistence was calculated as the net nuclear displacement divided by total path length [13]. Nuclear shape change was defined by the maximum difference of the elliptical Fourier analysis index during migration [14].

Statistical Analysis Data figures and statistical analysis were made using R 4.0.3 software. All statistical comparisons were analyzed using the nonparametric Kruskal-Wallis tests.

RESULTS

To determine the influence of wavy structure on MSC migration, we fabricated open microchannels with straight and wavy shapes. Cells conformed to the microchannels and the wavy structure led to wavy cytoskeletal organization and deformed nuclei (Fig. 1, 2). Wavy cells had short and discrete stress fibers and straight cells assembled stress fibers along their entire length in a continuous network. Microtubules in general followed cell structure, with a dense network near the nucleus. This network colocalized with acetylated tubulin, a marker for stable microtubules. Live imaging revealed a more persistent migration by the straight cells, while the wavy cells had more frequent changes in direction, leading to smaller displacement over time (Fig. 2). Quantifying nuclear translocation with time revealed that cells in wavy channels had reduced migration speed and persistence compared with straight cells, indicating that the wavy cells had suppressed motility and persistent polarization (control group, Fig. 3). This reduction corresponds with increased nuclear shape dynamics during migration.

Microtubule-mediated cell polarization involves the formation of stable microtubule network near the centrosome [9, 15]. We thus deduced that the wavy cells were less persistent due to increased microtubule dynamics. By suppressing tubulin deacetylation with the small molecule inhibitor tubacin, we hypothesized that the increased microtubule stability would enhance persistent migration. Contrary to our hypothesis, increasing microtubule stability further suppressed wavy cell persistence, while having no effect on migration speed or in the straight cells (Fig 3). Further exploration of nuclear shape change during migration found tubacin treatment significantly suppressed nuclear shape changes in the wavy cells.

DISCUSSION

Using mostly microcontact printed or nanotopographic substrates, previous studies have found decreased cell motility and persistence in wavy topography, corresponding with metastatic ability of cancer cells [2, 16]. In this work, we investigate the migration changes in 3D structures. Different from previous reports, cells exhibit wavy morphology in our system, with significant changes in actin and nuclear structure, but similar reduction in motility and persistence (Fig 1 and 3, [2, 4, 17]). This reduction is accompanied by more frequent changes in migration direction (data not shown). We also observe significantly increased nuclear dynamics during wavy cell migration, suggesting that nuclear restriction may contribute to the reduction in motility (Fig 2 and 3, [18]). As the establishment and stability of cell polarization controls migration [7, 8], we investigate the role of microtubule stabilization on wavy cell motility and persistence. Contrary to our hypothesis, increasing microtubule stability by tubulin hyperacetylation reduces wavy cell migration persistence, with no effects on motility (Fig 3). At the same time, nuclear shape change is attenuated with tubacin treatment in the wavy cells. These results suggest that tubulin hyperacetylation stabilizes nuclear structure and suppressed migration persistence in the wavy cells. It is not clear if the change in nuclear shape dynamics is due to altered microtubule structure, nucleus-microtubule engagement, or chromatin organization. It also does not explain the underlying mechanism behind low motility and persistence in wavy cell migration. Together, our results show that wavy cells have changed cytoskeletal organization, with lower motility and persistence, and tubulin acetylation is not involved in the regulation. Our system recapitulates the physiological and pathological structures in 3D connective tissues and permits mechanistic investigations of cancer metastasis and wound healing. Future studies will focus on investigating the role of actin-based cell polarity, focal adhesion dynamics, centrosome positioning, and nuclear restriction on cell migration in wavy channels.

INTRODUCTION

A functional renal system is vital to remove waste from blood and maintain organ homeostasis and physiological functions. Chronic kidney disease affects 37 million American adults¹. Currently, there are two treatments options: dialysis or transplantation, which are necessary when >85-90% of kidney function is lost. Kidney transplantation is less restrictive to lifestyle compared to dialysis, and has an over 80% five-year survival rate². However, there is a huge shortage of organs for transplantation due to unavailability of donors leading to a widening gap between the percentage of patients on the waiting list and the percentage of transplanted patients. Indeed, only 20,161 kidney transplants were performed in 2016 out of the 100,000 patients on the waiting list¹. As a result, dialysis remains a life-saving treatment for these patients.

Hemodialysis is the most common type of dialysis, with approximately 90% of dialysis patients undergoing this treatment². The disadvantage of hemodialysis is its high costs, with a total spending of \$28 billion in 2016². Notably, in 2011, 1.4% of US end stage renal disease (ESRD) patients on Medicare accounted for 7.2% of the overall Medicare spending³. During hemodialysis treatment, blood is drawn from the patient and transferred to a dialysis machine via a vascular access, usually an arteriovenous (AV) fistula, with a 14- or 15-gauge needle. There are several complications associated with vascular accesses such as aneurysm, infection, damage, and uncontrolled bleeding. Due to these risks associated with incorrect cannulation, vascular access complications limit treatment opportunities outside of the clinic setting, such as at home since it would require self-cannulation by patients.

To address this issue, improve patient lifestyle, and reduce complications associated with vascular access, we developed a prototype access port, called Safe Entry Port for AV fistulae (SEAL), that integrates well with fistulae, guides self-cannulation, and prevents aneurysms with minimal risk of back-bleeding and infections (Figure 1). Initial *in vitro* prototype testing on an artificial closed loop circuit

demonstrated that cannulation of the device can be safer and simpler, potentially reducing vascular damage, infection and enhancing durability.

Figure 1: SEAL Device and Valve (Raw & TiN/Ag Coated)

METHODS

We optimized the device design for 3D printing via direct metal laser sintering of Ti-6Al-4V *in silico*. We also evaluated variations on valve parameters to ensure smooth operation. Printing was performed by Protolabs®. Self-sealing capabilities of the colinear valve were confirmed using a mock circulation system via a peristaltic pump (Cole-Palmer Masterflex C/L® Model 77120-62) and a hydrostatic pressure gradient. Device valves were treated and evaluated *in vitro* for biofouling to determine valve antimicrobial properties using bacterial spreading area and bacterial turbidity assays. The system was fatigue tested to determine smooth operation of valve overtime and the force required to displace the valve. A micro linear actuator (Progressive Automations, Model:PA-07-1-5) was mounted to a 10 lbs. load cell (Transducer Techniques, Temecula, CA, MLP-10-CO). The load cell was connected to a data acquisition system (DAQ, National Instruments, Austin, Texas, SCB-68), which in turn was connected to a computer running LabVIEW® (National Instruments, Austin, Texas) for data processing and transfer.

A clinical-like *in vivo* model was developed by surgically creating an arteriovenous fistula in the forelimb of a sheep and implanting the device under the skin and on top of the fistula.

RESULTS

In repeated cannulations of the device during *ex vivo* simulations with 14-15G dialysis needles, the peak force required to engage the valve recorded in our dialysis fatigue cycling simulation was 0.1605 ± 0.000018 N (Figure 2). Furthermore, the colinear valve smoothly opened for continuous flow through the needle guide (Figure 3). The valve descended to its closed position when the needle was withdrawn, immediately blocking flow through the channel. Antibacterial TiN/Ag coated valves showed greater bacterial growth resistance than raw and polished titanium valves in both assessments (Figure 4). The device was implanted under the skin and on top of a mature fistula (Figure 5). 10 days after implantation, *in vivo* cannulation assessment of the sheep access was performed twice a week for 3 weeks with a 14G dialysis needle. Blood flow into the dialysis needle and bleeding after the needle was removed was noted. The fistula was accessed through the device and upon removal of the needle there was no back-bleeding or hematoma that may normally occur with a fistula after treatment.

Figure 5: AV Fistula matured for 12 weeks (A). Implanted SEAL devices (B).

DISCUSSION

The SEAL device is engineered to integrate directly over a fistula via an external metallic foam and to utilize an internal colinear valve that uses the tensile energy of the subcutaneous tissue to self-seal the channel immediately following needle removal. SEAL provides guided cannulation for 14-gauge dialysis needles. The device, therefore, has the potential to make treatment initiation easier and to provide a safer method of cannulation. Easier and safer cannulation can give patients and caregivers more comfort for treatment options in the home setting, which are known to yield better outcomes due to the possibility of more frequent treatments and reduced visits to centers that carry additional social contact risks. SEAL was shown to reduce back-bleeding due to its unique valve-needle interaction. The device is durable and withstood 14 years of *in vitro* cannulations. In addition to this durability, the valve only requires about a tenth of a newton to allow access to the underlying fistula wall. The coated valve was shown to significantly prevent bacterial biofilm growth when compared to raw and polished valve samples. Lastly, *in vivo* cannulation showed that the device allowed access to blood flow in a developed fistula and that the valve occluded blood flow through the device and needle site without the need to apply pressure for long periods. SEAL has the potential to change the future of dialysis treatments and improve the quality of life for dialysis patients due the reduction of complications and freedom to have in home treatments.

INTRODUCTION

Tendon homeostasis is maintained by a balance between the magnitude and duration of mechanical loading and a disruption in this balance can lead to tendon degeneration. Tendon degeneration is a widespread pathology and current treatments are not consistently effective due to an incomplete etiological understanding of the disorder. Additionally, tendon disorders are typically asymptomatic until later stages when pain or rupture occur, making it difficult to determine mechanisms underlying the initiation and progression to degeneration. Therefore, animal models of altered loading are needed.

Most animal models cause tendon degeneration by overuse, such as treadmill running. [1] However, many tendon disorders are related to overloading, not overuse, thus, we recently established a rodent overload model of synergist ablation (SynAb) where the Achilles tendon was resected, overloading the synergist plantaris tendon, without increasing the number of loading cycles. [2,3] We showed multi-scale structural changes associated with tendon overload, such as an increased cross-sectional area (CSA) from MRI, increased fibril diameter and density from Scanning Electron Microscopy (SEM), and increased cell density and decreased collagen alignment from histology. While these outcomes suggest tendon degeneration, it was unclear whether the degeneration was induced exclusively from structural changes, since some of the parameters could be either adaptive or degenerative. As such, it was necessary to evaluate functional changes of tendon following overload, as a decrease in stiffness and strength is a key hallmark of tendon degeneration. Therefore, the objective of this study was to investigate the mechanical changes induced by tendon overload. We hypothesized that there would be a decrease in mechanical properties would decrease 8 weeks post-surgery indicating tendon degeneration.

METHODS

Bilateral plantaris tendons from 7-month-old female Long Evans rats were randomly assigned to three groups: SynAb (Achilles tendon resected to overload plantaris tendon), Sham Control (incision made but Achilles not transected), and Intact Control (n=6 tendons/group). At 8 weeks post-surgery, rats were sacrificed and stored in a -20°C freezer until the day of testing. Each rat was thawed at room temperature and the plantaris tendons were dissected. The tendon sheath was removed by sectioning off 150µm of the tendon surface using a freezing stage microtome. CSA was measured across the tendon midportion using a laser displacement device.

Mechanical Testing and Data Acquisition: Each tendon was gripped and placed in a bath solution containing 8% SPEG and mounted on a custom uniaxial device. [4,5] The sample was preloaded to 5mN (0.5g) to establish the reference length and preconditioned for 5 cycles between 0 and 5% strain. Testing included 1) a ramp and hold at 25% strain for 10 minutes, unloaded to reference length for a 15 minute

Figure 1: A) Mechanical testing protocol included Ramp & Hold and Ramp to Failure B) Representative stress-strain curve showing mechanical parameters of interest

recovery, and 2) ramp to failure (Fig 1A). All loading and unloading rates were 1%/s.

Data analysis: Stress was calculated by dividing the force by the CSA and strain (ϵ) was calculated by dividing the change in grip-grip displacement by the initial reference length. The stress-strain curves were analyzed for transition point, yield point and linear region modulus (Fig 1B). [6] The transition point was defined as the end of the toe region and beginning of the linear region. The yield point was calculated first by fitting a cubic smoothing spline using the *csaps* function in MATLAB and finding the first zero crossing point of the second derivative. Yield point was only calculated in the Ramp to Failure because the Ramp & Hold did not always reach a detectable yield point. A nonlinear exponential constitutive model was fit to the stress-strain curve up to the yield point to obtain the transition strain (p), transition stress (q), and linear region modulus (E):

$$\sigma = \begin{cases} A * (\exp(B\epsilon) - 1), & |\forall \epsilon \leq p \\ E * (\epsilon - p) + q, & |\forall \epsilon > p \end{cases} \quad (1)$$

Percent stress relaxation was calculated by dividing the stress at the end of the stress relaxation period by the peak stress.

Non-parametric t-tests were performed between the Intact and Sham groups and there was no difference between the groups for any of the parameters, so they were combined as one Control group to compare with the SynAb group. Differences in material properties were analyzed using Mann-Whitney t-tests. All material properties were compared between treatment groups and the linear region modulus and transition point were additionally compared between Ramp & Hold and Ramp to Failure.

RESULTS

The modulus in SynAb was 54% lower than Control in the Ramp & Hold and 47% lower in the Ramp to Failure ($p < 0.05$), but there were no differences in modulus between ramps (Fig 2A). There were no differences in the transition strain between the treatment groups or loading ramps ($p > 0.6$, Fig 2B). The transition stress in SynAb was 41% lower than Control during the Ramp to Failure ($p = 0.02$) but was not significantly different during the Ramp & Hold ($p = 0.2$, Fig 2C). The transition stress in the Control was 52% higher during the Ramp & Hold

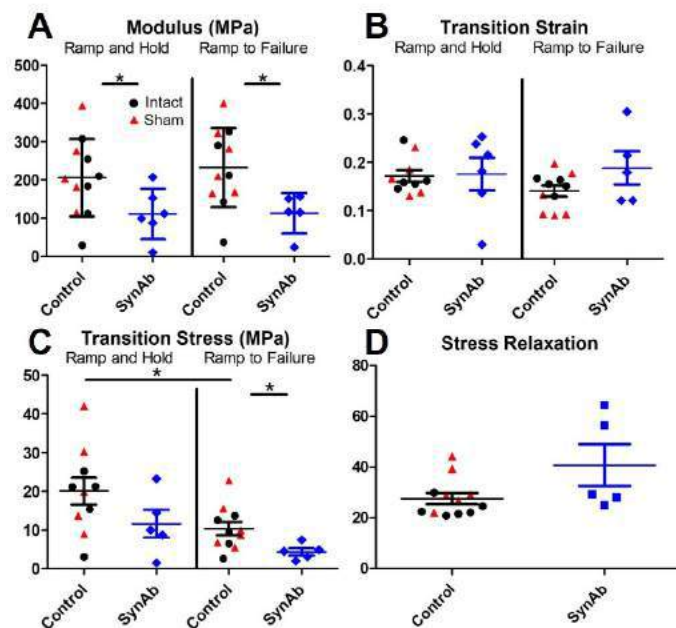

Figure 2: A) Modulus, B) Transition strain, C) Transition stress, and D) Stress relaxation. Where * indicates $p < 0.05$,

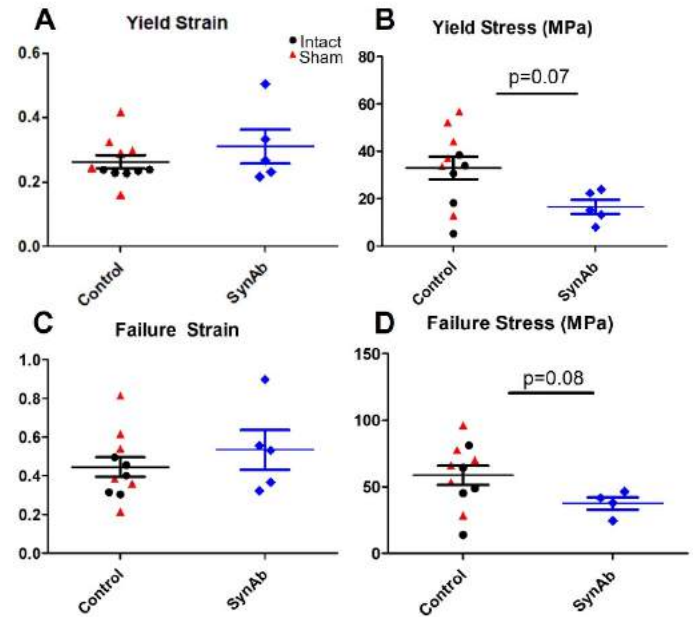

Figure 3: A) Yield strain, B) Yield stress, C) Failure strain, and D) Failure stress. Where * indicates $p < 0.05$

than the Ramp to Failure ($p = 0.03$). There was no significant difference in stress relaxation between treatment groups ($p = 0.1$, Fig 2D).

Yield strain and failure strain were not statistically different between the treatment groups, however, the SynAb yield stress was 52% lower than Control ($p = 0.07$) and the SynAb failure stress was 65% lower than Control ($p = 0.08$, Fig 3).

DISCUSSION

This study showed degenerative mechanical changes following 8 weeks of tendon overload from synergistic ablation in a rat model. Specifically, we observed a decrease in modulus in the SynAb group indicating that increasing mechanical load from SynAb impairs mechanical function. The decrease in modulus could be caused by the observed decrease in matrix organization and collagen alignment from our previous work using the SynAb model. [2,3] The yield stress and failure stress also decreased, with trending significance, likely due to the limited sample size.

The mechanical and structural outcomes in our SynAb overload model are similar to the outcomes observed in overuse treadmill running models. [1] Although both model types cause a degenerative change in mechanical and structural properties, the mechanisms leading up to this degenerative state and the clinical manifestations (rupture versus painful tendinopathy) may be different. Therefore, we will use the SynAb model of tendon overload in future work to explore these potential mechanisms and the progression of these degenerative changes.

MECHANICAL PROPERTIES OF PORCINE IRIS STROMA USING MICRO-INDENTATION: THE EFFECT OF TEMPERATURE AND HYDRATION

INTRODUCTION

Glaucoma is the leading cause of irreversible blindness worldwide, affecting roughly 80 million people [1]. Two major types of glaucoma are categorized by the angle between the iris and the cornea: primary open-angle glaucoma and primary angle-closure glaucoma (PACG). In PACG, the iris bows anteriorly thus blocking the outflow of aqueous humor. The resulting increase in intraocular pressure in the eye could potentially lead to blindness. Previous experiments have shown that the stiffness of the iris in patients with history of PACG is higher than those of healthy subjects [2,3]. Due the importance of iris mechanical properties in the pathophysiology of PACG, experiments such as micro indentation have been used to quantify such properties *ex vivo* [2, 4]. Given the varying experimental environments used in these studies, we aimed to identify how factors such as keeping samples in phosphate-buffered saline (PBS) solution or conducting the experiments in room temperature (RT) versus physiologically relevant 37°C affects the iris stromal mechanical properties. We hypothesized that the samples submerged in 37°C PBS would have significantly different elastic modulus compared to the other groups.

METHODS

Porcine eyes (N=9) were harvested within a 24-h period from 6-month-old pigs (4 male, 5 female). The irides were excised and their posterior surfaces were attached to a flat surface using a biocompatible adhesive. Three irides were used for 3 experimental groups: 1) sprayed with PBS, 2) submerged in RT PBS, and 3) submerged in 37°C PBS. The iris from each group was then indented in 6 clockwise points from 1 to 11 o'clock (Fig. 1). A spherical indenter (Mach-1, Biomomentum, Canada) with 0.5mm diameter was used to indent the iris at 0.005mm/s. Once the surface of the iris was identified, the thickness was recorded, and the tissue was indented to 0.15mN. The sample was then left in that same environment for 20 minutes before being submerged in 37°C PBS. The indentation procedure was repeated for each iris.

Figure 1: Example of indentation experiment (left) with the indentation points marked on the schematic (right).

The resulting load-displacement data were used to calculate the elastic modulus (E) using the method provided by Dimitriadis et al. [5]:

$$F = \frac{16E}{9} R^{1/2} \delta^{3/2} [1 + 1.133\mathcal{X} + 1.283\mathcal{X}^2 + 0.769\mathcal{X}^3 + 0.0975\mathcal{X}^4], \quad (1)$$

where F is the indentation force, R is the indenter radius, δ is the indentation depth and the constant \mathcal{X} is defined as

$$\mathcal{X} = \sqrt{R\delta}/h, \quad (2)$$

where h is the sample thickness. Dimitriadis et al. established this approach for the indentation of soft biological tissues with finite thickness bonded to a substrate using a spherical indenter. Additionally, since most biological samples can safely be assumed to be incompressible, the Poisson's ratio (ν) was set at 0.5 in our calculation.

Using the *fminsearch* function in MATLAB (MathWorks, Natick, MA), we determined the elastic modulus that minimized the error between the experimental force-displacement data and that of Eq. 1.

Statistical analyses were performed in R (R Core Team). The homogeneity of variance for each group was determined using the Levene's test. A two-way ANOVA and Tukey post hoc test were used to identify relationships between the groups where $p < 0.05$ was considered significant. All data are reported in the format of mean \pm standard deviation.

RESULTS

An example of load-displacement plot that was fitted with Eq. 1 is shown in Fig. 2. For this typical example, the R^2 of the fit was 0.92. The R^2 for all fitted parameters ranged between 0.51 and 0.97.

Figure 2: Load-displacement plot showing the raw data in green and fitted line in blue.

Figure 3: Distribution of iris elastic modulus for the before and after environments with the mean marked with a black diamond.

The moduli of initial experiments in the different environments were 4.29 ± 2.60 , 3.73 ± 3.03 , 3.35 ± 2.89 kPa, for groups 1, 2, and 3, respectively. The respective moduli after all samples were submerged in 37°C PBS were 4.66 ± 3.27 , 2.98 ± 2.51 , and 2.13 ± 1.13 kPa. We found that the data was not normally distributed when lumped together

and in the individual groups, but they had equal variances in both instances. We found no statistical difference between the lumped before and after conditions from the ANOVA as seen in Fig. 3. There was, however, a significant difference between the group interactions. The Tukey post-hoc test revealed there was no significant difference between any of the groups except for group 1 and group 3 ($p=0.02$).

Figure 4: Distribution of iris stiffness data, E, for each group with the mean marked with a black diamond.

DISCUSSION

Our hypothesis was not supported since our study indicates that the mechanical properties of iris stroma may not change significantly whether the samples are tested in room temperature or in 37°C in the given timeframe. We could not make any reliable conclusions about the difference in environmental salinity despite there being a significant difference in the stiffness of irides that were sprayed by PBS and those that were submerged in 37°C PBS. The insignificance in stiffness between the initial environment and the final environment in any of the groups muddies our abilities to make a strong conclusion regarding how the tissue is kept hydrated.

We stipulate that with a larger sample size we might be able to observe the difference being negligible across all methods of hydration. We ran a power analysis with a large effect size (0.5), and it showed that for a 95% confidence interval and power of 0.8, N would have to be at least 25. The increased sample size could also potentially lead to a normalized distribution of data.

Accordingly, the biggest limitation in our study was the small sample size. Despite being able to collect multiple data points per iris, we believe having more irides per sample group would behoove us in drawing more obvious conclusions. This study furthers our understanding on how to obtain reliable characterization of the mechanical properties of irides that may be exposed to prolonged environmental factors.

TOMOGRAPHIC X-RAY PARTICLE TRACKING VELOCIMETRY AND POSSIBLE APPLICATIONS IN BIOLOGICAL FLUID DYNAMICS

Jason T. Parker, Simo A. Mäkiharju

Mechanical Engineering, UC Berkeley, Berkeley, CA, USA

INTRODUCTION

Studying biological fluid flows outside of their natural environment introduces uncertainty compared to true in-vivo measurements. Boundary conditions, material properties, and scale in an artificial environment differ from a true biological environment. These challenges make in-vivo measurement techniques particularly valuable. Recent developments in laboratory-scale X-ray particle tracking velocimetry (XPTV) [1–3] present an opportunity for non-invasively measuring biological flows with comparatively high spatiotemporal resolution.

Tomographic- and stereo-XPTV (TXPTV and SXPTV) capture all three velocity components in 3D space (3D3C), and will soon be able to supplement ultrasound and magnetic resonance imaging (MRI) as an in-vivo measurement option. For example, MRI's voxel resolution, $O(0.1 - 1 \text{ mm}^3)$, and temporal resolution, $O(100 \text{ ms})$, [4–6] could in many cases be surpassed with TXPTV and SXPTV. 3D ultrasound scans have limited penetration depth that must be balanced with spatial resolution. Scans often take a few seconds and thus have limited temporal resolution.

The experiments presented herein are a proof-of-concept showing that TXPTV is currently able to capture velocity measurements at 2 Hz with a voxel resolution of $4 \text{ }\mu\text{m}$, a marked improvement in spatial resolution over the state of the art and alternative techniques. There is room for future improvement to TXPTV that will increase temporal resolution and reduce radiation dose. Naturally, one of the concerns with X-ray measurement techniques in biological applications is the absorbed radiation dose. Approximate absorbed dose calculations are provided in the Methods section.

We hope to introduce these techniques to the biological fluid dynamics community as a uniquely capable measurement option that will see rapid improvement over the next few years. For example, the TXPTV measurements presented here are an order of magnitude faster than Mäkiharju et al. [3].

METHODS

Tomographic X-ray Particle Tracking Velocimetry (TXPTV) is used to measure the 3D3C velocity of Poiseuille pipe flow and a rising Taylor bubble. A model of the experiment can be seen in figure 1. Experiments are

conducted in pure glycerine to minimize the entrance length considering the pipe length is only 15 cm. Glycerine also retards the rise of the Taylor bubble so we can resolve its motion. For the pipe flow the glycerine is pumped at a constant 0.0950 mL/min flow rate by a Harvard Apparatus Pump 33 DDS syringe pump ($Re = 8.8 \times 10^{-4}$), well within the Stokes viscous flow regime. For the Taylor bubble, 0.5 mL of air is injected into static fluid ($Re = 0.014$). The 6.35 mm (0.25 in.) inner diameter pipe is rotated at 720 dps for the pipe flow and 1080 dps for the Taylor bubble. Alternatively, one could rotate the source-detector pair to keep the object static. In this setup, though, we are limited to keeping the source-detector pair static. SXPTV requires no rotation if multiple source-detector pairs are used.

Figure 1: The X-ray imaging setup for Poiseuille pipe flow. A pipe is secured to a rotation stage in front of the Metaljet E1+ X-ray source.

A Metaljet E1+ liquid metal X-ray source is set to operate at 160 kV and 700W; projections are captured with an XC-Thor photon counting detector at 1 kHz. The source-to-detector distance (SDD) and source-to-object distance (SOD) are 521.5 mm and 56.5 mm, respectively, yielding a field of view that is 2.17 cm wide by 0.28 cm tall. In both experiments $O(50 \text{ }\mu\text{m})$ diameter tungsten-coated hollow carbon microsphere (CW) particles – developed by Parker and Mäkiharju in [1] – are used as tracer particles. These particles generate better contrast than other available particles, reducing the necessary exposure time, thereby increasing temporal resolution and

reducing radiation dose.

An approximate dose can be obtained using the Beer-Lambert law, which calculates the number of entrained photons, and thus the deposited energy, in a material of a given thickness for a given incoming X-ray source.

Table 1 shows the calculated dosage in 10 cm^3 blood and soft tissue if the Metaljet E1+ X-ray source is used to capture 1 sec worth of data (equivalent to a two-exposure measurement at 720 dps rotation). The 10 cm^3 represented the exposed volume assuming the same field of view as is used here and assumes a 16.5 cm depth. NIST X-ray attenuation coefficients and densities based on ICRU-44 materials are used to calculate these dosages. In reality, a much larger area would be exposed for a biological scan, reducing the equivalent dose. Furthermore, different approaches such as SXPTV could be taken to reduce the exposure time, which will be reserved for the Discussion section. These equivalent doses should be taken to be a vast overestimate of the real equivalent dose a subject would experience. Nevertheless, these dosages are equivalent to approximately six full-body CT scans [7].

Table 1: The equivalent dose in 10 cm^3 of three ICRU-44 materials calculated with the TXPTV settings used in this study.

Material	Dose (mGy)
Average Annual	6.2
Blood	125
Soft Tissue	126

RESULTS

The measured Poiseuille pipe flow profile can be seen in figure 2. The data show qualitative agreement with the theoretical profile, although the peak velocity is underestimated. There is also substantial spread in the data that could be due to particle localization error. A rudimentary particle tracking code is used to process the data and is an area for future improvement. The data suggest that erroneous particle tracks are the root cause for the slower measured velocity profile.

Figure 2: The Poiseuille pipe flow velocity profile measured with TPXTV. The flow rate is 0.0950 mL/min for a maximum speed of 0.01 cm/s.

The streamlines measured from the rising Taylor bubble can be seen in figure 3. Due to the limited FOV, only the flow atop the Taylor bubble was measured. Interestingly, it is possible to reconstruct the flow environment with TXPTV. We can, for example, reconstruct the Taylor bubble in 3D as it moves through the FOV. This capability could potentially be used in tandem with velocimetry to identify patient/specimen-specific morphology.

Figure 3: Short streamlines of the flow atop a Taylor bubble, captured over the course of six reconstructions (2 sec), i.e. frames.

DISCUSSION

These experiments demonstrate the potential of TXPTV as a non-invasive 3D3C flow measurement tool in opaque media applications in a laboratory environment. The spatiotemporal resolution in this study is an order of magnitude better than previous TXPTV measurements, indicating that rapid improvement is possible in the near future. The next step is to apply TXPTV to flow systems that are otherwise difficult to observe. Non-invasive 3D3C flow measurement techniques are of high value for in-vivo biological fluid dynamics applications such as hemodynamics. TXPTV experiments such as those done here offer a nearly three order of magnitude improvement in spatial resolution compared to MRI and the fundamental limit to temporal resolution (detector frame rate) is much higher than MRI. TXPTV could complement or, in certain situations, be substituted for MRI measurements.

While the dosage for TXPTV may currently be comparatively high, techniques such as SXPTV can dramatically reduce the exposure time. The temporal resolution for SXPTV would not be limited by the object rotation speed, but instead by the detector frame rate. Using the same procedure as above, the equivalent dose drops to 0.5 mGy for 10 cm^3 of blood and soft tissue with SXPTV. These are, again, overestimates of the actual equivalent dosage. SXPTV can also be achieved with limited-angle rotations of the object, which is not attempted here.

In-lab TXPTV is presently able to measure optically opaque biological systems in-vivo, offering the potential to observe biological flows with unprecedented spatiotemporal resolution.

QUANTIFICATION OF EMBOLUS TRANSPORT TO THE BRAIN FROM CAROTID STENOSIS SITES

Ricardo Roopnarinesingh (1), Neel Jani (2), Michelle Leppert (3), Debanjan Mukherjee (1)

INTRODUCTION

Embolic stroke accounts for a majority of all ischemic stroke patients with some studies categorizing up to 60% of these cases as Embolic Stroke of Undetermined Source (ESUS) [1]. Current ability to identify embolic stroke etiology are limited and improvement can lead to increased treatment efficacy and reduced recurring stroke events [2]. Carotid arteries are one major source of stroke, where build up of atherosclerotic plaques can create thromboemboli that move into the cerebral arteries. Carotid endarterectomy (CEA) is a procedure commonly used for severe cases of carotid atherosclerosis to remove plaque buildup. Specifically, CEA is indicated when a patient has a North American Symptomatic Carotid Endarterectomy Trial (NASCET) severity greater than 70% in the ipsilateral carotid along with corresponding symptoms such as transient ischemic attacks (TIA) according to the American Heart Association (AHA) guidelines. CEA is considered if the patient has a severity between 50% and 69% along with symptoms but is not required [3]. It is commonly thought that emboli directed into the Circle of Willis (CoW) will cause ipsilateral embolic events but there have been known cases where emboli cause contralateral cerebral stroke events. Although contralateral events are less frequent, these cases contribute to the inherent difficulty in disambiguating stroke etiology. With both carotids being suspect to combinations of severe and non-severe levels of plaque buildup, the source of ambiguity in contralateral events could lead to a patient who would benefit from receiving a CEA not being qualified per the AHA guidelines. There is currently a lack of understanding in how patients with carotid disease may experience contralateral embolic events in various levels of carotid stenosis. Here, we present an *in silico* study analyzing how different combinations of varying carotid stenosis may present contralateral embolic events and how the altered hemodynamics with the introduction of a stenosis can affect embolus transport.

METHODS

Image-Based modeling: A patient-specific model was created from the aortic arch to the CoW using the open-source program Simvascular [4, 5]. This patient had a complete CoW anastomosis with healthy

(non-stenotic) carotid arteries. Stenosis were computationally applied to each carotid artery using this healthy patient segmentation model by manually decreasing the diameter of the carotid bulb area to the corresponding NASCET severity. The stenosis degrees were categorized into three non-severe NASCET scores of [10%, 25%, 40%], and three high-moderate/severe NASCET scores of [50%, 70%, 85%]. These severity ranks were paired to where one carotid would have a non-severe stenosis and the other would have a high-moderate/severe stenosis for both the left and right carotid arteries. This totaled to 18 different models each with a unique pair of non-severe and high-moderate/severe stenosed carotids. The modeling of these differing severities can be seen in Figure 1.

Figure 1: Patient-specific heart-to-brain pathway with varying applied left and right stenosis modifications of the carotid arteries. [4]. SB³C2023-497
Copyright 2023 SB³C Foundation, Inc.

Hemodynamics simulation: Hemodynamics across the aorta-CoW model was simulated using a stabilized finite element method for incompressible Navier-Stokes equations implemented in SimVascular [5]. Blood was assumed to be a Newtonian fluid with viscosity 4.0 cP and bulk density 1.06 g/cc. A validated pulsatile flow profile with a cardiac cycle of 0.83 seconds was applied to the aorta inlet [6]. Downstream vascular beds were accounted for by applying resistance boundary conditions to the outflow vessels of the model. These resistance values were acquired by calculating a total arterial resistance and distributing this resistance proportionally to each outflow artery based upon target flow divisions. 65% of the flow was set to exit the descending aorta [7]. The six cerebral artery outflows were split based upon data reported in [8]. The remainder flow was assigned to the subclavian and external carotid arteries based on their cross-sectional area [9]. The resistance values remained the same across all 18 models to see how flow patterns differed solely due to introduction of the stenosis.

Embolus Transport: Embolus transport was modeled using a custom modified version of the Maxey-Riley equation [10]. These modifications included adding near-wall shear gradient lift forces, particle collisions with the walls of arteries, and elasto-hydrodynamic effects near-wall [4]. Particles were given the mechanical properties of thrombo-emboli [11] and an embolus size of 500 μ m. The emboli were assumed to be spherical particles with a one-way coupled fluid interaction. For each model, approx. 5,500 emboli were released along the artery wall (mimicking release from plaque wall) from the stenosis surface to model plaque emboli. Cardiac emboli were also modeled by releasing emboli from the inlet of the aorta to see how different combination of stenosis severities may affect the pathway of cardiogenic emboli to the CoW.

RESULTS

Figure 2: Proportion of emboli that distribute contralaterally. Emboli are released from both the left carotid and the right carotid arteries for each stenosis model of differing severity.

Embolus distribution was computed as the percentage of particles that exit each of the six outlets of the CoW. Figure 2 presents the proportion of emboli that distributed contralaterally into the CoW from the respective carotid in each stenosis model. Each model is labeled by their combination of left-right severity respectively (i.e. 10L50R corresponds to the model with a 10% left carotid stenosis and a 50% right carotid stenosis). Each model produced a non-zero contralateral distribution, meaning that all combinations of severe and non-severe stenosis show the potential for contralateral occlusions. The largest proportions of contralateral movement were found in the models with 85% stenosed carotid, where contralateral movement was highest from the non-severe carotid release. These models had a contralateral proportion between 6% and 10% which was much higher than the other releases that were mostly between 0.5% and 4%. Additionally, distribution fractions for cardiogenic emboli were computed. These distributions were acquired to inform how emboli from the heart would be influenced by the altered hemodynamics due to presence of a stenosis. The distribution of cardiac emboli across all models averaged 55% and 45% (standard deviation of 4.78%) for the left and right hemi-

spheres respectively. Cardiogenic emboli are not strongly directionally influenced by the presence of stenosis and distributions were marginally affected by the stenosis severity, indicating that significant number of emboli travel across the communicating vessels of CoW for these models.

DISCUSSION

Our investigation implemented a patient-specific embolus transport model to characterize embolus transport contralaterally from the left and right carotid arteries in the presence of varying degrees of stenosis. Altered hemodynamics to the CoW cause differing embolus transport patterns due to the stenosed carotids. Specifically, the CoW is supplied with blood flow through three arteries: the left internal carotid (L.ICA), the right internal carotid (R.ICA), and the basilar artery. Since all models have same total cerebral blood flow, Figure 4 illustrates how the proportion of flow through each of these three arteries changes with respect to stenosis severity. Models with high severity could see up to a 30% decrease in flow through the stenosed ICA, wherein the less stenosed carotid and basilar artery compensate with increased flow rates. The increased compensatory flow can in turn drive contralateral movement of emboli from the mild-moderate stenosis sites, while preventing contralateral transport of emboli from the severe stenosis sites. Communicating vessels of the CoW such as the anterior communicating artery (AcoA) will facilitate these contralateral movement, which needs further quantification in future works. Likewise, cardiogenic embolus distribution has a consistent trend across stenosis severity due to compensatory flow from the basilar artery as observed from our simulations. Ultimately, these cases of contralateral movement present difficulties in disambiguating embolus source that can lead to inconsistent recommendations for procedures such as CEA.

Figure 3: Proportion of flow rate through each of the three arteries feeding the CoW: the left internal carotid artery (L.ICA), the right internal carotid artery (R.ICA) and the basilar artery (BA).

INTRODUCTION

The long-term goal of this project is to develop an injectable and translational mRNA delivery platform specifically designed to localize therapeutic expression within a fracture site. Approximately 15 million fractures occur annually in the United States with 10-20% of fractures resulting in delayed healing or non-union.^{1,2} There are currently no pharmaceutical approaches approved to accelerate fracture healing or to treat non-unions. Current standard of care for non-unions involves surgical intervention to enhance stability and/or to promote regeneration through bone grafting. Delivery of mRNA is an attractive strategy recently popularized by the novel coronavirus vaccine that delivers genetic material without genomic integration.³ Liposomes have been frequently employed for the delivery of mRNA to combat limitations seen with mRNA stability; however little mRNA work has been completed in the field of orthopaedics. Recently, localized gene delivery has shown to be therapeutically efficacious in healing a large osseous segmental defect through having a scaffold delivering modified BMP-2 mRNA.^{4,5} In this study we aimed to test various mRNA delivery platforms specifically for fracture healing, including lipid nanoparticles (LNPs) complexed with Firefly luciferase mRNA. We hypothesize that the fully translational and injectable-based LNP therapeutic will sufficiently prolong transfection efficacy in order to be used for orthopaedic applications as tested in our murine tibial fracture healing model.

METHODS

LNPs have previously been found to encapsulate various genetic material and were assembled using microfluidic technology producing scalable and reproducible nanoparticles. Two different LNPs were tested involving the same synthesis steps, yet phospholipids MC3 and SM-102 were used separately during synthesis. All *in vitro* studies were performed using the ATDC5 chondrocyte cell line. Transfection kinetics and efficiency were studied using Firefly mRNA (TriLink Biotechnology) as a reporter gene and mRNA was isolated at various timepoints following delivery. Firefly luciferase (FFLuc) was used to measure the level of transfection and inflammatory markers (*IL-1 β* , *TNFA*) were used to assess platform interference with fracture healing. All of the procedures listed in this study were approved by our Institutional Animal Care and Use Committee (IACUC) and ARRIVE guidelines will be followed in reporting *in vivo* results. Delivery platforms were tested *in vivo* using a murine tibial fracture model stabilized with an intermedullary rod and all mRNA platforms were injected into

the fracture callus 6 days following fracture induction, within the fibrovascular phase of murine fracture healing. IVIS imaging was used to locate and quantify firefly luciferase protein. RNA was isolated from the fracture callus to measure inflammatory and osteogenic genes using qRT-PCR.

RESULTS

LNPs have previously been reported to deliver mRNA *in vitro* yet have not been studied *in vivo* for fracture repair applications.⁶ To determine LNP's capabilities for transfecting a fracture callus, mRNA encoding for FFLuc was delivered in BM-MSCs testing for luciferase expression and metabolic activity. Significantly more transfection efficacy resulted when delivering FFLuc mRNA encapsulated in SM-102 LNP's as compared to MC3 LNPs (**FIG 1A**). No significant differences were found in metabolic activity using either MC3 or SM-102 LNPs (**FIG 1B**). Biodistribution study revealed that no significant differences were found in luciferase expression between treatment groups in any of the organs tested, except in the fracture callus (**FIG 2**). *In vivo* transfection efficacy and kinetics of LNPs over 10 days post-injection into the fracture callus revealed that SM-102 LNPs had prolonged transfection kinetics over the MC3 LNP group (**FIG 3**). RNA isolated from fracture callus suggested that SM-102 does not interfere with fracture repair (**FIG 4**).

Figure 1 (Above) A). Transfection efficacy of mRNA delivery platforms, MC3 and SM-102 LNPs, *in vitro*. **B).** No differences in metabolic activity were noted.

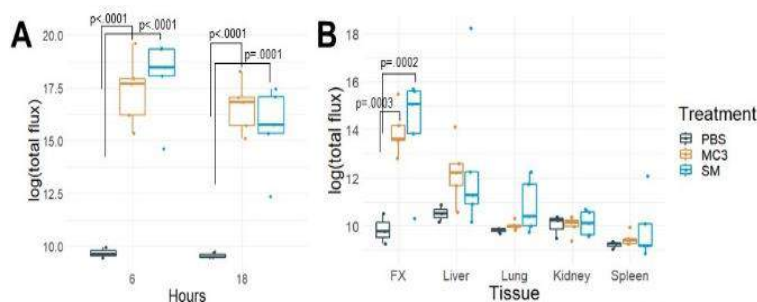

Figure 2 (Above) A. Quantification of IVIS images. **B.** Biodistribution study shows minimal off-target distribution when delivering Firefly luciferase mRNA using various delivery platforms.

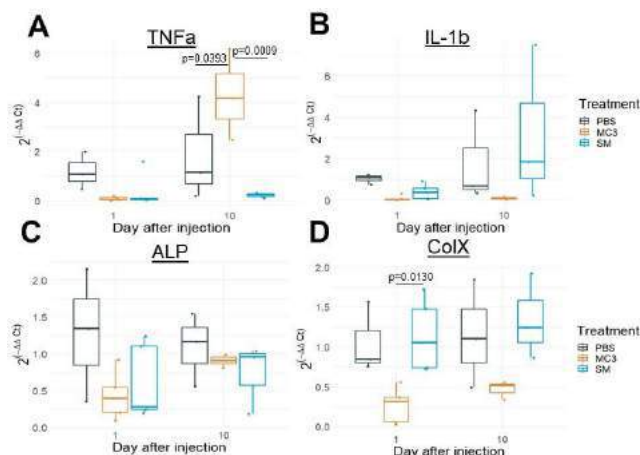

Figure 4 (Above) qRT-PCR analysis of RNA isolated from fracture callus shows reduced inflammatory response (A-B) for SM-102 and suggests that LNPs do not interfere with fracture repair (C-D).

DISCUSSION

There exists an unmet clinical need to stimulate bone regeneration through a non-surgical delivery platform. In order to combat the precedence of non-union and delayed healing in fractures, we are developing an injectable-based mRNA therapeutic using engineered LNPs to deliver mRNA locally to the site of the fracture callus. In this study, we aimed to develop a fully translational and localized mRNA delivery platform to improve therapeutic mRNA delivery for fracture repair. Here we show, for the first time, that SM-102 LNPs has the capabilities to extend and prolong mRNA transfection up to 10 days following injection with significantly more expression over PBS control up to 7 days. This LNP system can be utilized to deliver an osteogenic promoting mRNA transcript which shows that it does not interfere with fracture healing or promote an inflammatory response on its own.

INTRODUCTION

Machine learning (ML) techniques, especially deep neural networks (DNNs), have been developed to build surrogates of finite element analysis (FEA) and computational fluid dynamics (CFD) in a variety of applications, with the goal of speeding up the computations. In our previous studies related to thoracic aortic aneurysm (TAA), we developed DNNs for aortic wall stress analysis [1], steady-state hemodynamic analysis [2], and inverse estimation of material properties [3], which all perform much faster than traditional methods.

ML techniques have a fundamental limitation: ML model output may have large errors if the input is out of the distribution (OOD), i.e., very different from the training samples. For data-driven applications, such as image classification, this OOD issue is unavoidable [4].

In this study, we integrate the finite element method (FEM) and DNNs for forward and inverse analysis of human aorta, which guarantees the accuracy of the final output. Our contributions include: (1) a Pytorch implementation of FEM for aortic wall deformation and stress analysis, (2) five types of DNNs for aortic wall large deformation prediction, (3) integration of DNNs and FEM for aortic wall deformation and stress analysis, and (4) integration of DNNs and FEM for inverse estimation of hyperelastic material properties.

METHODS

Using the Pytorch library, which is an open-source library for implementing DNNs, we implemented FEM for aortic wall deformation and stress analysis. We have validated our implementation by comparing it with Abaqus, and the discrepancy is negligible. As shown in Figure 1, it has a modular design and therefore supports different material models and geometries. The basic finite element is similar to C3D8 in Abaqus, which unitizes selective-reduced-integration technique to handle volumetric-locking issue that may be present for nearly-incompressible materials. The optimizer uses a quasi-newton method that needs the hessian (i.e., stiffness) matrix. Since Pytorch has

auto-differentiation ability, all of the differential calculations are done automatically by using Pytorch functions. Given the material parameters and zero-pressure geometry as the inputs, the goal of the FEM is to compute the aorta geometry at the target blood pressure by minimizing the total potential energy [5].

Figure 1: The Pytorch-implementation of FEM for aortic wall stress and deformation analysis.

In this study, we use the well-known GOH material model $\Psi = C_{10}(\bar{I}_1 - 3) + \frac{k_1}{2k_2} \sum_{i=1}^2 [\exp\{k_2[\kappa \bar{I}_1 + (1 - 3\kappa)\bar{I}_{4i} - 1]^2\} - 1] + \frac{1}{D} [\frac{J^2 - 1}{2} - \ln J]$, which has five material parameters $\{C_{10}, k_1, k_2, \kappa, \theta\}$.

To build ML-surrogate models (i.e., DNNs), we created a dataset of 342 shapes using statistical shape models of the zero-pressure geometries, similar to our previous approach [1]. By inflating the 342 zero-pressure geometries with 125 sets of material parameters from zero pressure to the systolic pressure (18KPa assuming hypertension), we obtained a large dataset for training and testing DNNs. The dataset is further divided into a training set including 50% of the shapes and 80% of the material sets, a validation set including 10% of the shapes and 10% of the material sets, and a test set including 40% of the shapes and 10% of the material sets.

We developed five types of DNNs to serve as ML-surrogate models, to predict the aorta geometry at the systolic pressure. Given a predicted aorta geometry from a DNN, we use the FEM method to

calculate the stress distribution on the aorta. The baseline DNN is a simple multilayer feedforward DNN (a.k.a. MLP). We adapted the MeshGraphNet [6] for our application, which is a state-of-the-art graph neural network to simulate mesh deformation. We implemented a U-Net to predict the aorta deformation, which is originally proposed for image segmentation [7]. We designed a TransNet based on the Transformer architecture that is originally proposed for natural language processing [8]. Finally, we designed a novel W-Net whose weights are determined by another network.

We conducted two experiments of ML-surrogate: (1) fixing the material set (using the mean material), and then training and testing the DNNs to predict the deformation given the zero-pressure geometry; and (2) using all the material sets and shapes, and then training and testing the best DNN from (1) to predict the deformation given the zero-pressure geometry and material parameters.

Integration of DNNs and FEM for forward computation: the output from a DNN serves as the starting state for the FEM. The idea is simple, but it won't work if FEM directly uses the DNN output because FEM assumes the starting state is in force-equilibrium that is not guaranteed by the DNNs. We modified the FEM optimizer to handle this issue.

Integration of DNNs and FEM for inverse estimation of material properties: similar to the forward task, to inversely estimate the material properties, we could simply re-define the inputs and outputs of a DNN and use the DNN-predicted material properties as the initial solution for a FEM-based inverse method. In this study, we show another way of integrating DNNs and FEM for inverse estimation of material properties: a DNN can serve as a smoothness constraint to estimate inhomogeneous material properties of the aortic wall, i.e., $m(x) = DNN(x)$ where m is a material parameter and x is the location of a point on the aortic wall. The predicted material parameter m will be one of the inputs to FEM (Figure 1). Because the FEM is implemented in Pytorch, backpropagation can be utilized to find the optimal values of the material parameters, such that the loss function is minimized: $loss = \frac{1}{N} \sum_i \|f_i^{internal} - f_i^{external}\|^2$ where $f_i^{internal}$ is the internal force (from stress) and $f_i^{external}$ is the external force (from pressure) on the node- i of the aortic wall mesh model that has N nodes. The $loss$ is a function of the material parameters and the weights of the DNN.

RESULTS

MRSE (mean root square error, unit: mm) measures the difference between the predicted geometry and true geometry at the systolic pressure. APE (absolute percentage error) measures the difference between the predicted and true peak von-mises stresses. Avg stands for average over the test samples.

Table 1: DNN Performance in Experiment-1.

	MRSE (avg)	MRSE (max)	APE (avg)	APE (max)

MLP	0.0003	0.0009	0.04%	0.11%	2.46%	6.37%

Table 3: DNN Performance in Experiment-2.

	MRSE (avg)	MRSE (max)	APE (avg)	APE (max)
W-Net	0.1072	2.6715	>100%	>100%

Table 4: DNN-FEM-Integration Performance in Experiment-2.

	MRSE (avg)	MRSE (max)	APE (avg)	APE (max)	Time (avg)	Time (max)
W-Net	0.0002	0.0032	0.02%	0.11%	1.47%	9.89%

Note: the computation does not converge for 3.65% of the test samples and therefore those are excluded.

Table 5: DNN-FEM-Integration Performance for The Inverse Task

MLP	C_{10}	k_1	k_2	κ	θ	loss
none	27.03%	15.35%	24.88%	3.64%	1.26%	0.2066
4-128	0.97%	0.66%	1.23%	0.14%	0.01%	0.0053
4-256	0.46%	0.27%	0.50%	0.06%	0.01%	0.0027
4-512	0.56%	0.32%	0.34%	0.06%	0.01%	0.0023
6-128	0.24%	0.15%	0.37%	0.03%	0.01%	0.0026
6-256	0.23%	0.12%	0.25%	0.02%	0.01%	0.0016
6-512	0.57%	0.34%	0.37%	0.07%	0.01%	0.0019

note: the table shows the percentage error of each estimated parameter. "none" means DNN is not used. "m-n" indicate the DNN (i.e., MLP) has m hidden-layers and each hidden-layer has n units. The computation takes about 1 to 2 hours for each DNN model.

As shown by Table 1 and 3, the maximum peak stress errors of the DNNs are unacceptably large for some samples in the test set, indicating the OOD issue. As shown by Table 2 and 4, DNN-FEM-Integration has negligible errors and minimal time cost, compared to FEM.

As shown by Table 5, the DNN-FEM-Integration was able to recover inhomogeneous material properties, and the loss could serve as the indicator for model selection.

DISCUSSION

This study demonstrates that the integration of DNN and FEM can resolve the OOD issue of the data-driven ML-surrogates. It also shows that DNNs can serve as spatial smoothness constraint for the estimation of inhomogeneous material properties (ex-vivo) of the aortic wall.

INTRODUCTION

Mechanical loads can stimulate growth and healing in soft tissue, and numerous studies have investigated this mechanobiological response *in vitro* using 3D scaffolding materials such as collagen or polyurethane. Yet, the physical mechanism that governs this response under complex in-vivo loading conditions remains unknown. This knowledge gap has hindered efforts to develop more effective therapies for soft tissues injuries that are responsible for 15 million hospital visits every year in the U.S. [1]. One intriguing theory is that cell mechanosensing is regulated by a material's strain energy [2].

Strain energy is a scalar measure of deformation in biological and nonbiological materials. It can be decomposed into hydrostatic energy that relates to volume change, and distortion energy that relates to shape change. Energy-based theories are reliable in predicting structural changes in materials. For example, hydrostatic energy is predictive of cortical bone remodeling [3] while distortion energy theory is an excellent predictor of failure in ductile materials [4]. Strain energy has the potential to create a unifying theory to predict cellular responses to any loading configurations (e.g. tension, compression, biaxial, triaxial), something that has not been possible using stress-based and strain-based mechanisms, but the lack of accurate experimental methods to apply targeted strain energy levels makes the investigation difficult.

Bioreactors can apply mechanical loads on 3D cellular constructs to study the resulting mechanobiological response. They often apply simple uniaxial loads (tension or compression) or more physiological complex loads (e.g., biaxial, triaxial), but no mechatronic control system has been developed to apply targeted strain energy levels, which is needed to hopefully develop a unifying theory to predict cellular response to mechanical loads.

The objective of this work was to develop a novel automated method to apply targeted energy levels to 3D constructs undergoing dynamic mechanical stimulation. The accuracy of the method will be verified with 3D constructs subjected to simple and complex loads.

METHODS

A custom biaxial bioreactor (Fig. 1) was previously created by our group to simultaneously apply tensile and compressive loads to cell-seeded constructs [5]. In brief, it consists of a tissue chamber where a specimen is clamped for testing, and each of its two axes uses an electromagnetic actuator for motion and a 1.0N-load sensor.

Two LabVIEW programs were developed. The first program optimized the force input to apply a user-specified strain energy under cyclic stimulation (Fig. 2), and the second program used the optimized input force to apply the targeted strain energy for a user-specified number of stimulation cycles and days. Strain energy was normalized to volume to compute strain energy density. Strain energy density W can be computed as the area under the characteristic stress-strain curve (Fig. 2), where σ and ϵ denote engineering stress and strain, respectively.

This area can be computed numerically using the trapezoidal numerical integration technique (Fig. 2). Additionally, the energy can be decoupled into its hydrostatic and distortion components using a numerical method previously developed and validated by our group [6]. Energy optimization is performed iteratively using a modified version of the secant root-finding algorithm (Fig. 2).

Figure 1: Biaxial tension - compression bioreactor

Method verification. Polyurethane foam samples were cut into dog bone shape, hydrated, then clamped inside the tissue chamber of the bioreactor. Samples were subjected to one of 3 loading conditions ($n=3$ per group): uniaxial tension (T), uniaxial compression (C), and biaxial

compression-tension at equal magnitudes (CT). A single targeted strain energy density of 100 J/m^3 was prescribed to the samples in all loading cases based on preliminary studies that show that this energy results in physiologically relevant tensile strains (2-5%) [7]. For each sample, the energy-optimization program was run first to determine the necessary input force, which was then entered in the force-

Figure 2: Novel energy optimization method

control program to stimulate the sample for 30 minutes at a 1 Hz-frequency. Correction factors of ~5% were applied to the forces in the biaxial loading case to account for frictional effects. The steady state energy was then computed and compared to the target energy to calculate accuracy (measured – target) and percent error. A one-way ANOVA and Tukey-HSD post-hoc was performed to detect differences in energies between loading configurations.

Application to cell-seeded constructs. To verify that our method did not accelerate cell death, it was applied to a cellular construct subjected to biaxial CT. Murine fibroblasts (Sigma Aldrich) were acquired, plated, allowed to grow in an incubator until confluency, and collected for seeding using standard protocols [7]. 3 polyurethane foam samples (DSM Biomedical) were cut into a dog bone shape, sterilized, seeded with 10^6 cells per sample, and statically cultured for 24 h.

The bioreactor (Fig. 1) was sterilized and placed inside the incubator for stimulation. After the static culture, one cellular construct was clamped inside the tissue chamber of the bioreactor and submerged with growth medium. The novel method was applied to dynamically stimulate the cellular construct in CT at a 1Hz-frequency, for 8 h per day, for 2 days, and at a total target energy of 100 J/m^3 . Two constructs stayed unstimulated inside the incubator to serve as controls. All constructs were analyzed with an XTT cell proliferation assay (Cayman) to determine metabolic activity using standard protocols. In brief, XTT solutions were added to sectioned-out middle regions of the constructs and left to incubate for 2 hours. The solutions were then collected and placed in a spectrophotometer (Fisher-Sci). Absorbance values were read at 450 nm and normalized to scaffold-only controls.

RESULTS

The novel method accurately applied the target energy with a percent error less than 5% (table 1) and with an average of about 6 iterations to convergence (Fig. 3A). To reach the target energy, the specimens required forces of $0.12 \pm 0.003 \text{ N}$ in T, $0.24 \pm 0.015 \text{ N}$ in C, $0.11 \pm 0.006 \text{ N}$ in CT-tension, and $0.16 \pm 0.007 \text{ N}$ in CT-compression. These resulted in strain values of $2.34 \pm 0.02\%$ in T, $7.45 \pm 0.49\%$ in C, $1.05 \pm 0.1\%$ in CT-tension, and $6.38 \pm 0.20\%$ in CT-compression. Additionally, the numerical method successfully decoupled the energy in the constructs and revealed a significant difference in distortion and hydrostatic energies in the combined loading case compared to the simple loading cases (Fig. 3B). Furthermore, the method preserved cell

activity in the fibroblast-seeded construct with an absorbance reading of about 11% higher than control samples.

Table 1: Average accuracy in applied energy per loading condition

	T	C	CT
Target Energy (J/m^3)	100	100	100
Actual Energy (J/m^3)	104.6	101.1	101.5
Percent Error (%)	4.55	1.11	1.49

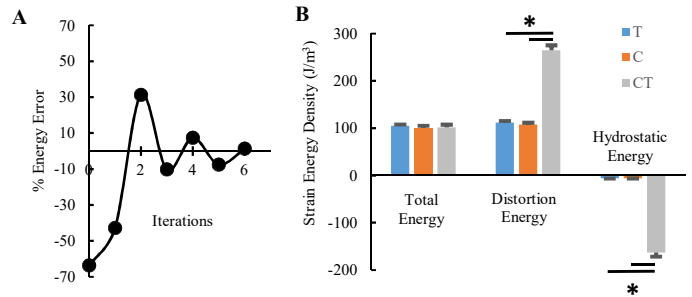

Figure 3: A) Energy optimization iterations. B) Total, distortion, and hydrostatic energies per loading condition (* $p < 0.05$).

DISCUSSION

This work presents a novel experimental methodology to apply targeted levels of strain energy to 3D constructs. The method accurately applied the selected target energy to acellular constructs that underwent similar total energy levels but significantly different distortion energy levels (Fig. 3B). Additionally, the method did not accelerate cell death in constructs that were subjected to a biaxial CT loading configuration.

Interestingly, negative hydrostatic energies were computed in the constructs in all loading conditions (Fig. 3B). This supports previous findings that large Poisson's ratio materials like polyurethane foams display negative hydrostatic energies [6]. Several soft tissues such as ligaments and tendons are also known to display unusually large Poisson's ratios [8]. This phenomenon has been explained by fluid exudation in those materials during loading [6, 8].

Several notable challenges were overcome in the development of this innovative method. For example, consistently optimizing energy regardless of loading condition required changes to the traditional secant method (Fig. 2) and implementation of load-limiting safeguards. The biaxial loading case required load correction factors that were determined analytically to alleviate the effects of additional friction resulting from the simultaneous tension-compression loading. These changes contributed to improving the rate of convergence of the method and making it fully automated. This new method will finally allow the investigation of new energy-based theories to predict cell responses to any loading configuration and potentially confirm that distortion energy is the driving factor for cellular changes in simple and complex loads.

FREQUENCY OPTIMIZATION OF A NOVEL SKIN BLOOD FLOW TRANSDUCER

Georgia E. Robles (1), Christopher M. Francis (2), Saeed I. Latif (3), David A. Nelson (1)

INTRODUCTION

There are a number of conditions for which it would be useful to have information about the rate of blood flow in the skin. These include detection of asymptomatic Peripheral Artery Disease (PAD), assessing healing of diabetic ulcers and other wounds, management of Raynaud's Disease, and identification of certain emergent conditions (heat stroke, shock). There is no fast, simple method for obtaining quantitative measures of skin blood flow however.

REFLO (Rapid Electromagnetic Flow) is a novel technology for noninvasive measurement of the blood flowrate in the microcirculation of the skin. The method utilizes the relationship between flowrate and tissue temperature increase during exposure to radio frequency (RF) energy in the 15 – 40 GHz range. At those frequencies, heating is superficial and can produce measurable increases in skin temperature, without affecting deeper tissues or organs. It has been shown that the rate of surface temperature increase is a function of the rate of blood flow in the underlying dermal vasculature.

We are developing a prototype REFLO device for measuring skin blood flow. The system incorporates a low-power RF transmitter and a handheld transducer to simultaneously heat the skin and measure the temperature response. As the depth of RF penetration is a function of wavelength, the transmitter frequency is a critical design variable. For example, energy penetration to a depth less than that of the dermal plexus may compromise measurement sensitivity. The depth and magnitude of the energy absorption in the skin depends on many factors, including the frequency and power density of the incident RF energy, and the thickness of the

dermal layer. The objective of this study is to determine the extent to which the magnitude and depth of heating are functions of (i) frequency, and (ii) power density. The results will enable optimization of frequency and exposure duration and allow development of a device and measurement protocol.

METHODS

RF energy absorption was simulated using xFDTD software (Remcom, State College, PA). The heterogeneous tissue models (one-dimensional) consisted of four tissue layers: Stratum Corneum (SC), Epidermis (ED), Dermis (D) and Hypodermis (HD) (Figure 1).

Figure 1: The four layer computational skin model with incident sinusoidal plane wave of various frequencies used to calculate electric fields and SAR values.

Dielectric values for each tissue were determined at frequency according to a Cole-Cole permittivity model. Exposures were far-field, continuous waves with power densities $P=100, 250, \text{ and } 500 \text{ mW/cm}^2$ and frequencies 15, 25 and 35 GHz. The resulting specific absorption rate (SAR) values were then used alongside a thermal solver based on the Pennes Bioheat equation to calculate the corresponding temperature increases as a function of time.

RESULTS

Figures 1 and 2 show surface temperature increases for a range of blood flowrates for incident power density of 250 mW/cm^2 . Results are shown for operating frequencies of 15 and 35 GHz.

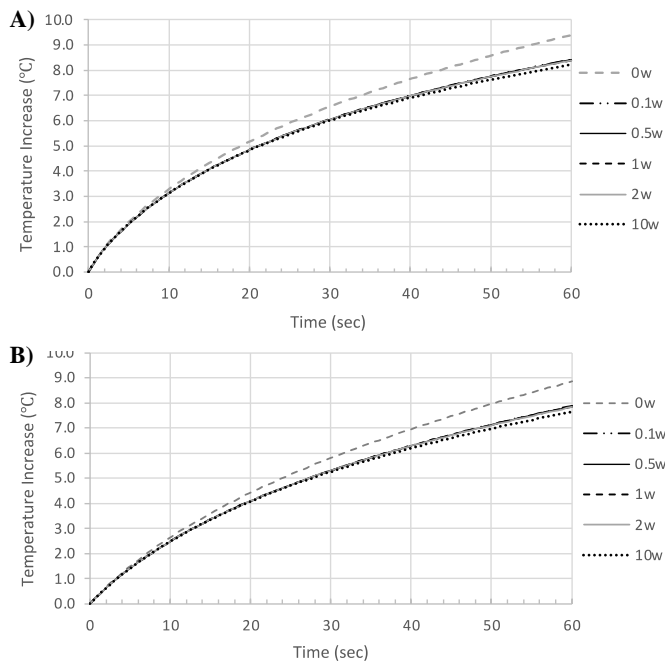

Figure 2: Surface temperature increases for varying perfusion rates over 60 sec heating period under exposure to 15 (A) and 35 (B) GHz with power density 250 mW/cm^2 . Base perfusion rate (w) 0.5 ml/s/ml

The surface temperature increase is important to device performance and safety. Both 15 and 35 GHz bring about similar surface temperature increases at 250 mW/cm^2 . At extremely low perfusion rates there is sufficient sensitivity to blood flow rate, but a greater degree is necessary to differentiate between mid and high level perfusion rates. The results presented here will be used to determine the impact on measurement performance and optimize device parameters.

DISCUSSION

A simple, one-dimensional model of RF absorption in skin is presented. Both 15 and 35 GHz are viable frequency options shown by the similar surface temperature increase curves.

Frequency is an important design consideration not only from a functional standpoint but will also determine the cost point of the device. Using a RF frequency lower than 35 GHz may offer an opportunity to reduce the cost of a device. Hardware costs for amplifiers in particular tend to be quite high for frequencies above 35 GHz. Hence the optimization of the operating frequency may be important to the success of the technology.

Efforts are currently being made to increase the sensitivity of the device to mid to low range perfusion rates. We are currently in the process of testing a prototype on human subjects

INTRODUCTION

Computational biomechanics is a valuable tool for understanding the physiology and potential impact of treatment in cardiovascular disease. Biomechanical modeling is known to predict the outcome of currently available surgical procedures and found to inspire novel procedures [1]. The knowledge gleaned from computational cardiovascular biomechanics can improve understanding of disease development and progression [2].

A continual challenge in these analyses is that medical imaging of cardiovascular structures, while providing significant detail on a patient's anatomy, occurs under arguably unknown cardiovascular loading conditions. In the context of the heart, blood pressure pressurizes the myocardium, introducing loads concomitant with unknown residual stresses [3]. Additionally, the surrounding pericardium, diaphragm, lungs and rib cage introduces additional uncertainty, challenging our interpretation of the loading state of the heart.

Several works have been introduced to address these challenges in cardiac mechanics. To understand the unloaded state, researchers have used inverse mechanics methods to define the impact of the assumed reference domain in the mechanical response [4] [5]. Additionally, a modified updated Lagrangian formulation (MULF) method has been utilized for model order reduction, shown to develop an accurate approximation of the unloaded state for specific applications [6]. For the challenge of residual stresses, researchers have found that including prestrain has a substantial overall impact on cardiovascular mechanics [3] [7]. The impact of epicardial force has been investigated through phenomenological boundary energy terms [8].

Despite these advances, we still must quantify the uncertainty and fidelity of these techniques in providing information about the unloaded state of the heart. In this abstract, we explore how uncertainty in external loads impact the accuracy and efficacy of cardiac biomechanics. This is done through using a simplified in silico analysis, showing how uncertainty in external loads can significantly impact the estimation of reference domains and strains. We then examine this in vivo, considering 3 patient-specific models, which examine how different interpretations of epicardial loads impact our assessment of cardiac mechanics.

METHODS

To study the impact of uncertainty in the cardiac load state, we explore two modeling systems. In the first, a simplified two dimensional geometry is exposed to a no-penetration spring condition, whereby force is linearly increased (with stiffness k_{wall}) with normal displacement (see Fig 1A). Pressurizing the interior of the model, provides a loaded state influenced by internal and external loads. Two methods of inverse mechanics are considered: a direct inverse approach [9] as well as the MULF method [6], examining their efficacy at predicting the load free reference domain – as well as additional loading geometries in the case of the direct inverse method. We then explore the significance of the no-penetration parameter, k_{wall} , and its influence on predicted reference domains. Lastly, we consider how adding additional load states could help provide determination of k_{wall} .

Extending this analysis to the human heart, we consider (n=3) patient-specific heart models created from dynamic computed tomography imaging. Examining the motion, we compare the normal displacement distributions observed in normal cardiac filling from end-systole to end diastole (Fig 2A). We then explore how joint estimation of external loads and inverse mechanics (across multiple states) could provide insight into the biomechanics of the heart and its external loading state. For both studies, simulations were conducted in CHeart [10]. Forward mechanical simulations were solved as described in [11]. reference domain estimates using direct inverse mechanics follows the techniques described in [9], and the MULF approach follows the technique introduced in [6].

RESULTS

In the case of the in silico two dimensional test, we found that inverse mechanics shows that significant uncertainty in the assumed boundary conditions generate significant differences in the estimated reference domain geometry. Figure 1D below shows the normalized root mean squared error (RMSE) between simple geometry points on the true reference mesh for different assumed boundary conditions. To normalize, we divide each RMSE value by the error between the original cylinder and the reference domain developed when $k_{wall} = 0$. The graph shows significant error between an inverse mechanics problem with no boundary conditions and an inverse mechanics problem with the correct boundary conditions.

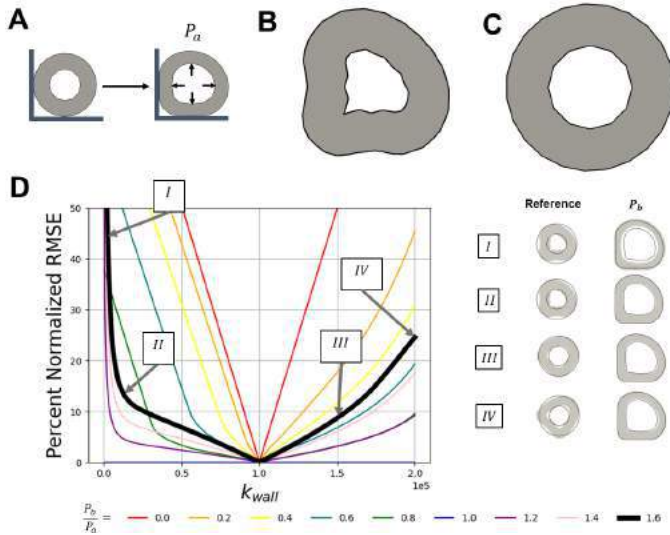

Figure 1: A - Depiction of the mechanical test. B - Reference domain geometry of the cylinder found without epicardial force. C - Reference domain geometry of the cylinder found using accurate epicardial force. D - Graph of RMSE between ground truth and test data for different no-penetration parameter values, with different ratios between the primary and secondary pressure constant as denoted in the legend. In the visualizations, the black outline denotes the ground truth simulation, and the grey cylinder denotes the k_{wall} value specified by the arrow.

In the forward simulations from end-systole to end-diastole, we captured the geometry of an inflated surface and to study the significance of epicardial force. We compare the cardiac epicardium of the end-systole configuration to the imaged end-diastolic epicardium. By doing so, we see the geometric differences due to many factors, one being the boundary conditions exerted on the heart. Figure 2A compares the difference in nearest-neighbor distance from the modeled end-diastolic state and the imaged end-diastolic state for each patient. Figure 2B compares the reference domain generated by the direct inverse and MULF methods from an example patient biventricular model. This case exhibits similar concave behavior to the simple case, depicted in Figure 1B.

Figure 2: A - Absolute nearest-node distance between an inflated end-diastolic and an imaged end-systolic epicardial surface for patient-specific data. B - Example reference domain geometries in three dimensions without boundary conditions. Green volume indicates the direct inverse method geometry and yellow volume indicates MULF method geometry. The black outline indicates the original model.

DISCUSSION

This study shows that in a two-dimensional test problem, the mechanical reference domain can be located with a reasonably accurate assumption about the boundary conditions on the heart. In our test case, we find a dis-

tinct minimum at the correct boundary condition when comparing between a wide variety of secondary pressure constant values. This means that through appropriate solvers, data routinely collected in the clinic could be utilized for approximating patient-specific boundary conditions, although the complexity of such conditions would increase significantly from the test case. We also see in this test that for a small change in pressure constant, the error of the result will remain relatively low - if we imprecisely estimate the epicardial force. Depending on the relationship of these parameters in vivo, and the accuracy requirements of the biomechanical calculations in question, weaker boundary condition estimations may be sufficient. Biomechanics researchers can better apply computational resources for personalized heart mechanical performance by understanding the assumptions and limits of different math methods used to quantify and represent the reference domain.

In the case of the biventricular surface analysis, we see significant differences in epicardial node distance in the different patients. This indicates that the epicardial force on each patient's heart may be highly variable. It's important to note that in this exploratory data, we ignore diastolic muscle contractions, which would also contribute to the heterogeneity we see. Regardless, the substantial differences show that consideration of cardiac boundary conditions would require patient-specific calculations and may play an important role in modeling.

A COMPARATIVE STUDY ON THE DIFFERENCE IN ARTERIOVENOUS FISTULA CFD SIMULATIONS BASED ON GEOMETRY LENGTH

INTRODUCTION

Over 15% of U.S. adults suffer from chronic kidney disease (CKD), which over time can progress to end-stage renal disease (ESRD). ESRD is characterized by extremely impaired renal function that can lead to death if unaddressed [1]. Treatments for ESRD include replacement therapy by hemodialysis, peritoneal dialysis, and kidney transplantation [2]. Hemodialysis requires the surgical creation of an arteriovenous fistula (AVF) to allow for increased blood flow through a dialysis machine and back to the right side of the heart [3].

Fistulas are created by surgically connecting an artery and a vein. The most common of these is the radiocephalic fistula, created by anastomosing the end of the cephalic vein to the side of the radial artery. Even though fistula formation is a common and an effective treatment it has been suggested as a risk factor for developing pulmonary hypertension (PH) [3]. Between 30 – 50% of ESRD patients can develop pre-capillary PH, which is associated with increased pulmonary artery pressures and resistance and can lead to eventual heart failure [2].

Considerable work has been completed using computational modeling to visualize flow patterns in AVFs, however there is conflicting evidence pertaining to the underlying cause of the development of pulmonary hypertension and the involvement of AV fistula flow rates. By modeling fistula hemodynamics metrics, this study may offer insight to physicians about AVF monitoring, which may lead to early surgical interventions to prevent the development of pulmonary hypertension. This improvement would cause fewer incidences of pulmonary hypertension and overall enhance the quality of life for those suffering with this condition. The objective of this preliminary study is to construct and compare AVF computational fluid dynamics models with geometry length variations. The length of the patient specific AVF will be shortened as a parameter in the study, and the effect will be examined. Evaluation of the simulation results with a more simplified

geometry could provide a model with fewer mesh elements, reduced computational cost, and a more efficient simulation.

METHODS

Patient inclusion criteria are as follows: patients must be over the age of 18, have an arteriovenous fistula actively being used for dialysis, have been diagnosed with PH by right heart catheterization (RHC), have no contraindications for MRI, have not been diagnosed with connective tissue disease, and do not have advanced left heart disease. The study has been approved by the Institutional Review Board (UMCIRB19-000708). Magnetic resonance (MR) imaging was performed with a Siemens Aera 1.5 Tesla MR machine. A total of 22 images (slice thickness of 8 mm and pixel spacing of 1.61 mm) were captured to obtain geometry in the proximal arterial and venous segments of the fistula. With the patient in the supine position, time varying velocity data, captured through the midplane of the AVF, was gathered using phase-contrast (PC) scans at 30 time points along the cardiac cycle (6 mm slice thickness and 1.77 mm pixel spacing). During the same imaging session, similar data were acquired for the pulmonary artery, as well as clinically standard cardiac measures. Patient files were anonymized prior to processing. MR images were imported into Mimics 20.0 (Materialise, Belgium) for model creation. A thresholding technique was used to segment the anatomical geometry captured in each MR slice and the “Calculate 3D” function was used to create a three-dimensional model of the highlighted region.

The model was then exported to 3-matic 15.0, where perpendicular cross-sectional cuts were created to define the inlet and outlets. A second geometry model was created by cutting the length of the proximal artery and proximal vein as shown in Figure 2. The length of the model was determined by multiplying the diameter of the proximal artery by 12. The 3-matic files were uploaded into ANSYS Workbench

22.1 (ANSYS Inc., USA) for discretization. Meshed using tetrahedral elements, the original and trimmed models were comprised of approximately 2.6 and 1.5 million elements, respectively. Orthogonal quality and skewness metrics were used to assess mesh quality [4].

Figure 2: Three-dimensional AVF models. A) original (6.8 cm) B) trimmed (3.6 cm). PA = pulmonary artery (inlet), PV = pulmonary vein (outlet), DA = distal artery (outlet).

Blood was characterized as an incompressible, Newtonian fluid with viscosity of 3.2 cP and density of 1060 kg/m³ [5]. The distal artery and proximal vein were assigned relative pressure-based outlets at 0 Pa. The inlet, or proximal artery, boundary condition was defined by the patients-specific flowrate waveform from the MR data. The MRI waveform was created with in house MATLAB files to crop and isolate cross sections of the AVF from the MRI, segment the AVF cross sections across 30 timesteps in the cardiac cycle, and lastly multiply the segmented AVF cross section images with the phase part of the images to calculate fluid velocity. A rigid wall assumption and no slip boundary conditions at the wall were also applied. A double precision, second order, transient flow pressure-based solver was used for CFD analysis. Simulation time duration was calculated by multiply the RR interval, which is the time elapsed between two consecutive R waves of a QRS signal from an ECG, by three to achieve three full cardiac cycles.

RESULTS

The results only include one patient to date. By RHC, the patient had a mean AVF flow rate, mean pulmonary arterial pressure, and pulmonary capillary wedge pressure of 1.97 L/min, 46.5 mmHg, and 19 mmHg, respectively. Velocity streamline contours (Figure 2) and WSS measurements at peak systole (Table 1) are shown below.

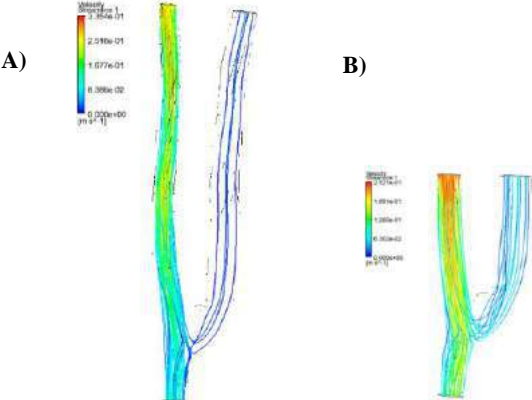

Figure 2: Velocity streamline of blood flow through the patient specific arteriovenous fistula at peak systole. The average inlet velocity was 17.6 cm/s. A) Original model. B) Trimmed model.

Table 1: Wall shear stress measurements at peak systole. Areas of low WSS were found along the proximal vein outlet.

Model	Minimum WSS (Pa)	Maximum WSS (Pa)	Distal Artery Area (cm ²)
Original	0.0006552	28.96	0.1652
Trimmed	0.0004122	24.44	0.1611

The original patient specific AVF model was seen to have relatively higher WSS values than the trimmed model. On the contrary, higher velocity values at peak systole were seen, specifically at the distal artery, for the trimmed model, 17.33 cm/s compared to 14.20 cm/s. The reduced vessel area of the distal artery of the trimmed model, seen in Table 1, can possibly explain the higher velocity, based on flow conservation.

DISCUSSION

Hemodialysis accounts for over 64% of renal replacement therapy plans for ESRD patients and requires the creation of an arteriovenous fistula [3]. While dialysis can work indefinitely to prolong patient’s lives, recent studies have suggested connections between fistula creation (size/shape) and the development of pulmonary hypertension.

Based on the results from the preliminary study, the trimmed model is potentially a viable option for a simplified AVF geometry. Similar flow patterns and WSS trends are present when comparing the two geometry models. However, additional quantitative measures of flow features should be considered. Furthermore, it is unknown if the observed difference in WSS is clinically or physiologically significant. Using a simplified geometry would allow for more rapid time to CFD solutions with minimal impact on the results [6]. These results are exploratory, only represent intermediate steps in the project, and do not provide any clinical value. Future work will include: 1) comparing computational AVF results to computational models of the pulmonary artery from the same patient and 2) examining the impact of fistula banding to control cardiac output and stress on the vessel walls.

There are many limitations to this study. The most evident being the small patient sample size, particularly due to difficult patient recruitment during the COVID-19 pandemic. The results presented include data from only one patient, which limits statistical interpretation of results. Additionally, the computational approach relies on several assumptions. Despite these limitations, a simplified *in-silico* approach could provide more accurate results with reduced computational cost. Overall, modeling fistula hemodynamics may elicit a link between fistulas and pulmonary hypertension; thus, identifying key monitoring parameters. Improved monitoring will allow physicians to intervene; thereby, preventing the development of pulmonary hypertension.

IDENTIFIABILITY OF POROELASTIC MODEL PARAMETERS USING UNIAXIAL TENSION DATA: ROLE OF 3D STRAIN AND UNLOADING

John M. Peloquin (1), Dawn M. Elliott (1)

(1) Biomedical Engineering, University of Delaware, Newark, DE, USA

INTRODUCTION

Computer simulations of biological systems are attractive because a model constructed from experimental data can make predictions for complex physiologic conditions that are not experimentally accessible. However, extrapolating a model to conditions different from those used to construct it risks substantial error. Fits of model parameters to data are often non-unique because the data does not fully constrain the parameter values. The parameters are then *non-identifiable* and may perform excellently in the conditions used for model fitting, but cannot be assumed to generalize to novel conditions [1]. Because parameter identifiability is independent of goodness-of-fit, it must be verified separately. To address the lack of tools to verify identifiability in biomechanics, we recently developed open-source software for this purpose (github.com/jpeloquin/spamneggs), and found that confined compression stress relaxation tests do *not* provide identifiability for commonly used nonlinear poroelastic models [2].

In this study, we now turn our attention to uniaxial tension. Whereas confined compression is essentially a 1D test due to the confinement chamber, uniaxial tension has the potential to provide 3D data if the transverse (λ_y) and through-thickness (λ_z) strain ratios are measured as well as the longitudinal stress (σ_{xx}). This is almost never done. Most analysis is 1D. Sometimes, λ_y is reported, yielding 2D data. Nevertheless, we recently found that uniaxial tension of knee meniscus in a loading-unloading cycle with 3D strain revealed new aspects of how tension affects meniscus volume and fluid flow [3]. Here, we hypothesized that 3D data and unloading would also improve parameter identifiability for a constitutive model of meniscus tissue. The objective of this work, therefore, was to quantify and compare parameter identifiability for a poroelastic model of meniscus in four variations of the uniaxial tension stress relaxation test with increasing richness of the data: (1) loading ramp and hold with 1D data (σ_{xx}); (2) same + 2D data (σ_{xx} and λ_y); (3) same + 3D data (σ_{xx} , λ_y , and λ_z); and (4) same + unloading, unloaded recovery, and 3D data (σ_{xx} , λ_y , and λ_z).

METHODS

Global sensitivity analysis was used with FEBio finite element simulations to generate synthetic data for analysis of parameter identifiability in each of the 4 test variants. Axes, specimen dimensions, and output variables are defined in Fig 1a. Tension was applied in x, representing tension in the meniscus' circumferential fibers (Fig 1b). The simulated test protocol consisted of a loading ramp to 6.4% strain at 0.1 mm/s, a loaded hold (stress relaxation) for 600 s, unloading at 0.1 mm/s to 0% strain, and unloaded recovery for 1800 s (Fig 2a), matching our experimental work [3]. Analysis of test variants 1–3 used only the ramp and hold portions of the output.

Meniscus tissue was modeled as a poroelastic mixture of a Holmes–Mow (HM) solid, toe–linear fibers, and constant permeability (7 parameters total) [4,5]. Each material parameter was varied using 3-level full factorial sampling spanning the full range of literature values [4–7], generating 2,187 simulations. Borrowing techniques from genomics, parameter effects were quantified as “sensitivity vectors”, Pearson correlation coefficients between the parameter and each output variable at each time point. The uniqueness of each parameter's effect on the output variables, and hence its identifiability, was quantified for each test variant using cluster analysis and eigenvector analysis of the matrix of sensitivity vectors, with eigenvalues > 1% of the variance considered significantly nonzero, indicating practical identifiability.

Figure 1: (a) Simulated specimen dimensions and output variables. (b) Relationship of simulation to meniscus physiology.

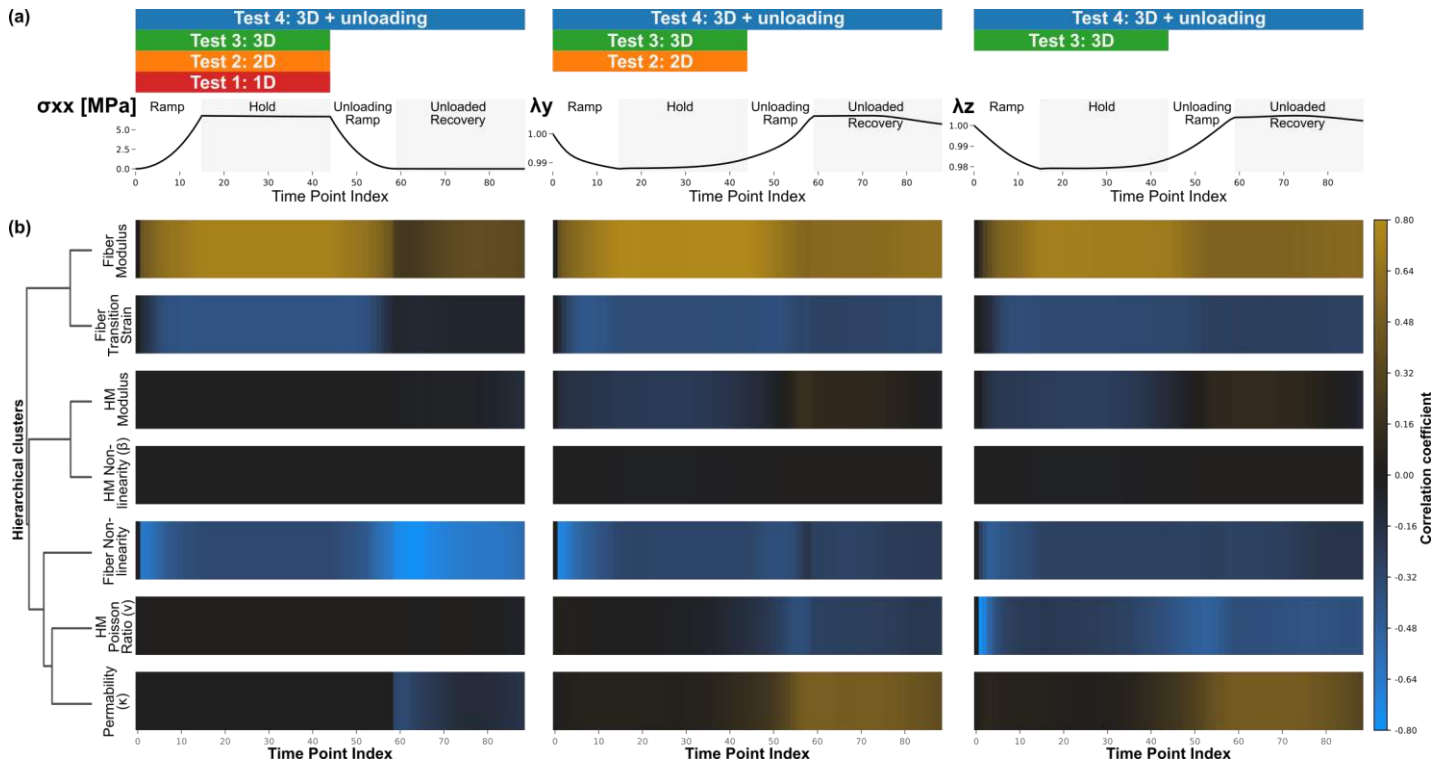

Figure 2: Parameter effects. (a) Representative simulation output. (b) Sensitivity vectors (correlation coefficients, r , between each parameter and each output variable (σ_{xx} , λ_y , & λ_z) across time and their cluster analysis (dendrogram, left). Subsets of this plot (top-edge labels) show parameter effects for the three test variants that used only the loading ramp and hold and a subset of variables.

RESULTS

The sensitivity vectors for test 4 (3D + unloading) showed that most parameters had distinctive effects on σ_{xx} , λ_y , and λ_z (Fig 2b). HM Poisson ratio (ν) appreciably affected only λ_y and λ_z , with little impact on σ_{xx} . Both ν and permeability (κ) had little effect on the loading ramp and hold, with their effects largely confined to unloading. Fiber modulus and transition strain were very similar in their effects. HM nonlinearity (β) had almost no effect. Parameter effects on λ_y and λ_z were slightly different, mostly with respect to ν and, more subtly, κ .

Eigenvector analysis, which also considers identifiability problems due to redundancy of multiple sensitivity vectors in combination, showed that identifiability suffered with the simpler test variants. Test 1 (loading & σ_{xx}) had only 3 eigenvalues > 0 , indicating that it only constrained 3 degrees of freedom in parameter space (Fig 3a). Adding λ_y data (test 2) yielded 5 eigenvalues > 0 (Fig 3b), and adding λ_z (test 3) yielded 6. Unloading was also beneficial as suggested by the unloaded-centric sensitivities for ν and κ , increasing the share of variance belonging to eigenvectors 2 through 6, aiding identifiability.

DISCUSSION

Use of 3D measurements (measuring both λ_y and λ_z) and unloading in uniaxial tension greatly improved identifiability of the nonlinear poroelastic model compared to simpler tests. Use of σ_{xx} and loading alone (test 1) only constrained 3 degrees of freedom, which is sufficient to fit the 3 fiber properties. Experienced modelers sometimes use 1D uniaxial tension data only to fit fiber properties, obtaining the other parameters from confined compression [e.g., 4], which is partly justified by the present results. However, confined compression does not constrain ν [2], so at least λ_y is needed in the uniaxial tension test.

With 3D data and unloading (test 4), uniaxial tension robustly supports identifiability of all parameters except HM nonlinearity (β). Confined compression did not allow identification of β either [2]; the parameter is in fact irrelevant with commonly used values for volume

strain < 30 –50% and may be ignored in most circumstances. When including 3D data but without unloading (test 3), all six relevant parameters are technically identifiable, but smaller eigenvalues 2–6 mean fit uncertainty will be larger (Fig 3c). Overall, these results demonstrate that 3D data is required to identify nonlinear poroelastic model parameters in uniaxial tension, and use of unloading data will further improve parameter identifiability.

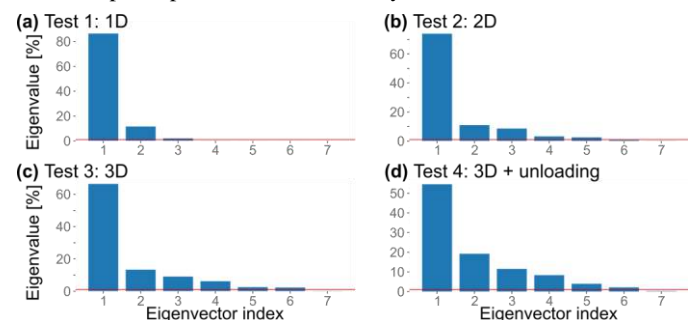

Figure 3: Eigenvalues of the parameter sensitivity vectors for each test variant. Larger eigenvalues indicate better identifiability.

INTRODUCTION

Atherosclerotic plaque rupture is responsible for a majority (>60%) of acute coronary syndromes (ACS), which affect millions of people each year [1]. These pathologic events are a significant problem, not only because of their frequency but also due to the challenge of stratifying risk for plaque rupture. Recent advancements in imaging techniques, such as intravascular ultrasound, offer methods to reliably identify high-risk plaques characterized by thin fibrous caps (<65 μm) and large necrotic cores [1]. However, the use of imaging for the prediction of plaque rupture has been proven not accurate. In particular, studies have shown that most high-risk plaques leading to ACS undergo rapid progression preceding the event, and they only precipitate an ACS if associated with sudden progression [2]. As a result, to improve clinical management decisions, plaque rupture risk-stratification strategies must move beyond image-based morphologic markers.

Plaque rupture is the direct result of material failure of the atherosclerotic tissue due to applied mechanical loads. Characterization of material properties of the arterial tissue and plaque constituents with *in vivo* imaging techniques holds tremendous promise in risk-stratifying coronary lesions. Ultrasound elastography and palpography have the potential to identify high-risk plaques. Nevertheless, their clinical impact has been limited due to the oversimplified assumptions for the analysis, including infinitesimal strain and uniform wall thickness. There remains a critical need to characterize the nonlinear and hyperelastic material behavior of the coronary environment. Accordingly, this study aimed to develop a novel image-based computational framework to evaluate the material properties of arterial tissue utilizing high-resolution magnetic resonance (MR) image data, which has the potential to be extended for *in vivo* imaging modalities.

METHODS

High-resolution Magnetic Resonance (MR) Imaging: MR imaging data were collected on excised healthy porcine carotid arteries

($n = 5$). A straight segment $\sim 35\text{mm}$ in length was cut from each specimen and then mounted to a custom MR-compatible apparatus that allowed controllable biaxial loading of the tissue during image acquisition. The device was connected to a height-adjustable saline fluid reservoir for pressurization, with an inline pressure transducer monitoring the lumen pressure. Using a T2-weighted TurboRARE sequence, MR images of the tissue were collected at axial stretch ratios of $\lambda_z^{\text{in vivo}} \pm 0.1$ at static pressure loads of 40, 80, and 120 mmHg (Bruker Biospin 7T MRI). In each sequence, 15 images across the center 10 mm region of the tissue were acquired over a 10×10 mm field-of-view (FOV) with an isotropic resolution of 80 μm (Fig. 1 A-B).

Figure 1: MR images of a porcine carotid artery at (A) $P = 40 \text{ mmHg}$ and (B) $P = 120 \text{ mmHg}$. (C) Template (unloaded) FE model constructed from A. (D) Deformed geometry and displacement magnitude derived from Hyperelastic Warping.

Deformable Image Registration: From the MR images, the strain fields across the deformation states were derived using a

deformable image registration technique termed Hyperelastic Warping [3]. This technique determined the deformation map that best aligned a “template” to a “target” image, where image data corresponded to MR data acquired at distinct lumen pressures. A finite element (FE) model was constructed that corresponded to the template image. The artery wall borders were manually segmented from the MR image (MATLAB, MathWorks, Inc). An outer buffer region, with dimensions of 10×10 mm, was added to provide tethering. The geometry was discretized with linear hexahedral elements (ANSA, BETA CAE Systems). To evaluate the impact of the constitutive model on the proposed framework, the arterial wall was described by either an isotropic or anisotropic strain energy function (SEF). The isotropic SEF (neo-Hookean) took the form,

$$\Psi_{iso} = C_1(I_1 - 3), \quad (1)$$

where C_1 is the material stiffness constant, and I_1 is the first invariant of the right Cauchy-Green deformation tensor. The anisotropic model featured a microstructurally-motivated SEF, which took the form,

$$\Psi_{aniso} = \mu(I_1 - 3) + \frac{k_1}{k_2} e^{k_2[(1-\rho)(I_1-3)^2 + \rho(I_4-1)^2]} - 1, \quad (2)$$

where μ describes the ground matrix stiffness, k_1 and k_2 capture the fiber stiffness, ρ is a measure of fiber dispersion, and I_4 is the fourth invariant of the right Cauchy-Green deformation tensor that describes two fiber families arranged symmetrically around the vessel [4]. The outer buffer region was defined as a compressible, neo-Hookean solid. Applied boundary conditions included pressure on the lumen surface and full constraint of the outer edges of the buffer region. Warping was performed in *FEBio Studio* (www.febio.org), and the first principal strain (E_1) fields were evaluated [5].

Material Parameter Optimization: A forward FE model, identical to the Warping model (Fig. 1C), was constructed and analyzed to quantify strain fields under loading. To determine SEF material parameters, the material parameter optimization module in *FEBio Studio* was employed to identify coefficients that minimized the difference between the forward FE and Warping model strain fields. The objective function was defined as,

$$e = \sum_{i=1}^N [(E_1^{FE} - E_1^{HW})_i^2], \quad (3)$$

where N is the element number and superscripts *FE* and *HW* denote the FE and Warping-determined values, respectively.

RESULTS

Hyperelastic Warping was successfully implemented to derive strain fields from MR images across static pressure loads from 40 to 120 mmHg. A representative Warping-derived strain field from the MR images shown in Fig. 1 A-B is presented in Fig. 2A. Across the 5 imaged tissues and 12 MR slices analyzed, it was observed that elements located on the inner arterial wall had larger deformation than those on the outer wall. For example, in the representative analysis, elements on the inner wall and outer wall had first principal strains of 0.102 ± 0.005 and 0.042 ± 0.009 , respectively (Fig. 2A).

Figure 2: (A) Warping-derived first principal strain (E_1) field. (B) Representative objective function reduction as the material coefficient C_1 in the isotropic constitutive model was optimized.

Analysis of the optimization data indicated a reduction in the objective function value as best-fit material parameters were determined, with final objective values (e_{final}) of 0.24 ± 0.27 across all analyses (Fig. 2B). The best-fit material coefficients for the isotropic and anisotropic SEF when analyzing the center MR image slices across the 5 tissue samples are presented in Table 1. Variability across tissue samples (i.e., inter-sample variability) was evident. In addition, variability was observed when analyzing different MR slices from the same tissue sample (i.e., intra-sample variability). In one tissue sample, the isotropic material parameter, C_1 , ranged from 501.53 to 596.06 kPa across image data acquired in the proximal, central, and distal FOV. In that same sample, the anisotropic SEF parameters μ , k_1 , and k_2 had ranges of 3.81-12.20 kPa, 34.15-71.10 kPa, and 28.72-143.71, respectively. Lastly, analyzing image data across varying axial stretch ratios from the same tissue sample demonstrated that the framework could detect a stiffening of the tissue. For example, at axial stretch ratios of 1.8 and 1.9, the anisotropic SEF parameters μ , k_1 , and k_2 were 4.32 kPa, 34.43 kPa, and 18.58 and 7.65 kPa, 24.08 kPa, and 4.94, respectively.

Table 1: Estimated material coefficients

SEF	Coefficient	Value	e_{final}
Isotropic	C_1	424.66 ± 147.50 kPa	0.10 ± 0.09
Anisotropic	μ	6.16 ± 2.74 kPa	0.14 ± 0.14
	k_1	51.01 ± 14.93 kPa	
	k_2	14.75 ± 8.34	

DISCUSSION

In this study, we present an innovative approach to estimate arterial material properties directly from imaging data. Utilizing healthy porcine carotid arteries, we demonstrated the success and robustness of the framework by determining the material coefficients in isotropic and anisotropic SEFs for hyperelastic materials. Importantly, the derived material parameters demonstrate agreement with published reports on coefficients derived from experimental biaxial mechanical testing [4,6]. Moreover, intra-sample variations in the material parameter values observed across different locations and axial stretch ratios comply with previous observations [7]. We recognize that the presented framework must be validated across samples by comparing Warping-derived material coefficients to values derived from “gold standard” mechanical testing results, and these investigations are ongoing. Future studies that integrate this computational framework with clinical imaging modalities of coronary tissue have the potential to characterize the material properties of diseased arteries and examine their predictive values to risk-stratify human coronary lesions.

INTRODUCTION

There is a pressing need to understand perfusion and metabolic activity across the myocardium in health and disease. Metrics such as coronary flow can give a global view of myocardial perfusion and oxygen delivery. However, perfusion hemodynamic and metabolic patterns vary transmurally from the epicardium (outer-most layer) and the endocardium (inner-most layer). This local variation across the myocardium can be attributed to transmural differences in intramyocardial pressure. Transmural differences in hemodynamics and perfusion are key to understanding myocardial ischemia, which is more likely to occur in the endocardium than the epicardium [1]. Further, it is important to understand how transmural hemodynamics and regional perfusion change in response to risk factors such as obesity, which have previously been linked to disorders such as coronary microvascular disease and cardiac ischemia [2].

In this work, we studied transmural myocardial perfusion by combining two different multi-scale models: (1) a 1D nonlinear model of aortic flow and pressure and (2) a three-layer lumped parameter model (LPM) of myocardial perfusion. These models will be applied to study a control (lean) and a diseased (obese) Ossabaw porcine model. Each animal model is supported by a rich set of experimental data including aortic, ventricular, and coronary hemodynamics. The models are calibrated to match the available data for both pigs. In doing so, we are able to gain insight into quantities not readily available through experiments, such as flow waveforms in representative vessels in the endocardium and epicardium regions.

METHODS

Experimental Data: Two anesthetized Ossabaw pigs were used: a lean subject (34.1 kg), and a disease model of heart failure with preserved ejection fraction (HFpEF) (68.4 kg), obtained by a combination of high fat diet for 14 weeks and cardiac pacing for 4 weeks [3]. Pressure was measured in the left ventricle (LV) using a pressure-

volume transducer and in the descending aorta (DA) using a fluid filled transducer. Body weight, heart weight, cardiac output, and left anterior descending (LAD) coronary flow rates were collected for each pig (Figure 1). Microspheres were injected into the left atrium. Samples of the LV wall were divided into three equal layers and the number of microspheres in each layer was measured to estimate the relative perfusion ratios of the endocardium, midwall, and epicardium.

Figure 1: Experimental data included myocardial flow in the LAD and pressure recordings in the LV and descending aorta (DA)

Computational Models: A 1D nonlinear model of arterial pulse wave propagation was used to estimate ascending aorta (AA) pressure [4]. Then, a three-layered LPM of myocardial perfusion was used to study transmural flow [5,6].

- **Model 1:** The 1D model of pulse wave propagation requires an inflow waveform and impedance-based boundary conditions. A simplified aortic valve model was developed to iteratively estimate aortic inflow from the available LV pressure. Information on vessel diameters was obtained from a CT study. Circumferential stiffness

values were defined as a function of vessel radius using available literature data [7]. Stiffness values, aortic valve resistance, and vessel radii were iteratively adjusted to fit DA pressures while maintaining stroke volumes given by the experimental data.

Model 2: An LPM of myocardial perfusion with three parallel components representing the endocardial (ENDO), midwall (MID), and epicardial (EPI) layers of the heart was considered. Input data for this model are: LAD flow, AA pressure, LV pressure, and ENDO/EPI and ENDO/MID microsphere perfusion ratios. Parameters specifying resistance and relative compliance between the three layers (Figure 2) were iteratively adjusted to fit the available data.

Figure 2: Three-layered LPM of myocardial perfusion. R_{pa} and R_m (highlighted in yellow) are two of the adjusted parameters.

RESULTS

Using the 1D flow solver with a simplified aortic valve model, we successfully estimated AA and DA pressures given the available data on LV pressure, cardiac output, stiffness, and vascular geometry (Figure 3). Computed DA pressures (dashed red line) matched well the experimental DA pressures (purple solid line).

Figure 3: Results from 1D Model for (A) a lean pig and (B) an obese pig. Experimentally pressures shown with solid lines: LV (green) and DA (purple) pressure. Model results are shown with dashed lines: AA (blue) and DA (red) pressure.

Although lean and obese pigs had similar heart rates, mean blood pressure, and ENDO/EPI ratios, other quantities such as cardiac output, stroke volume, and average coronary flow rate were approximately two times larger in the obese pig. The fit of myocardial flow calculated by the LPM to the experimental data is shown in Figure 4 A-B, whereas transmural variations in flow are shown in Figure 4 C-D. For the lean pig, the computed EPI and ENDO mean flows were 9.00 and 8.89 ml/min (orange and blue lines, respectively). For the obese pig, computed EPI and ENDO mean flows were 18.25 and 17.33 ml/min. Both animals show high diastolic endocardial flow and a noticeable negative endocardial flow during late systole.

DISCUSSION

A 1D nonlinear model of arterial pulse wave propagation was used to estimate AA pressure by implementing a simplified aortic valve model and imposing the available LV pressure data. Model results of DA pressure were compared to known experimental data. This method was successful in producing realistic AA pressure waveforms while matching the expected stroke volumes.

Using the LPM of myocardial perfusion we simulated myocardial flow patterns while matching the available LAD flow waveforms and the measured ENDO/EPI and ENDO/MID ratios. Our myocardial flow patterns also reproduce previous work in showing that the endocardial layer experiences significant back flow in late systole [5, 6, 8].

Figure 4: (A-B) LAD flow in Lean (A) and Obese (B) pigs- experimental data (black) and LPM model results (pink). (C-D) Computed endocardial (blue), midwall (green), and epicardial (orange) flows in lean (C) and obese (D) pigs.

Further, this work shows similar flow patterns between a lean and an obese pig with similar ENDO/EPI ratios, despite the obese model having an approximately double coronary flow rate compared to the lean model. A key limitation of this study is that we only explored one lean and one obese animal, with similar ENDO/EPI ratios. Future work is required to explore transmural flow differences in more diseased models, particularly in animals with low ENDO/EPI ratios. However, this work does suggest that the LPM myocardial model can be used to understand transmural flow patterns in models of obesity.

INTRODUCTION

Peripheral artery disease (PAD) is a pervasive condition which is commonly undiagnosed but affects approximately 13% of the Western population aged over 50 years [1]. Individuals experiencing PAD commonly present with claudication (pain while walking) or critical limb ischemia, significantly reducing health-related quality of life. Major risk factors for PAD include diabetes mellitus and atherosclerosis, which exacerbate inward vascular remodeling and result in impaired blood flow to the extremities [2]. While complications from PAD may go undetected, the effects of diseased endothelium and excessive inflammation can accumulate over time and initiate different cell populations to alter vascular structure [3,4]. Thus, it is feasible that vascular adaptation depends on both vessel wall composition and type of injury, which may require different approaches to address healing.

In this study, we sought to characterize the remodeling of murine peripheral arteries in response to two types of vascular injury: 1) an angiotensin II (AngII) infusion model of hypertension [5] and 2) intraluminal mechanical injury [6]. We first characterized biaxial wall mechanics in the femoral artery and compared its behavior to that of another transitional artery – the common carotid. Initial comparisons revealed lower stored energy and axial stretch in femoral compared to carotid arteries, with stored energy correlating with vascular elastin content. Next, we observed differential remodeling of the femoral artery following hypertension and intraluminal injury. Namely, following AngII infusion, femoral arteries demonstrated minor, yet detectable, remodeling whereas after intraluminal injury, drastic alterations in meaningful metrics of vessel function (axial stretch, stored energy, and stiffness) were observed. As both wall structure and the type of injury influence vascular remodeling, it is important to assess the remodeling of transitional arteries under similar disease conditions to better understand the biomechanical factors contributing to PAD progression.

METHODS

Animal Models - Hypertension was induced in 11-13 week old, male, WT mice by Ang II infusion (490 ng/kg/min) for 14 days. Intraluminal mechanical injury of femoral arteries was performed in 21-23 week old *Rag1*^{-/-} animals through insertion of a 0.38 mm straight spring wire into the common femoral artery. The wire was left in place for 1 minute to denude and dilate the artery, and the arteriotomy was sealed via cautery following removal of the wire. Either 14 or 28 days after injury, femoral and carotid arteries were excised, cleaned of perivascular tissue, and prepared for biaxial mechanical testing.

Biaxial Mechanical Testing – Vessels were cannulated onto a custom computer-controlled mechanical testing device [7]. Specimens were placed in Hanks buffered physiologic solution and underwent 4 preconditioning cycles at approximately the *in vivo* axial stretch. Following estimation of the unloaded geometry and *in vivo* axial stretch, vessels were subjected to 3 cyclic pressure-diameter protocols (10 to 140 mmHg at 95%, 100%, and 105% of the *in vivo* axial stretch) followed by 4 cyclic axial force-length protocols from 0 to f_{\max} (with $f_{\max} = 5.5$ mN for femoral arteries and 15 mN for carotid arteries) at constant pressures of 10, 60, 100, and 140 mmHg. Axial load and vessel geometry were continuously recorded throughout the testing protocols for material parameter identification using the constitutive equation W :

$$W(\mathbf{C}, \mathbf{M}^i) = \frac{c}{2}(I_c - 3) + \sum_{i=1}^4 \frac{c_1^i}{4c_2^i} \left\{ \exp \left[c_2^i (IV_c^i - 1)^2 \right] - 1 \right\} \quad (1)$$

Here, W is used to model the contribution of an isotropic elastin and four families of locally parallel collagen fibers to the transmurally averaged material properties of the aortic wall. Material metrics of stress and stiffness can then be computed from first and second derivatives of W , respectively, with respect to an appropriate measure of strain.

Structural Characterization – Tested arteries were sectioned and histologically stained with AlexaFluor™ 633 Hydrazide to label elastic fibers. Vessel geometries were visualized by optical coherence tomography (OCT) volumes acquired using a commercially available system (Ganymede; Thorlabs, Inc.) with a center wavelength of 930 nm and an index of refraction of $n = 1.38$. Cross-sectional images from each vessel were used to calculate wall thickness based on radial projections from the inner to outer wall. Quantitative image analysis was performed using an adapted custom MATLAB script [8].

Statistical Analysis – Mechanical metrics were compared using either a Student's t-test for the AngII studies or one-way ANOVA for the intraluminal injury studies, respectively, with post-hoc Tukey HSD test for multiple comparisons.

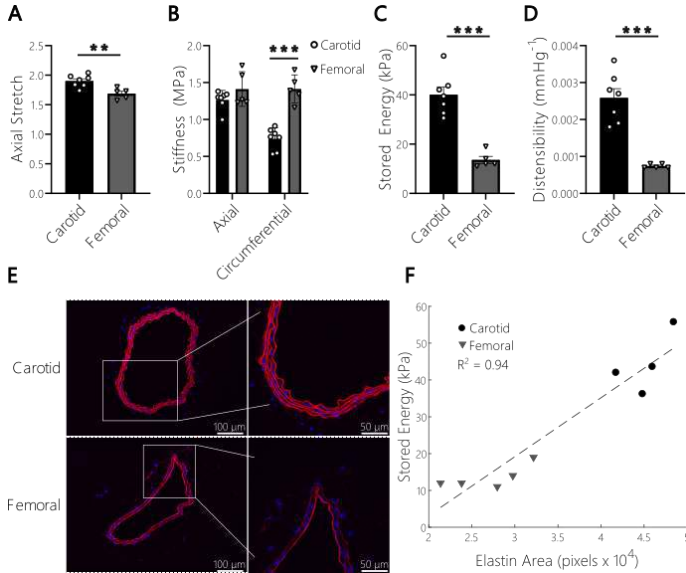

Figure 1: (A-D) Axial stretch, stiffness, stored energy, and distensibility of healthy carotids and femoral arteries. (E-F) Correlation of vascular elastin area and stored energy.

RESULTS

Biomechanical properties of carotid and femoral arteries are shown in Fig. 1A-D. Femoral arteries have a lower *in vivo* stretch and higher circumferential stiffness at 100 mmHg compared to carotid arteries ($p < 0.01$ and $p < 0.001$, respectively). Additionally, stored energy density and distensibility were both lower in femoral arteries ($p < 0.001$) than in carotids. Since we observed differences in circumferential vessel properties, we next quantified elastin area and observed a strong correlation between energy storage and vascular elastin content in these two arteries ($R^2 = 0.94$, Fig. 1E-F).

Mice were treated with AngII for two weeks to induce hypertensive vascular remodeling. While AngII-treated femoral arteries exhibited slightly decreased range of distension over physiological pressures and a left-shifted force-length curve (Fig. 2A, B), stiffness and stored energy values were similar to that of control vessels (Fig. 2C, D).

Following intraluminal mechanical injury, femoral arteries exhibited excessive remodeling and significant biomechanical alterations. In particular, overdistention injury led to increased vessel diameter and a significant loss of distensibility. These pronounced effects were observed as early as 2 weeks after injury and progressively worsened at 4 weeks after injury (Fig. 3A). Furthermore, injured vessels failed to elongate more than 10% before reaching f_{max} , indicative of pronounced axial remodeling (Fig. 3B). Energy storage dropped exponentially and was correlated with increasing vessel wall cross-sectional area, as measured by OCT (Fig. 3C).

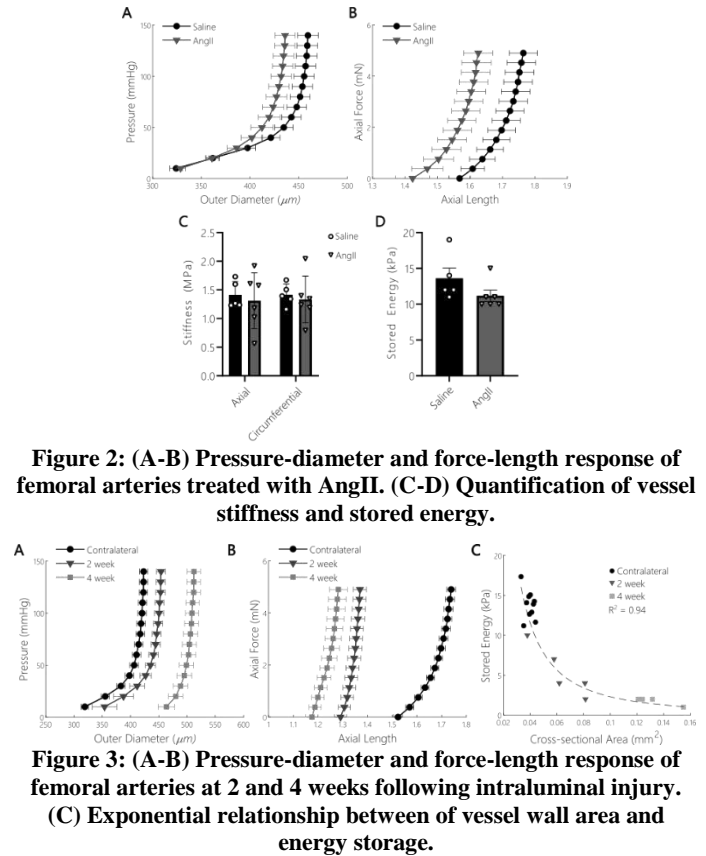

Figure 2: (A-B) Pressure-diameter and force-length response of femoral arteries treated with AngII. (C-D) Quantification of vessel stiffness and stored energy.

Figure 3: (A-B) Pressure-diameter and force-length response of femoral arteries at 2 and 4 weeks following intraluminal injury. (C) Exponential relationship between vessel wall area and energy storage.

DISCUSSION

Incomplete knowledge of the progression of vascular remodeling associated with PAD has limited the development of strategies to effectively improve the quality life for affected individuals. Current management strategies – particularly revascularization surgery to improve critical limb ischemia – warrants further investigation into the relationship with peripheral vessel remodeling [9]. Here, we utilized two models associated with the development of PAD, hypertension and intraluminal injury. To our knowledge, this is the first report of biaxial testing of murine femoral arteries, so we compared their mechanics to well-characterized carotid arteries [10]. Since the femoral arteries are more peripheral than carotids, they appear to have less need for storing energy to propel blood flow. Thus, minimal alterations in vessel behavior were observed in response to AngII-induced hypertension. However, following obliterative intraluminal injury, significant remodeling and neointima formation resulted in drastic alterations to vessel wall mechanics. These findings demonstrate the need to carefully consider both the primary driver of vessel injury (hypertension vs. mechanical injury) as well as the structure of the vessel wall (little vs. moderate elastin) and motivates a continued investigation into how these transitional arteries remodel under various conditions of interest.

INTRODUCTION

Easy access to explore-able blood flow data (i.e., data that can be quickly visualized and adjusted to the user's liking) is crucial for the task of bridging technical gaps between communities and involving researchers from different disciplines in cardiovascular research. Especially when viewing complex 3D flows, and potentially multiple complementary flow properties simultaneously (e.g., isosurfaces and streamlines), it is beneficial, and often necessary, for the viewer to be able to alter the visualization independently, such as adjusting the camera angle and altering the plotting thresholds. Designing visualizations to allow for real-time interaction increases the viewer's agency [1] and more closely mirrors the medical data viewing experiences of clinically oriented research collaborators such as radiologists and medical imaging specialists [2].

While robust engineering 3D visualization tools such as Paraview can be used interactively, setup requires multiple steps, including the downloading of large data files and software; and the data interaction requires familiarity with the software's often-dense interface [3]. Researchers more familiar with medical imaging software can find this challenging or time-consuming [2] and, as a result, it is more commonplace to share 3D visualizations with these researchers as static 2D images due to ease of access (e.g., 2D screenshots through email), at the cost of the user's agency. Certain academic journals such as the Journal of Fluid Mechanics have very recently provided solutions to this problem through cloud-hosted Jupyter notebooks [4]. These solutions involve their own trade-offs, such as the fees associated with cloud-based hosting services and the resulting data size limits. The goal of this pilot usability study was to understand the practical trade-offs of free or minimal-cost strategies for sharing 3D flow visualizations, using helical flow in the aorta as an example use-case [5].

METHODS

An aortic helicity visualization was created from 4D phase-contrast MRI data, and was shared using 3 free or low-cost techniques: a Google Colab notebook, a Docker contained notebook, and a Flask webpage

[<https://github.com/Biomedical-Simulation-Lab/web-viz>]. Biomedical engineering researchers with varying computational/programming skill levels were surveyed after accessing data through each technique. Each technique was evaluated on ease of setup and interactivity for the user, and ease of deployment for the visualization developer (i.e., the authors). The data was preprocessed in Paraview, where velocity streamlines and local normalised helicity (LNH) values were computed and saved as VTK unstructured grid files (*.vtu) files. All techniques utilized the PyVista Python library as their visualization basis.

Technique 1: Google Colab: Google Colab is a type of Jupyter notebook hosted on Google's cloud servers. For setting up shareable visualizations on Colab, the developer must store the data in an online storage service (in our case, GitHub) and simply specify the data location within the notebook. This method is quick and free to deploy but is mainly suitable for lightweight datasets due to the processing limitations available on the free version of Colab.

From a user perspective, a visualization created on Colab can be accessed through a web-link and requires no software setup on the user's local computer. The visualization is displayed as a static 2D image that can be rapidly updated by the user after changing the parameter variables (view angles, LNH threshold, streamlines on/off) directly in the PyVista notebook's displayed code.

Technique 2: Docker (Containerized Notebook): Python visualization scripts typically require installation of dependent libraries and require the user to set up their computational environment. As well, running a Jupyter notebook on a local computer can result in hardware related graphics errors for 3D rendered objects. For this reason, it is considered best practice to run local notebooks within a container environment (here, we used Docker) to standardize visualization rendering for different computers and increase stability [6]. To set up the Docker visualization the developer is required to have knowledge of container-based development, such as creating Docker images (containing the notebook and the data) and pushing the images to Docker Hub.

For the user, this technique requires the most setup time and technical skill, requiring the installation of Docker software, and using terminal commands to start the container before the notebook can be viewed. In our survey example, participants adjusted parameters by editing the notebook code as in the Colab technique. However, the Docker technique has the added benefit of 3D object rotation, as the customizability of Docker allowed us to specify the necessary 3D graphics back-end libraries. There was no cost associated with this method.

Technique 3: Flask Web-page: Flask is a Python framework that can be used to build web applications. Utilizing a web-page to display visualizations requires all of the knowledge of the previous two techniques plus knowledge required to develop a web application (familiarity with HTML and JavaScript) and to deploy the application through a chosen cloud server (e.g. Heroku, AWS). For our survey example, the application was hosted on the Heroku cloud platform for a monthly cost of \$5 USD which would cover up to 1000 hours of usage/month.

The user is able to access the visualization through a web-link, rotate the object in 3D, and use intuitive widgets (e.g. sliders, check boxes) for changing thresholds or turning visualization elements on/off.

Table 1: Summary table of visualization techniques for developer (top) and user (bottom).

	Colab	Docker	Flask
Ease of development	Easy	Intermediate	Advanced
Cost for sample dataset	Free	Free	Priced
Rendering location	Server	Local	Server
User setup	Web link	Software download	Web link
Interface	Notebook	Notebook	HTML Webpage
Threshold adjusting	Editable code	Editable code	HTML widgets
Object rotation	replotable 2D	Mouse rotatable 3D	Mouse rotatable 3D

Survey Design: Study participants ranged in educational level from Master’s and PhD students, to postdocs and professors. Each participant was surveyed on their prior experience using the data exploration tools. Participants described their familiarity in 4 skill areas (Python, notebooks, terminal commands, and Docker) by categorizing themselves as either Novice (never used this tool), Beginner (occasionally used this tool) and Experienced (comfortable using this tool) for each of the skills. Ease of setup and interactivity was rated for each method on a 0 to 5 Likert scale, with 0 indicating inability to access the data, 1 indicating extreme difficulty and 5 indicating extreme ease. Participants were also asked their overall likelihood of using each method (unlikely, maybe, likely).

RESULTS

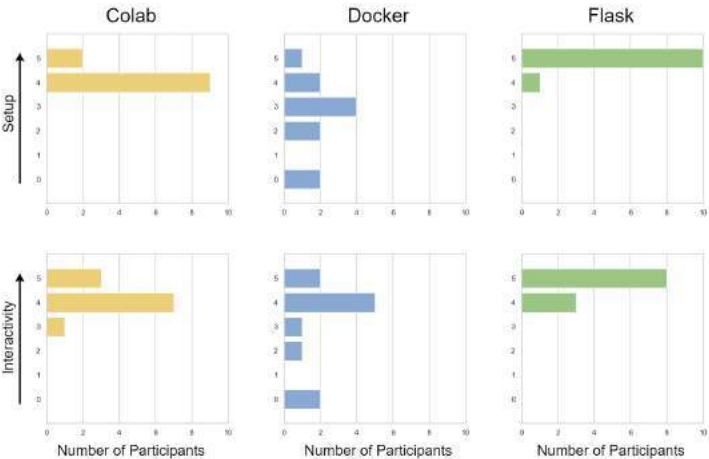

Figure 1: Survey results of setup and interactivity ratings for each data sharing technique.

Participants were generally Experienced at using Python, and Beginners at using notebooks and the terminal commands. Only 1 participant had prior experience using Docker. During the survey, all 11 participants were able to access visualizations shared through Flask and Colab. 2 participants were not able to access visualizations through Docker on their personal laptops due to technical challenges during installation. Flask had the highest average ratings for both ease of setup and interactivity. Docker had the lowest ratings for both categories. However, when asked their likelihood of using each data sharing method, only 4/11 responded likely to use Colab, compared to 7/11 for Docker and 11/11 for Flask.

DISCUSSION

One key question of interest for this study was to compare the preference of mouse rotate-able 3D objects in comparison to a 2D image that can be re-plotted by the user, the latter a low-tech solution which still allows some interactivity. However, the lack of interactive rotatability was reported as the main drawback to Colab by participants during the post survey discussion. While 3D objects do exist in some libraries available in Colab, 3D support is currently unstable and, in particular, is not recommended for dense meshes. We surmise that Google Colab could be a quick and preferred solution for rapid and low-cost sharing between colleagues, but not until there is stable 3D rendering support.

Initial setup of Docker containers was inconvenient for computer beginners due to difficulty installing and configuring on non-Unix based systems. This technique is well suited for situations involving processor-heavy visualizations and limited budget, as all computations are done locally rather than on a server. This places requirements on the user to have a suitable personal computer, which could be a viable option for motivated users for continued use.

Overall, users had a strong preference for quick setup time and rotatable 3D plots, as demonstrated by the clear popularity of the Flask web-page technique. The visual simplicity of the web-page displaying only the data plot and control widgets was also noted as a benefit by participants in comparison to the notebook/code interface, despite that fact the many users were themselves coders. This method also provides a high degree of customizability, and server hours can be scaled up as required. Indeed, during the Flask portion of the survey, multiple users accessing simultaneously caused server failure initially, and participant access had to be staggered. The estimated number of simultaneous users is therefore important to consider when determining computational resources to allocate for a web-page. This method would be the optimal solution for users with minimal technical background, and is a use case where it may be worth investing the extra time, money and effort for the developer.

For this pilot usability study, we desired to have all participants together online, hence it was limited to biomedical engineers due to the scheduling challenges for hospital-based clinical users. Lessons learned from this study will inform future testing with clinical users around the Flask web-page method, and consideration of the cost-benefit of more customizable paid cloud hosted notebook services, such as the Journal of Fluid Mechanics’ use of CoCalc [4].

INTRODUCTION

Elevation of intraocular pressure (IOP) in human and animal eyes deforms ocular tissues. The level of IOP is a risk factor in glaucoma, which is a chronic disease resulting in neurodegeneration of retinal ganglion cells followed by vision loss. Traumatic optic neuropathy, which occurs due to an acute injury to the optic nerve, also results in the neurodegeneration of retinal ganglion cells. The process of neurodegeneration is similar between chronic glaucoma and optic nerve injury. Furthermore, neuroprotection studies in animal models were similarly effective in nerve crush and elevated IOP models [1].

The purpose of the study is to compare these two models of retinal ganglion cell neurodegeneration in their biomechanical behavior of the astrocytic lamina cribrosa (AL). For the glaucoma mouse model, we used the microbead model of chronically elevated IOP [2]. For the traumatic optic neuropathy model, we performed optic nerve crush (ONC) in mice. We calculated the strain response to acute IOP elevations of the AL, and the evolution of the strain response 3 days to 6 weeks after the ONC or glaucoma.

METHODS

All experimental procedures were approved and monitored by the Johns Hopkins University School of Medicine Animal Care and Use Committee. Adult (5-8 month old) mice fluorescent in all cells were studied (heterozygous from crossing C57BL/6-Tg(CAG-EGFP)10Sb/J Jackson #003291 and C57BL/6J). One group of mice was subjected to ONC to model mechanical nerve injury, and another was subjected to the microbead injection model of glaucoma. Unilateral ONC was performed for 5 seconds with cross-action forceps, approximately 1 mm behind the eye globe. Unilateral microbead injection was performed to raise the IOP as in [1]. Mice were euthanized and their eyes were enucleated 3 days and 6 weeks after one of the surgical procedures. The fellow eyes of the microbead-injected eyes were used as control specimens. Sample sizes are in Table 1.

Mechanical testing was performed on enucleated eyes as previously described by raising the IOP from 10 to 30 mmHg [3,4]. Briefly, the anterior chamber of the eye was cannulated with a needle connected to fluid reservoir column. The microscopy system consisting of 2-photon laser source, Zeiss laser scanning microscope 710 was used to collect fluorescence signal from all cells expressing enhanced GFP in the AL. Two consecutive z-stacks were captured at 10 mmHg for calculation of errors. One of the stacks was warped (applied 3D strain) to later process and calculate the average absolute strain (E) error as $\sum(\sqrt{((E_{\text{applied}} - E_{\text{calc}})^2)})/N$ for every sample. A third z-stack at 30 mmHg was captured after 15 min equilibration. Post-processing of images and DVC algorithms were used [3-5]. After removing decorrelated data [3,4], the Green-Lagrange strains were calculated from the displacement gradients. Strain was calculated in the Cartesian coordinate system (E_{xx} , E_{yy} , E_{xy}), with x =nasal-temporal and y =inferior-superior axes, and in the cylindrical coordinate system (E_{rr} , $E_{\theta\theta}$, $E_{r\theta}$), and E_{zz} with z =optic nerve axis. The in-plane principal strains: maximum (E_{max}), minimum (E_{min}), and shear (γ_{max}) were calculated as well. The outer perimeter of the AL was traced by an ellipse. Specimen-average strain of the AL refers to the average of strain at all points within the outer ellipse of the AL. Central strain refers to the average of points within a central ellipse whose diameter equal half of the concentric outer ellipse's diameters. Peripheral strain refers to the average of points within the elliptical ring between the outer and central ellipses. Unpaired Student's t -tests were performed for statistical comparison of strain between two groups, with the significance level $p \leq 0.05$.

RESULTS

Specimen-average strain in 3-day glaucoma specimens was compared to the strain in control specimens. Glaucoma 3-day $E_{xx} = 0.046 \pm 0.028$ and $E_{\theta\theta} = 0.063 \pm 0.035$ tended to be greater than control $E_{xx} = 0.029 \pm 0.024$ and $E_{\theta\theta} = 0.030 \pm 0.028$, but the comparisons were

not statistically significant. Six weeks later, $E_{xx} = 0.025 \pm 0.008$ and $E_{\theta\theta} = 0.028 \pm 0.024$ in the 6-week glaucoma group were lower than in the 3-day glaucoma group and similar to the control group. The comparison of $E_{\theta\theta}$ between the 6-week glaucoma and the 3-day glaucoma groups was statistically significant ($p=0.03$, $n=8$ per group). The comparisons of other strain components were not significant.

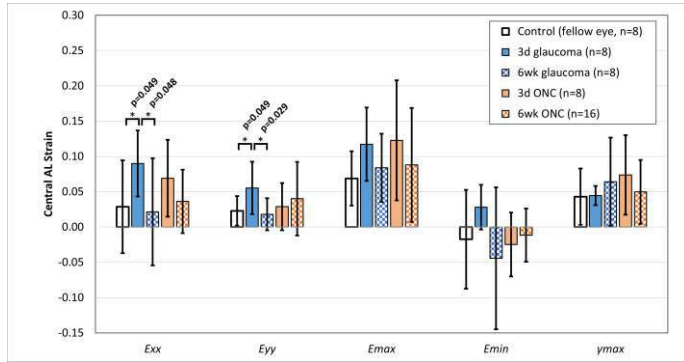

Figure 1: Bar graph of the Central Strain. E_{xx} and E_{yy} were greater in the 3-day glaucoma group compared to the control and the 6-week glaucoma groups. d=days, wk=weeks. * p -value ≤ 0.05 from Student's t -tests. Mean \pm stdev.

Table 1: Strain averaged in the central ellipse of the AL. Unpaired comparisons performed with Student's t -test, with significance level 0.05. * p -value ≤ 0.05 vs. control group. # p -value vs. 3-day glaucoma group. Mean \pm stdev.

	Control (n=8)	3-day glaucoma (n=8)	6-week glaucoma (n=8)	3-day ONC (n=8)	6-week ONC (n=16)
E_{rr}	0.025 ± 0.030	$0.066 \pm 0.038^*$	$0.016 \pm 0.043\#$	0.045 ± 0.045	0.031 ± 0.041
$E_{\theta\theta}$	0.027 ± 0.052	$0.080 \pm 0.044^*$	$0.024 \pm 0.054\#$	0.053 ± 0.039	0.045 ± 0.052
E_{xx}	0.029 ± 0.066	$0.090 \pm 0.047^*$	$0.022 \pm 0.076\#$	0.069 ± 0.054	0.036 ± 0.045
E_{yy}	0.023 ± 0.021	$0.055 \pm 0.037^*$	$0.018 \pm 0.023\#$	0.029 ± 0.033	0.040 ± 0.052
E_{zz}	0.005 ± 0.023	-0.001 ± 0.013	0.003 ± 0.030	0.016 ± 0.021	0.002 ± 0.023
E_{max}	0.069 ± 0.039	0.117 ± 0.052	0.084 ± 0.048	0.123 ± 0.085	0.088 ± 0.081
E_{min}	-0.017 ± 0.070	0.028 ± 0.032	-0.044 ± 0.101	-0.025 ± 0.045	-0.012 ± 0.038
γ_{max}	0.043 ± 0.040	0.045 ± 0.014	0.064 ± 0.063	0.074 ± 0.056	0.050 ± 0.045

Strains were averaged in the center of the AL. The central strain of 3-day glaucoma specimens were compared to the central strain of control specimens. Central strain calculated in the cylindrical coordinate system, E_{rr} , $E_{\theta\theta}$, and in the Cartesian coordinate system, E_{xx} , E_{yy} , were statistically greater in the 3-day glaucoma group compared to the control

group (Figure 1, Table 1). The maximum and minimum principal strains in the central region of the AL, E_{max} and E_{min} , tended to be greater than control, but the comparisons were not statistically significant (Table 1). Six weeks later, central E_{rr} , $E_{\theta\theta}$, E_{xx} , and E_{yy} , in the 6-week glaucoma group were lower than in the 3-day glaucoma group and similar to the control group. The comparison of central E_{rr} , $E_{\theta\theta}$, E_{xx} , and E_{yy} , between the 6-week glaucoma and the 3-day glaucoma groups were statistically significant ($p < 0.05$, $n = 8$ per group).

Specimen-average strain in 3-day ONC specimens was compared to the strain in control specimens. ONC 3-day $E_{xx} = 0.065 \pm 0.055$, $E_{\theta\theta} = 0.067 \pm 0.047$ tended to be greater than control $E_{xx} = 0.029 \pm 0.024$ and $E_{\theta\theta} = 0.030 \pm 0.028$, but the comparisons were not statistically significant. Six weeks later, $E_{xx} = 0.031 \pm 0.032$ and $E_{\theta\theta} = 0.037 \pm 0.040$ in the 6-week ONC group were lower than in the 3-day ONC group and similar to the control group. The comparisons of these strain components, E_{xx} and $E_{\theta\theta}$, between the 6-week ONC and the 3-day ONC groups were not statistically significant. Central and peripheral strain in the 3-day ONC group and in the 6-week group were compared to the respective strain in the control group. The central and peripheral strain components after ONC were similar to the central and peripheral strain components in the control group.

DISCUSSION

The strain response of the AL to IOP was greater in the 3-day glaucoma group compared to the control specimens. This was statistically significant in the central region of the AL. Six weeks later, the strain response in the glaucoma specimens became similar to the strain response of the control specimens. These results were similar to our previous findings in mice of a different genetic background [3]. In this mouse model of glaucoma, astrocytes lose the connections to their peripheral basement membrane at the sclera within 3 days. These connections were re-established 6 weeks later [6]. Studies using the rodent glaucoma model of IOP elevation reported similar structural changes in astrocyte structure [7,8]. This transient change in the astrocyte structure may contribute to the transient changes in the strain response. The increase in the strain of the AL seen in the glaucoma eyes at 3 days were not present in ONC specimens, neither 3 days nor 6 weeks after ONC. The limitation of the ONC procedure is the high variability in the degree of neurodegeneration across samples. Nevertheless, our findings suggest that the effect on the AL strain response with 3-days of glaucoma model is not primarily due to axon degeneration in the optic nerve head. Axon loss due to ONC does not significantly alter the mechanical response of the astrocytic network in the AL.

INTRODUCTION

Abdominal aortic aneurysm (AAA) is a condition where the terminal aorta begins to dilate more than 50% of the arteries original size [1]. AAA will continue to grow until the diameter reaches a maximum diameter (5.0 cm for women or 5.5 cm for men) or a patient experiences rupture. However, the maximum diameter criterion has been reported to have a high false positive rate, as many aneurysms below the threshold experience rupture events (~13-23.4% have been reported [3].

There are two central hypotheses that have been investigated to understand AAA rupture: 1) The aneurysm wall or material begins to weaken, and rupture occurs within a normal range of systolic blood pressure (120 mmHg), or 2) an elevated wall stress due to hypertensive systolic blood pressure exceeds the aneurysm wall. Interrogation of material properties of aneurysmal tissue and intraluminal thrombus (ILT) have been performed to develop material models. The previously developed material models have been incorporated into computational models to assess the biomechanical wall stresses of patient-specific AAA. These techniques are often reserved biomechanics experts and are inaccessible in a clinical setting but may potentially provide greater insight for clinicians to assess patient aneurysms than the current standard of care using the maximum diameter criteria.

The advent of widely available artificial intelligence software packages/toolkits and hardware (cloud-based computing and graphics processing units) present a viable pathway to enable stress-analysis into a clinical setting. In previous work, an artificial intelligence framework was developed to predict wall stresses using trained machine learning (ML) models from automatically segmented medical images using a trained convolutional neural network (U-NET), **Figure 1** [3]. However, the major limitation was the low sample size ($n = 10$), and the limitation of the ML training approach that incorporated the testing dataset.

This study presents an expansion of the stress-prediction ML training approach and incorporates a rendering pipeline to visualize the biomechanical wall stresses of patient-specific AAA using an augmented reality system,

the Microsoft HoloLens 2 (Microsoft Inc., Redmond, WA, USA). A recent push of creating a visualization layer to interact with data (metaverse) has garnered interest for the potential to use a combination of approaches to maximize the utility of medical imaging and biomechanics. This approach may enable clinicians without biomechanics expertise to view the wall stresses on patient aneurysms without adding significant time to their clinical workflow.

METHODS

A total of 274 deidentified patient medical images from a larger cohort was delivered by the Health Research Record Request (R3), an honest broker service provided by the University of Pittsburgh Department of Bioinformatics. The computed tomography (CT) images were manually segmented to extract the lumen and aneurysm wall. The point-clouds from the segmented images were used to create a computational mesh that included three distinct regions (aneurysm wall, lumen, and ILT). Computational wall stress analysis was performed

Figure 1: A) Tradition stress analysis pipeline for stress analysis and B) automatic segmentation and wall stress prediction using AI.

using Abaqus Standard (Dassault Systemés, France) using a well-established methodology using material models for the ILT and aneurysm wall [4, 5]. The results from the wall stress analysis were served as the ground truth dataset for the development of the ML model. Machine Learning Approach to Predict Wall Stresses: A custom data preparation MATLAB (MathWorks Inc., Natick, MA) script was used on the entire cohort that included various clustering and labeling methods developed in a previous study [3]. This included computing a neighborhood of principal curvature values, computing the ILT thickness, and retrieving the position of a node relative to the origin of the aneurysm surface placed at (0, 0, 0) in Cartesian coordinates. The last column of the prepared dataset was the computed nodal Von Mises wall stress. The training and testing datasets were split 75% (n = 206 patients) and 25% (n = 68 patients) randomly. Various ML models were selected for training to include ‘representative’ models tree-based, ensemble boosted trees (XGBoost), and neural networks. After the models were trained, the testing dataset was input into the model and compared to the ground truth wall stress values by computing the RMSE, R^2 , and Pearson statistics of a linear fit for each model to assess performance. To understand the effect of certain variables, ILT thickness was removed and neighborhood of principal curvatures in attempts to reduce the number of total variables used in the model. Augmented Reality Pipeline for Visualization: The predicted wall stresses and base geometry from the nodal positions in Cartesian coordinates were used to render a 3D model that can be visualized in the HoloLens 2 system. The total number of nodes were reduced to 20,000 and the wall stress predictions were and ‘baked’ into a rendered 3D model and exported into the cloud for visualization. The embedded software application in the HoloLens 2 app was used to visualize and interact with a patient’s AAA.

RESULTS

The representative trained ML models were tested, and the results were tabulated (Table 1). The highest performing model was the

Table 1: Reporting average wall stresses, RMSE, R2, and linear trendline slope of stress predictions vs. ground truth.

Model Name	Avg Stress N/cm²	RMSE	R²	Slope
Ground Truth	2.65 ± 5.63	-	-	-
Linear Regression	3.21 ± 5.13	3.41	0.56	0.80
Bagged Trees	3.28 ± 5.72	3.16	0.70	0.93
Coarse Trees	3.28 ± 5.84	3.34	0.67	0.93
Neural Network	3.33 ± 5.86	3.23	0.70	0.95
Boosted Trees	3.16 ± 5.40	2.99	0.69	0.88

neural network that had an R^2 closest to 0.70 and a slope of 0.95 of a linear fit that underestimated the wall stresses by 5% overall. It can also be qualitatively seen that the wall stress predictions for the neural network best mimicked the heat map of the ground truth wall stress analysis (Figure 2). The poorest model was the linear regression model (non-ML) that failed to provide any of the banding found in the ground truth models. It was also found that the residual plots (not shown) pertinent to using all variables

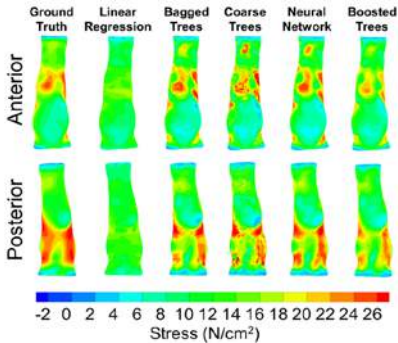

Figure 2: Anterior and posterior views of the ground truth stress map and the predicted wall stress maps from trained ML models.

performed better than the models trained without ILT thickness and node neighbors of principal curvatures with respect to RMSE, R^2 , and slope from a linear fit. The wall stress predictions took on average of 2 seconds with an additional 3 seconds for the rendering pipeline to be performed using a local workstation with an NVIDIA (NVIDIA Inc. Santa Clara, CA USA) A5000 GPU.

DISCUSSION

This study presented the expansion of wall stress predictions by increasing the number of patient cases by 20-fold for training (n = 206). The current study was able to predict the wall stresses using an unseen testing dataset (n = 68) with relatively high accuracy when compared to the ground truth results from traditional stress analysis. However, the best performing model, the neural network still underestimated the wall-stresses by 5% on average. In addition to wall stress predictions, a method to render and view 3D stress maps in HoloLens 2 was also created for potential future use for clinicians to assess a patient’s aneurysm. Previous studies have developed physics-based neural-network approaches to compute stresses in models [6] with high accuracy to investigate a wide range of organs. The potential to generalize an approach may enable such systems to be used for all types of systems within the body (cardiovascular, organ, musculoskeletal, etc.). Although this type of approach is appealing, a reliance remains on experimentally validated biomechanical behavior of such systems within the body that must be continually explored and evaluated. Accelerating biomechanics with AI may provide augmented reality systems the necessary engine for adoption into the clinic without the need for engineering expertise.

There are limitations to the presented study. The number of cases increased but still underestimated the overall stress at each point within the surface of the aneurysm. The expansion of the 3D image-reconstruction using various deep learning techniques was not presented but remains necessary for confirming the accuracy of wall stress predictions directly from CT images. It is unclear whether 206 patient cases are sufficient for training, or if an increased sample size is required to improve overall accuracy of the model. After a suitable sample size for training is found, an expedited feedback process to re-run stress analysis on newly developed material models from experimental measurements may allow for continual updates to the ML stress prediction models.

Future work will expand on the previously trained 3D image classification model from the ground truth manually segmented images from this study. Additional datasets will be incorporated to understand the effect of increasing the sample size with accuracy of the stress prediction models. Lastly, the technology and ability to view the biomechanical wall stresses on patient-specific aneurysms will be tested by clinicians to receive critical feedback with regards to the methodology presented in this study.

INTRODUCTION

Preterm birth, defined as fetal delivery before 37 weeks gestation, affects 11% of births globally [1]. Cervical insufficiency is a form of spontaneous preterm birth marked by premature dilation and shortening of the cervix. While the etiology of cervical insufficiency is unknown, improper elastic fiber and smooth muscle cell (SMC) remodeling may contribute [2, 3]. Cervical SMCs are critical to maintain contractile behavior and cervical shape [4]. Multiple proteins, such as Fibulin-5 (*Fbln5*), are involved in proper elastic fiber formation which allows the cervix to stretch and recoil [5]. In the vagina and blood vessels, disruption of elastic fibers resulted in lower contractility [6, 7]. However, the relationship between elastic fibers and SMCs in the cervix remains unknown. Therefore, the objective of this study is to leverage the cervixes of *Fbln5* global knockout mice to quantify multiaxial contractility.

METHODS

Animal Care. 28 nulliparous C57BL6 x 129SvEv female mice aged 3–6 months at estrus were used (Tulane IACUC approved). Mice were divided into groups based on genotype wherein $n=10$ mice were wildtype (WT) controls with both copies of the *Fbln5* gene, $n=10$ were heterozygous (HET) mice with one copy of the *Fbln5* gene, and $n=8$ were knockout (KO) mice with *Fbln5* deficiency. ***In Vivo* Contractility.** To determine *in vivo* contractile behavior, transcervical measurements were taken in WT ($n=5$), HET ($n=5$), and KO ($n=3$) female mice at estrus. Mice were anesthetized with 2% isoflurane mixed with 100% oxygen. A 2F Millar catheter was inserted into the vaginal canal until the cervix was reached. The presence of phasic contractions indicated proper placement in the cervix. The catheter was equilibrated in the cervix for five minutes, followed by five minutes of recording in which the baseline pressure, contractile pressure, and contraction frequency were measured (Fig 1A). **Specimen Preparation.** A separate group of mice ($n=5$ /genotype) at estrus were sacrificed via guillotine to

preserve SMC viability. The cervix was dissected from the reproductive tract and cannulated onto a biaxial extension inflation device in Krebs' Ringer Buffer (KRB). The estimated physiologic length was determined following the assumption that soft tissues seek to preserve a constant force over a range of physiologic pressures [9]. Five cycles of preconditioning were performed to achieve consistent and repeatable results [7, 8]. SMCs were preconditioned by inducing contractions with 20 mM of potassium chloride (KCl). ***In Vitro* Contractility.** After SMC preconditioning, the bath was replaced with fresh KRB, and the tissue was equilibrated for 10 minutes. Next, 10 mM of KCl was added to the bath, and the tissue contracted for five minutes. The changes in outer diameter and axial force were recorded. After five minutes, the bath was replaced with fresh KRB, and the tissue was equilibrated for five minutes. This process was repeated for KCl doses of 15–100 mM. **Data Analysis.** Circumferential contractility was determined as the change in outer diameter from the resting to the contracted state. Axial contractility was defined as the change in force measured by the force transducer. **Statistical Analysis.** For the statistical analysis described herein, the Shapiro-Wilks test indicated that the error of the data was normally distributed. Statistics were performed by hypotheses. Paired t-tests determined differences between the *in vivo* baseline and contractile pressure within each genotype. Next, a one-way ANOVA evaluated the effect of the *Fbln5* genotype on the *in vivo* baseline pressure, contractile pressure, and contractile frequency, followed by Tukey's post hoc test. To determine if the concentration of KCl and *Fbln5* genotype influenced contractility, a two-way ANOVA (dose, genotype) evaluated changes in outer diameter and axial force. Post hoc t-tests with Bonferroni corrections were utilized when appropriate.

RESULTS

***In Vivo* Contractility.** The paired t-tests determined the maximum contractile pressure significantly increased from the baseline pressure in the WT ($p=0.007$) and HET ($p=0.029$). However, there was no

significant difference between the baseline and maximum contractile pressure in the KO group. A one-way ANOVA showed significant baseline pressure differences ($p=0.02$) between genotypes. Post hoc testing showed that the KO baseline pressure (6.73 ± 2.90 mmHg) was significantly lower than the HET (12.1 ± 1.58 mmHg) baseline (Fig 1B). No significant differences were identified in maximum contractile pressure or frequency.

Figure 1: *In vivo* cervical contractility. (A). Representative recording of *in vivo* pressure measurements. Average pressure between contractions determined the baseline pressure (black box). The peak of each contraction (black open circle) was averaged to determine the maximum contractile pressure. Time from peak to peak determined the frequency of contraction (black closed circles). (B). Mean *in vivo* baseline pressure in the WT ($n=5$), HET ($n=5$), and KO ($n=3$) cervix. The KO cervix (6.7 ± 2.9 mmHg) was significantly ($p=0.02$) lower than the HET (12.1 ± 1.5 mmHg) but not the WT (10.4 ± 2.2 mmHg).

***In Vitro* Contractility.** A two-way ANOVA identified significant differences in circumferential contractility with respect to genotype ($p<0.0001$) but not KCl concentration. Post hoc tests showed no significant differences in circumferential contractility between the WT and HET samples. Circumferential contractility significantly decreased in the KO cervix versus the WT cervix for all doses except 10 mM ($p<0.01$ for 15 mM and 60–80 mM, $p<0.001$ for 20–50 mM, and $p<0.05$ for 100 mM) (Fig 2A). Additionally, circumferential contractility significantly decreased in the KO cervix versus the HET cervix for all doses of KCl ($p<0.01$ for 10 and 100 mM and $p<0.001$ for 15–80 mM). A two-way ANOVA (genotype, KCl concentration) detected differences with axial force ($p<0.0001$) (Fig 2B). Post hoc testing showed a significant decrease in contractility ($p<0.05$) between the HET and KO cervix at 15 mM KCl. No other significant differences in axial force were detected. All samples exhibited spontaneous phasic contractions once mounted on the device.

Figure 2: *In vitro* KCl dose response contractility results for the WT (black), HET (blue), and KO (grey) cervix ($n=5$ /group). (A). Circumferential contractility, measured via the change in outer diameter, significantly decreased in the KO cervix compared to the WT cervix ($p<0.01$ for 15 mM, 60–80 mM, $p<0.001$ for 20–50 mM, and $p<0.05$ for 100 mM). Additionally, circumferential contractility decreased in the KO cervix compared to the HET cervix ($p<0.01$ for 10 and 100 mM and $p<0.001$ for 15–80 mM). No significant changes were detected between the WT and HET cervix. (B). The HET cervix increased axial force significantly ($p<0.05$) compared to the KO cervix at a KCl dose of 15 mM dose. No other significant changes were detected.

DISCUSSION

This study investigated *in vivo* and *in vitro* contractility of the murine cervix with varying *Fbln5* genotypes. The cervix exhibits phasic contractions with a significant pressure difference in the WT and HET. The lack of significant changes in the *in vivo* KO contractile pressure may suggest a potential interaction between elastic fiber components, such as *Fbln5*, and SMC modulation from the contractile to the synthetic phenotype. Studies in the vagina showed decreased contractile-associated proteins with *Fbln5* deficiency. [7] Further, previous work suggests that elastin, the main component of elastic fibers, is a regulatory phenotypic modulation cue in vasculature [10]. Contractile-associated genes in arterial SMCs are also significantly downregulated in elastin knockout mice [11].

Additionally, the *Fbln5* KO cervix had the lowest contractile behavior *in vivo* and *in vitro*, suggesting matrix composition and properties may influence contractile behavior. Similarly, decreased contractility was observed in the *Fbln5* deficient vagina compared to the wild-type control [7]. Further, primary cervical SMCs obtained from patients with cervical insufficiency showed decreased contractility when exposed to soft matrix. [3] Studies in vasculature suggest that a decrease in elastic fiber formation leads to increased stiffness, contributing to a lower contractile potential [6, 12]. Further studies are needed to investigate the material properties of the KO cervix.

Similar to the murine vagina, direction-dependent contractile behavior was observed. There was a significant decrease in circumferential contractility in the KO cervix but not axial contractility. The murine cervix of nulliparous CD-1 mice presents with greater axial contractility compared to circumferential [8]. Further, in the murine vagina, increased elastin area fraction along the axial direction coincides with a greater contractile response in the axial direction compared to the circumferential [13]. This may suggest a direction-dependent organization of elastic fibers and cervical SMCs.

This study is not without limitations. The cervix is heavily influenced by gestation and hormones. While investigating cervical contractility throughout gestation is of interest, initial studies in the nulliparous state must first be completed to have a baseline understanding of cervical function and microstructural composition. Further studies employed to understand the relationship between elastic fiber composition and contractility in the cervix will improve our understanding of cervical insufficiency and spontaneous preterm birth.

LAMINA CRIBROSA BEAM INSERTIONS. THE HUMBLE HEROES OF THE LAMINA – SCLERA INTERPLAY

Fengting Ji (1), Hua Yi (2), Ian A. Sigal (1,2)

INTRODUCTION

The lamina cribrosa (LC) is a specialized structure in the posterior pole of the eye that supports the retinal ganglion cell axons as they exit the globe on their way to the brain [1]. The LC biomechanical support is necessary to withstand the forces and deformations caused by intraocular pressure or other mechanical challenges. The ability of the LC to support the neural tissues is intrinsically dependent on the much stronger surrounding peripapillary sclera. While much has been learned about the LC, the peripapillary sclera and the crucial interplay between them [2], far less is known about the LC beam insertions through which these two tissues interact. Studies of the LC-sclera simplify the interface between the tissues as a smooth continuum surface, ignoring that the LC beam insertions are discrete with complex shapes [3].

Using recently developed microscopy tools we obtained detailed information on the LC and sclera. Inspecting the LC-sclera interface it is readily visible that the LC insertions are complex, and that they vary greatly in shape. Some insertions resemble the wide roots of old trees, whereas others look much thinner (**Fig. 1**). These shapes suggest that the LC insertions likely also vary in how well they can satisfy the mechanical demands of the LC-sclera interface. **Our goal was to characterize LC beam insertion shape in sheep, pig, monkey and human.** We test the hypothesis that the LC insertion width and insertion angle vary between species (**Fig. 2**). In addition, we present the early stages of the development of a direct fiber-based finite element method to model the mechanics of the LC insertions. We use this tool to evaluate the biomechanical consequences of the differences between insertions.

Figure 1: Instant polarized light microscopy images of LC and sclera of eyes from the four species. For each species a close-up is shown to illustrate typical insertions.

METHODS

Sample preparation: two monkey eyes, three sheep eyes, two human eyes, and three pig eyes without known abnormalities were fixed. The LC and peripapillary sclera were trephined and cryosectioned coronally. From each eye, three sections located close to the LC midplane were selected for analysis.

Imaging: Sections were imaged with instant polarized light microscopy (IPOL) with a 10x strain-free objective (Olympus, Tokyo, Japan, 0.66µm/pixel) [4]. Because of the lower collagen density the LC region often appears darker than the sclera. We therefore acquired images with various exposures to allow clear visualization of both tissues. Mosaics with 10% overlap were used to image whole sections. IPOL images reveal local collagen orientation and density in each pixel which helps visualize the LC beam and canal collagen structure.

Insertion quantification: We measured two parameters of each insertion: width and angle. Width was measured at the edge of the scleral canal. Angle was between the LC beam and the tangent of the sclera canal. Insertion angles range from 0 to 90°, with 90° being an LC insertion perpendicular into the canal wall. The parameters were measured from lines drawn manually using Fiji. Calculations were done in MATLAB v2022 (MathWorks, Natick, MA, USA).

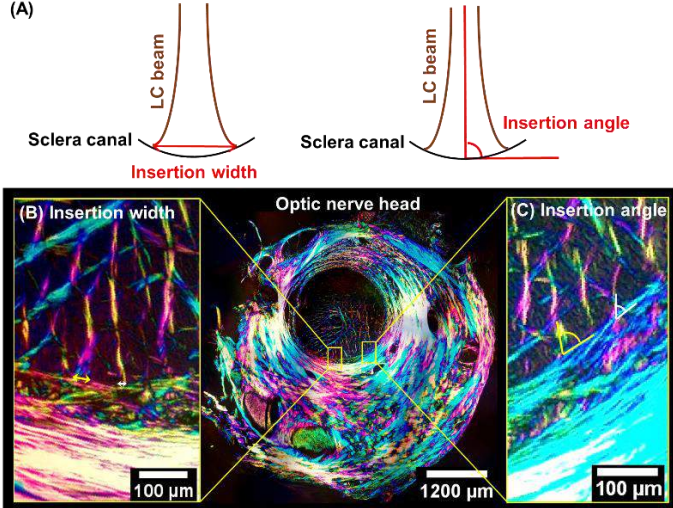

Figure 2: (A) Diagrams showing the definition of (left) insertion width and (right) insertion angle. (B,C) Example images of monkey ONH illustrating insertions of different widths or angles.

Statistics: Linear mixed effects models, accounting for autocorrelations between measurements from the same sections, eyes and species, were used to assess if the parameters of insertions were associated with species.

Finite element analysis: We built two models to simulate two pig insertions with different shapes, one was straightly inserted into the canal while the other one was wide and spread (Fig. 3). The models were built using the direct fiber modeling technique as described elsewhere [5]. Briefly, we manually traced on IPOL images two groups of fibers representing the LC beam and sclera canal. The fibers were discretized with linear truss elements (T3D2) of circular cross-section and linear elastic material properties. Fiber overlaps were resolved using an iterative algorithm that refined and displaced them, resulting in discrete, interwoven realistic-looking fibers.

To compare the difference in the mechanical responses of the two insertions, a 15% equi-biaxial expansion was simulated on both models. Fiber-fiber interactions were incorporated using general contact to prevent fiber interpenetration. The solution was obtained using Abaqus/Explicit. We compared the stress responses of the two models.

RESULTS

Figure 3 shows the direct fiber modeling results of the two pig LC insertions with different shapes.

Figure 4 shows the distributions of insertion widths and angles of the four species across all eyes. Insertion widths were significantly different between all species ($p < 0.001$), with widths (mean \pm SD, μ m) in human (55.28 ± 27.07), sheep (95.40 ± 49.09), pig (137.02 ± 79.91) and monkey (27.58 ± 16.11).

Insertion angles of sheep and pig were larger than monkey and human ($p < 0.05$), with angles (mean \pm SD, $^\circ$) in human (70.74 ± 14.4), sheep (76.43 ± 11.66), pig (74.28 ± 14.17) and monkey (70.88 ± 16.06). No difference was detected in insertion angles between sheep and pig, and monkey and human.

Figure 3: A comparison of the mechanical response between a spread and wide insertion (top row) and a straight and narrow insertion (bottom row). Direct fiber models (middle column) were created by tracing collagen fibers on IPOL images (left column). The stress responses of fibers under 15% equi-biaxial stretch are shown (right column). The insertion with spread and wide LC beam bears substantially less load (lower stress) than the other one, illustrating that LC insertion shape has a large effect on the local sensitivity to IOP.

Figure 4: Box plots of (A) insertion widths and (B) insertion angles of each species. There were significant and large differences in insertion widths between species.

DISCUSSION

We present the first characterization of LC insertion width and angle. The discrete LC beam insertions could mean that the interaction between LC and surrounding load-bearing tissue is nonlinear and discontinuous over the canal, with forces concentrated in some regions. Different shapes of insertions can represent different levels of robustness of the LC periphery. The differences could result in different species susceptibilities to glaucomatous damage. Future work involves extending the numerical models to include a wider diversity of insertions and boundary conditions. Further work is also necessary to understand the potential consequences of differences in angle.

INTRODUCTION

There is an inherent risk of injury in auto racing due to high speeds and risk of collisions. With significant improvements to safety, severe brain injury in motorsports has significantly decreased [1]. A retrospective analysis of all National Association for Stock Car Auto Racing (NASCAR) data between 2002 and 2008 found that concussion occurred in 27 of the 274 (9.9%) impacts selected for numerical simulation [2]. In addition to the risk of concussion resulting from crashes, drivers also experience perturbations under normal racing conditions, however further research is necessary to understand the neurocognitive effects of these perturbations [3]. Previous studies have examined the application of earpieces instrumented with tri-axial accelerometers in motorsport but have differing conclusions [4,5]. Mouthpiece sensors have been used in football, soccer, and hockey to examine head acceleration events (HAEs), including direct head impacts. However, mouthpieces have not been widely used to study HAEs in motorsports. Examining these events can help inform driver safety systems and mitigate HAEs. Thus, this study aims to characterize HAEs experienced during professional racing across tracks using an instrumented mouthpiece.

METHODS

Six drivers in the NASCAR Cup Series were outfitted with custom mouthpiece sensors containing a tri-axial accelerometer and an angular rate sensor for 20-minute practice sessions at seven different tracks. Track names were assigned based on track type: short track (ST, n=4), intermediate (I, n=1), superspeedway (SS, n=1), and road course (RC, n=1). Mouthpiece data was excluded from analyses if a driver did not wear their mouthpiece for the entire duration of the practice session. The mouthpiece sensors recorded linear acceleration and rotational velocity at 200 Hz, and kinematic data was transformed to the head center of gravity using subject-specific transformation matrices. Time-synchronized video was collected at each practice session to segment

the kinematic data on a per-lap basis. After segmentation, a 100-point moving average filter was calculated and subtracted from the data to remove periodicity associated with movement around the track to obtain “adjusted” data. This process is demonstrated in Figure 1. The adjusted resultant data was then calculated from the adjusted component data. Peak resultant kinematics were compared across drivers at each track. Summary statistics were quantified by number of laps (n), peak resultant linear acceleration (PLA), peak resultant rotational velocity (PRV), and peak resultant rotational acceleration (PRA) for laps. Lap data with a lap time, PLA, PRV, or PRA greater than the 95th percentile (%ile) were excluded from analysis.

Figure 1: Process for obtaining “adjusted” kinematic data.

Six separate one-way ANOVA (analysis of variance) tests were conducted to determine statistically significant differences between peak kinematic data across tracks and track types using SAS (Cary, NC). Pairwise t-tests were subsequently performed to determine which track types differed. Using driver, track, and track type as categorical

variables, preliminary statistical analyses exploring them as predictors for peak head kinematics were performed in SAS using simple linear regressions. Finally, mixed effects models were prepared to determine whether the driver added random variance in head motion for tracks and track types.

RESULTS

The mouthpiece sensors recorded 506 complete laps at seven tracks. After excluding laps recorded by the mouthpiece when the driver was not wearing the device ($n=19$), summary statistics for PLA, PRV, and PRA were computed. Median (95th %ile) PLA, PRV, and PRA for all laps excluding laps with invalid mouthpiece data were 1.16 (1.77) g, 0.78 (1.57) rad/s, and 7.90 (18.0) rad/s², respectively. Summary statistics were computed by track and track type as shown in Figures 2 and 3. Track RC1 has the greatest median PLA, PRV, and PRA and is the only track identified as a “Road Course”, thus road courses also had the largest magnitude peak head kinematics. Track ST4 had the lowest magnitude median peak kinematics.

Figure 2: Peak resultant linear acceleration (left), rotational velocity (middle), and rotational acceleration (right) per lap across tracks.

Figure 3: Peak resultant linear acceleration (left), rotational velocity (middle), and rotational acceleration (right) per lap across track types.

From the ANOVA tests, a significant difference ($p < .0001$) in PLA, PRV, and PRA was observed across the seven tracks and four track types. The road course (track RC1) had significantly greater PLA and PRA than the other track types. Additionally, the road course had significantly greater PRV than short tracks ($\Delta=0.34$ rad/s) and the superspeedway (track SS1, $\Delta=0.32$). The intermediate track (track I1) had significantly greater PRV than the superspeedway ($\Delta=0.38$ rad/s) and the short tracks ($\Delta=0.32$ rad/s). However, the short tracks had significantly greater PLA than intermediate tracks ($\Delta=0.22$ g). The linear regressions showed a significant association between track and PLA ($p=.0065$), PRV ($p<.0001$), and PRA ($p=.0174$) and between track type and both PRV and PRA ($p<.0001$). The mixed effects models showed significant differences in peak head kinematics between drivers at the intermediate track (I1), PRA at short tracks (ST2, ST3, ST4), and PLA at track ST3 between drivers.

DISCUSSION

The objective of this study was to quantify differences in peak resultant head kinematics experienced by NASCAR drivers during

practice laps. Previous work has shown differences in peak lap kinematics between drivers and tracks [6]. The “Intermediate” track type had the lowest magnitude median PLA, the “Short Track” track type had the smallest magnitude median PRV, and the “Superspeedway” track type had the smallest magnitude median PRA. Track type analysis is limited as Intermediate, Road Course, and Superspeedway types comprised of one track as opposed to the four tracks identified as Short Tracks.

Despite the significant association between PRA and driver via linear regression, there were not any significant differences in PLA and PRV across the six drivers. This may suggest that while each driver has some variations in their safety system (e.g., HANS vs. Hybrid, seat design), the performance of the systems to reduce linear motion of the head do not significantly differ.

Findings from this study show that peak resultant head kinematics are influenced by the type of track. Particularly, peak kinematics at the Road Course were significantly greater than the other track types. This can potentially be explained by the elevated presence of rumble strips on road courses and turning both left and right. When racing on a road course, the car’s outside tires go often pass over the rumble strips or other track edge markers at high speeds. It was also found that peak resultant rotational velocity at the intermediate track differed from the other three track types. The distance between the driver’s helmet and foam in the head surround may influence the differences in head kinematics. However, further investigation of component data is needed to determine the mechanisms behind the differences in head kinematics.

ACKNOWLEDGEMENTS

The authors would like to thank the drivers for their participation in the study and acknowledge all members of the research team who assisted with data collection.

ENDOTHELIAL NUCLEAR MORPHOLOGY IS INCREMENTALLY SENSITIVE TO SHEAR STRESS MAGNITUDE AND DIRECTIONALITY

Jaideep Sahni (1), Mehwish Arshad (2), Peter D. Weinberg (2), Ryan M. Pedrigi (1)

INTRODUCTION

Vascular endothelial cells form the inner lining of arteries and are exquisitely sensitive to shear stress magnitude and directionality [1]. Unidirectional shear stress at an average physiologic magnitude promotes a healthy endothelial phenotype, while multidirectional shear stress at a low magnitude promotes a dysfunctional phenotype. Although there are many mechanisms by which endothelial cells transduce shear stress into a biological response, a principal one that has received little attention is changes in nuclear morphology. The endothelial cytoskeleton is connected to the nucleus to allow load transmission that directly regulates gene expression [2] by causing nuclear deformation [3]. Different shear stress conditions likely deform endothelial nuclei differently and promote different behaviors. Yet, little work has characterized this relationship. Since local arterial segments around bifurcations and highly curving arteries contain a range of shear stress conditions from low and multidirectional to high and unidirectional [1], it is critical to understand how incremental changes in these conditions affect drivers of endothelial functions to better predict diseases such as atherosclerosis. Therefore, in this study, we quantified nuclear area and aspect ratio over a range of shear stress conditions using an orbital shaker model. We found high correlations with two shear stress metrics previously associated with atherogenesis.

METHODS

Cell Culture. Human umbilical vein endothelial cells (HUVECs) were seeded at passages 4-7 into 6-well culture plates with type I collagen at 40,000 cells/cm². Experiments were run one day after seeding with 2.41 ml of media per well to give a medium height of 2.5 mm. In each experiment, well plates were either subjected to orbital flow or static conditions (control) for 72 h. Orbital flow was induced using an orbital shaker, which moves the culture plate in a planar circular orbit of 5 mm radius, and rotating it at 120, 250, or 350 RPM within a humidified incubator at 37°C and 5% CO₂.

Staining and Imaging. After orbital flow, cells were fixed in 4% paraformaldehyde in PBS for 10 mins and then incubated with 10 μ M DAPI for 2 min. Cell layers were imaged with a Zeiss LSM 800 confocal microscope using a 10x objective and tile scan from the center to periphery of each well. Images of the DAPI stain were automatically processed to quantify nuclear area and aspect ratio using a custom script in ImageJ. These metrics at each radial location of all cell layers under orbital flow are reported relative to their average value at each radial location of the static controls seeded at the time of each experiment.

Computational Fluid Dynamics. Star CCM+ was used for all flow simulations. A single well of a 6-well culture plate was represented as a cylinder with a height of 10 mm and radius of 17.4 mm. The culture medium had a height of 2.5 mm at rest and the remaining space was filled with air. The geometry was discretized using a structured cylindrical mesh with 360,000 grid elements. A no-slip condition was imposed at all walls and surface tension was neglected. The top surface of the cylinder was defined as a pressure outlet. The dynamic viscosity and density of the medium were 0.78 mPa.s and 1003 kg/m³, respectively, whereas the dynamic viscosity and density of air were 0.0187 mPa.s and 1.1115 kg/m³. All three orbital velocities used in the cell experiments were simulated: 120, 250, and 350 RPM. The primary output was the instantaneous wall shear stress (WSS) vector at each element on the base of the well at each time increment over one complete revolution. This was used to calculate magnitude of the mean WSS (MagMeanWSS) and oscillatory shear index (OSI).

Statistics. Quantities are reported as mean \pm standard deviation. Normality was determined by a Shapiro-Wilks test and either a two-tailed *t*-test or Mann Whitney U test was performed. Multiple comparisons were accounted for using a Holm-Bonferroni correction. To quantify the linear association between nuclear morphology and WSS metrics, a Spearman's rank correlation coefficient (ρ) was computed. For this test, a Bonferroni correction was used. An adjusted *p*-value of less than 0.05 was considered statistically significant.

RESULTS

Endothelial nuclear area and aspect ratio were highly dependent on the shear stress condition (Figure 1A-B). Nuclear area (relative to controls) in the central one third of the radius of cell layers, where low and multidirectional shear stress is present, exhibited a significant increase from controls (1.00 ± 0.02) with values of 1.03 ± 0.01 at 120 RPM and 1.05 ± 0.02 at 250 RPM (Figure 1C). In the peripheral one third of the radius of cell layers, where high and unidirectional shear stress is present, nuclear area significantly decreased compared to controls (1.00 ± 0.02) with values of 0.95 ± 0.02 at 120 RPM ($p = 0.0007$), 0.94 ± 0.01 at 250 RPM ($p < 0.0001$), and 0.90 ± 0.01 at 350 RPM ($p < 0.0001$). Nuclear aspect ratio at these angular velocities showed an inverse trend to area (Figure 1C). The most significant changes compared to controls (1.55 ± 0.02) were seen at the periphery with values of 1.62 ± 0.02 at 250 RPM ($p < 0.0001$) and 1.68 ± 0.02 at 350 RPM ($p < 0.0001$). Note that 350 RPM could only be assessed at the periphery of cell layers due to the central portion being nearly devoid of medium.

Figure 1: (A) Plots of MagMeanWSS and OSI from center to periphery of a CFD-simulated culture well on an orbital shaker at 250 RPM. (B) Images of endothelial nuclei at three radial locations (top) after 72 h at 250 RPM and (bottom) static conditions (control). (C) Plots of nuclear area and aspect ratio relative to the mean of static controls over each culture well from center to periphery.

We next evaluated how shear stress magnitude (MagMeanWSS) and directionality (OSI) separately associated with nuclear area and aspect ratio. Nuclear area exhibited a high negative correlation with MagMeanWSS of -0.74 ($p = 0.0007$) and a high positive correlation with OSI of 0.8 ($p < 0.0001$). Nuclear aspect ratio showed an inverse trend of a high positive correlation with MagMeanWSS of 0.9 ($p < 0.0001$) and high negative correlation with OSI of -0.81 ($p = 0.009$) (Figure 2).

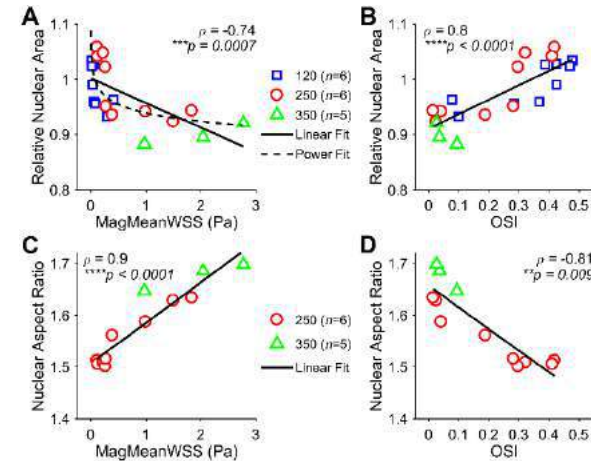

Figure 2: (A, B) Endothelial nuclear area as a function of (A) MagMeanWSS and (B) OSI. (C, D) Endothelial nuclear aspect ratio as a function of (C) MagMeanWSS and (D) OSI. Data points were averaged over all cell layers (indicated by n) for each orbital velocity (120, 250, and 350 RPM) at each duration and radial position in the well (because no statistical difference in nuclear aspect ratio was seen at 120 RPM compared to controls, these data were removed from the correlation calculations). The black line represents a best-fit line (solid) and power (dashed) function across all data points to visualize the trend.

DISCUSSION

To our knowledge, this study is the first to characterize changes in nuclear morphology over a range of WSS conditions that are similar to those found around bifurcations and the inner curvature of highly curving arteries, including with a similar range of WSS magnitudes (e.g., MagMeanWSS ranged from 0.01 to 2.8 Pa) and directionality (e.g., OSI ranged from 0.01 to 0.48). We also demonstrated high correlations (positive and negative) between these endothelial behaviors and WSS metrics of magnitude and directionality, which indicated a strong ability of these metrics to predict endothelial function. These findings demonstrate the sensitivity of the endothelium to incremental changes in WSS over a range of conditions, which may be leveraged to aid in predicting arterial function and dysfunction. In addition, these findings suggest that the susceptibility of an arterial segment to atherosclerosis has a similar level of high sensitivity to the blood flow condition that may be important in determining, not just initiation, but also progression to different plaque phenotypes.

UNDERSTANDING MECHANOTRANSDUCTION OF THE DISTAL COLON AND RECTUM BY MULTISCALE AND MULTIMODAL COMPUTATIONAL MODELING

Amirhossein Shokrani (1), Ashkan Almasi (1), Bin Feng (2), David M. Pierce (1,2)

(1) Department of Mechanical Engineering, University of Connecticut, Storrs, CT, USA
(2) Department of Biomedical Engineering, University of Connecticut, Storrs, CT, USA

INTRODUCTION

Irritable bowel syndrome (IBS) is a common reason why patients visit gastroenterologists, with the main complaint of chronic visceral pain [1]. Mechanotransduction, the process of transducing visceral mechanical stimuli into action potentials by sensory nerve endings in distal colon and rectum (colorectum), plays a central role in visceral pain associated with IBS [2]. Thus, investigating the biomechanical behavior of the colorectum can lead us to better understanding of the generation of pain. We and others have made many significant findings experimentally by investigating both the biomechanics of the colorectum and the neural encoding functions of colorectal afferents.

Siri et al. [3] revealed significant mechanical heterogeneity in the colorectum in all three curvilinear directions: longitudinal, circumferential, and radial. They took the distal 30 mm of the colorectums from mice, divided these evenly into three 10-mm-long segments (colonic, intermediate, and rectal), and completed both biaxial mechanical extension tests and opening-angle measurements with each of these segments. They also presented evidence that the submucosa is load-bearing layer of the colorectum that undergoes elevated mechanical stresses. Feng et al. [4] systematically studied the neural encoding function of colorectal afferents by single-fiber recordings. They tested the afferent endings using three distinct mechanical stimulations: circumferential stretch, punctuate probing, and mucosal shearing. Based on the response profiles they measured experimentally, they functionally characterized colorectal afferents into five major subtypes wherein four of them are mechanosensitive subtypes. Guo et al. [5] completed a recent anatomical study using optically clearing that allowed systematic quantification of afferent fiber densities within different layers of the colorectum. Their results revealed that the colonic submucosa contains a significantly higher density of afferent fibers relative to the other sublayers. The focal presence of afferents in the submucosa strongly suggests their nociceptive roles [6].

In this study we aimed to establish a multiscale computational framework which leverages finite element (FE) simulations of the colorectum to predict the patterns of afferent-ending spikes induced by mechanical loading, i.e. simulations of the mechanotransduction process in the colorectum that causes chronic pain.

METHODS

Experimental evidence. We utilized previous evidence from our experiments on mouse colorectums including the biomechanics [3,6,7] and both the encoding function [4] and the intra-tissue morphology of colorectal afferents [5].

Finite element model. We developed a macroscopic FE model that accounted for tissue mechanical heterogeneity in longitudinal, radial, and circumferential directions, see fig. 1(a). In the FE model, we considered colorectum as a three-layered, incompressible, hyperelastic continuum with embedded collagen fibers [8]. We meshed the geometry

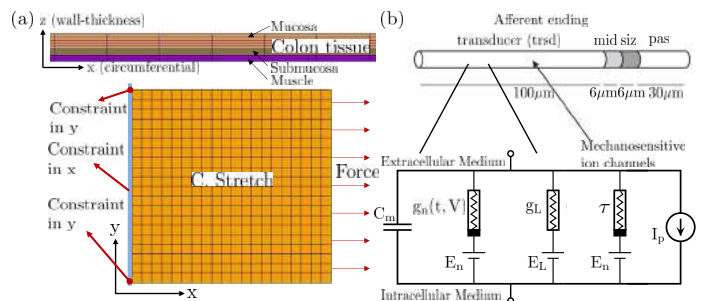

Figure 1: (a) Representative finite element model of a segment of the colorectum undergoing uniaxial, circumferential stretch. (b) Schematic of our Hodgkin–Huxley-type model of action potential generation in the colorectal afferent endings, including mechanosensitive ion channels.

using eight-node hexahedra and applied boundary conditions modeling a uniaxial extension test consistent with previous experiments, i.e. we applied a linear ramp in force to generate uniaxial extension. To prepare for further analyses we extracted representative deformation gradients and Cauchy stress tensors from the submucosal layer of the colorectum as a function of time. We completed all finite element simulations using FEBio (University of Utah).

Morphology of nerve fibers. We quantified the morphology of nerve fibers within submucosa using our second harmonic generation (SHG) images [5] and custom image processing tools. We extracted individual afferent fiber morphologies from confocal image stacks. We then represented these complex data as a series of piece-wise cylinders (diameter = 1 μm) using a custom program [8]. We returned these fiber morphologies to their (stress-free) reference configurations from the deformed configurations required to perform the SHG imaging (i.e. 20 mmHg internal pressure) [5]. To complete this mapping, we established a finite element model of the three-layered colorectum and estimated the inverse deformation gradient.

Micromechanics of nerve fibers. We derived the local mechanical stress/strain profile along the entire length of arbitrary afferent endings embedded in the colorectal wall using a custom program. We depicted the curved nerve fibers as separate microscopic cylinders embedded within a continuous fibrous matrix [8]. Specifically, we used the results of our finite element simulations of the bulk colorectum undergoing uniaxial extension (deformation gradient and Cauchy stress tensors from the submucosal layer of the colorectum as a function of time), pushed the morphology of the afferent ending into the current configuration and then calculated the local membrane tension acting on the surface of the afferent ending.

Generation of action potentials. We used our custom, mechanosensitive neural membrane model to simulate the encoding of afferent stress/strain into action potentials from the local membrane tension along the surface of the afferent ending. We calibrated our neural membrane model to produce results consistent with the experimental data measured from single fibers [4]. Specifically, we utilized the equations established by Feng et al. on the rule of NaV1.6 ion channels and mechanosensitive ion channels in spike initiation at stretch-sensitive colorectal afferent endings. Thus, the deformation and stress derived from FE analysis drove the spike initiation and propagation [9]. We performed all the simulations of action potentials generated by afferent endings using NEURON (Yale University).

RESULTS

Macro- and micro-mechanics of tissue stress distribution. We used a global Cartesian coordinate system to align the FE results with the (assumed) embedded nerve fibers. We traced a representative nerve fiber to demonstrate our modeling framework, see Fig. 2(a). We completed a FE simulation a specimen of colorectum undergoing uniaxial extension, see Fig. 2(b). Using the results from this simulation we predicted the local mechanical conditions acting on the embedded axons embedded within the macroscopic fibrous tissue, see Fig. 2(c). We assumed that the stress and strain distributions acting on each piece-wise cylinder responded uniformly to loading of the bulk colorectum.

Action potential generation pattern. We simulated the response of a single, representative afferent ending during the uniaxial extension test performed experimentally (wherein the total force increases linearly from 0 to 61.8 mN. In Fig. 3 we show the experimental measurement of the action potential (Fig. 3(a)) versus our prediction of the membrane potential (Fig. 3(b)). The result from simulation compares favorably with the experimental results: the initiation time of the action potential spikes and increasing frequency of spikes are consistent between the experiment and the prediction. Moreover, the shape of the spike plotted in Fig. 3(b) is consistent with spikes measured experimentally.

Figure 2: (a) Representative SHG image of and afferent ending in the submucosa and nerve fiber trace (green). (b) Applied circumferential force on the bulk colorectum and the resulting stretch ratio. (c) Resulting average shearing stresses acting on each piece-wise cylinder representing the afferent ending.

Figure 3: (a) Representative experimental measurement of colorectal afferent endings activated by circumferential stretching (0-170 mN at 5 mN/s). (b) Corresponding prediction of action potential propagation pattern in colorectal afferent endings.

DISCUSSION

We utilized our experimental results to establish a novel multimodal and multiscale computational framework enabling us, for the first time, to investigate mechano-transduction in the distal colon and rectum. Each step of our framework is driven by experimental data. We show a representative example demonstrating mechano-transduction within colorectum, the main cause of IBS-related pain. We aim to complete sensitivity analyses of our modeling framework and assess the relative importance of fiber location, orientation, and curviness on the resulting neural encoding function. Future analyses of the colorectum may help to identify key components triggering neural responses to visceral mechanical stimuli in both health and disease.

INTRODUCTION

Regenerative tissue scaffolds are often designed with functional gradients in chemistry and mechanical properties. Mechanical property gradients enable control of mechanical cues delivered to encapsulated cells. By spatially controlling scaffold stiffness, cell behavior (*e.g.* extra-cellular matrix secretion) may be influenced to recapture native tissue organization.¹ Additionally, an implant that mimics the local tissue stiffness may better integrate with surrounding tissue and improve treatment outcomes.

Controlling mechanical gradients is especially desired in osteochondral tissue engineering. Osteochondral tissue engineering aims to treat defects in articular cartilage that, if left untreated, lead to osteoarthritis. By replacing damaged tissue with a spatially graded tissue engineering scaffold, we seek to regenerate both cartilage and underlying bone and recapture the native organization of articular cartilage. Recently, we demonstrated control over mechanical stiffness by incorporating a load-bearing 3D printed structure within a soft ($E = 25 \text{ kPa}^2$) cell scaffold that featured a stiff bone-regenerative region and a softer cartilage-regenerative region.^{2,3}

Here, we designed stiffness gradients within the cartilage region of an osteochondral scaffold to mimic depth-dependent deformation patterns of articular cartilage⁴ and provide spatially controlled mechanobiological cues to cells. We verified these gradients via experimental testing of digital light processing (DLP) 3D printed, stiff hydrogel micro-truss structures at high ($\sim 10 \text{ }\mu\text{m}$) resolution.⁵ We also present a novel method for verifying sub-millimeter mechanical gradients in composite tissue scaffolds by combining X-ray microscopy (XRM) imaging during compression testing to evaluate regional stiffnesses within a composite osteochondral scaffold.

METHODS

Design and Finite Element Analysis (FEA): Unconfined compression of two selected designs (Fig. 1.b,c) was modeled with

finite element analysis (FEA) in Abaqus CAE while considering non-linear geometric effects. Models used linear elastic material properties ($E = 32 \text{ MPa}^5$, $\nu = 0.45$) contained 310k and 767k second-order tetrahedral elements with hybrid formulation in single (*i.e.*, uniform) and bilayer structures, respectively. Strut diameter in the uniform structure was iteratively varied to establish the influence on structural stiffness, E_{struct} (Fig. 1.a). Using this relationship, we designed a stiffness gradient in the “cartilage” layer that ranged from 0.75-1.0 MPa (Fig. 1.c). The bottom “bone” layer of the bilayer design (Fig. 1.c) used vertical pillars to maximize stiffness and structural efficiency.

Figure 1: a) Relationship between strut thickness d/a and stiffness; b) uniform structure with consistent stiffness; c) bilayer structure with a gradient in stiffness incorporated in the top “cartilage” region.

Fabrication and materials: Structures were fabricated using our custom DLP printer, described in detail previously.⁵ Materials included an acrylate-based resin, poly(ethylene glycol) diacrylate with pentaerythritol tetrakis(3-mercaptopropionate) (PEGDA:PETMP), and the photoinitiator diphenyl(2,4,6-trimethylbenzoyl) phosphine oxide (TPO). A thermal initiator, 2,2'-Azobis(2-methylpropionitrile) (AIBN) was introduced for post-processing cure. Structures were then mechanically tested (see below) before being stained with iodine (1 wt% Lugol's iodine, 29% water, 70% ethanol) to increase X-ray opacity. Structures were infilled with a poly(ethylene glycol)-based pre-polymer

solution² and photopolymerized to form composite structures (Fig. 2.b,d).

Figure 2: Fabricated structures; a) uniform structure without infill; b) composite uniform structure stained with iodine; c) bilayer structure without infill; d) composite bilayer structure stained with iodine.

Combined Mechanical Testing and X-ray Microscopy (XRM): The regional mechanics of fabricated structures were measured from unconfined compression testing while XRM imaging. Unconfined compression testing was performed to 12% strain (MTS Insight II). The same structures were imaged in undeformed and deformed (10% strain) states using XRM (Zeiss Xradia 520 Versa; 4 \times , 80kV, 7W, 2s exposure; 201 images, 5 μ m voxel size) to measure regional deformations. Average stress, from stress-strain curves, and regional and global strain measurements during XRM imaging allowed estimation of regional stiffness within each structure (Figs. 3, 4).

RESULTS

The uniform structure design was predicted by FEA to have uniform stiffness of $E_{struct} = 1.0$ MPa (Fig. 4.a). Mechanical testing of the empty structure resulted in 10% higher stiffness than predicted by FEA with $\sim 10\%$ variation between regions (Fig. 4.b). However, infilling scaffolds with hydrogel led to a $\sim 25\%$ decrease in global stiffness with greater variability of regional stiffness values.

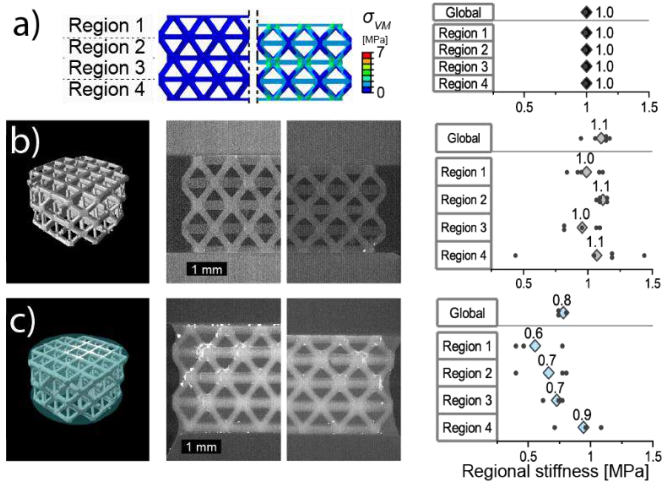

Figure 3: Uniform structure results. a) FEA predictions with von Mises stress visualized; b) empty structure and c) infilled composite results. From left to right in b) and c): 3D XRM rendering, 2D cross-sections of deformed and undeformed states, and regional stiffness.

FEA of the bilayer gradient structure design predicted that the structural stiffness increased with depth in the cartilage region and that the bone region roughly attained the desired stiffness of ~ 10 MPa (Fig. 5.a). Mechanical tests confirmed the cartilage region gradient in the empty structure (Figure 5.b), while the infilled bilayer structure also possessed a stiffness gradient in the cartilage region but that was generally lower than that of the empty structure (Figure 5.c).

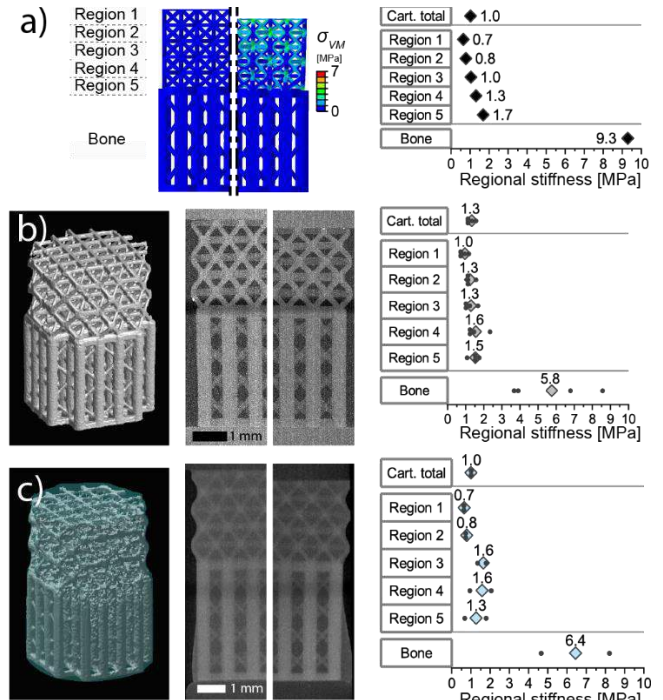

Figure 4: Bilayer structure results. a) FEA predictions with von Mises stress visualized; b) empty structure and c) infilled composite results. From left to right in b) and c): 3D XRM rendering, 2D cross-sections of deformed and undeformed states, and regional stiffness.

DISCUSSION

We successfully fabricated bilayer composite scaffolds for osteochondral regeneration that featured a cartilage region with graded stiffness and an underlying bone region. The regional stiffnesses were characterized at a resolution of approximately 0.5 mm and were similar to our target stiffness. Evaluating the uniform structure demonstrated that the infilled, composite scaffolds had lower average stiffness and greater variability between regions as compared to empty structures. We speculate that the iodine stain that was needed to visualize infilled structures degraded the 3D printed material and led to a lower composite stiffness. Also, swelling stresses from the infilled gels may have introduced local buckling that we observed in the deformed micro-trusses and contributed to variability of regional strains.

The presented bilayer structure may improve upon osteochondral tissue engineering implants through its incorporation of multiple mechanical gradients. Additionally, the presented method of combining XRM imaging with unconfined compression is a useful tool to evaluate gradients in composite scaffolds on a sub-millimeter scale. Through improved mechanical characterization, regenerative implants may be further optimized to improve treatment outcomes.

INTRODUCTION

Biologics, pharmaceutical products derived from biological origin, are emerging because of higher efficacy and lower toxicity than synthetic drugs. These drugs include recombinant proteins, antibodies, vaccines, blood components, and reprogrammed cells [1-4]. In 2021, eight of the top 10 selling drugs are biologics [5]. However, the effective delivery of biologics is still challenging due to the large molecular weights and the sensitive molecular structure to the environmental condition. Intravenous delivery may be effective, but it typically needs hospital care and professional administration, drastically increasing the treatment cost [6]. Thus, subcutaneous (SQ) injection has been considered a promising delivery route because it can be self-administered [7]. One of the most critical drawbacks, however, is that pain and discomfort are induced during SQ injection. This injection-induced pain and discomfort (IPD) pose significant huddles for the broader use of biologics, the design of injection devices and drug formulations, and the quality of patient's life [8-10].

However, the mechanism of the IPD is not well understood yet. To assess the impact of SQ injection, current studies rely on pain intensity scales which include the faces pain scale (FPS), the numerical rating scale (NRS), the verbal rating scale (VRS), and the visual analogue scale (VAS) [11, 12]. However, these measures of FPS, NRS, VRS, or VAS are subjective and often lead to inconclusive measures. Thus, the identification of quantitative biomarkers of the IPD is highly desirable for the design of formulation and SQ injection protocols of biologics to minimize the IPD.

Thus, we hypothesize that the SQ injected induces changes in the mechanical microenvironment of the skin tissue, which in turn stimulate nociceptor neurons in the dermis. To test this hypothesis, we develop a tissue engineered SQ injection platform and quantify the changes in the tissue's mechanical microenvironment both experimentally and computationally. The results are further discussed to identify potential markers for the IPD.

METHODS

SQ Injection Simulation System

An experiment method named cell image deformetry (CID) was used to measure the spatiotemporal deformation of engineered tissue construct (ETC) during the injection of model biologics. The CID method was also described in our previous work on tissue deformation during freezing [13]. A schematic of the experimental platform constructed for CID is shown in **Fig. 1**. The platform consists of an

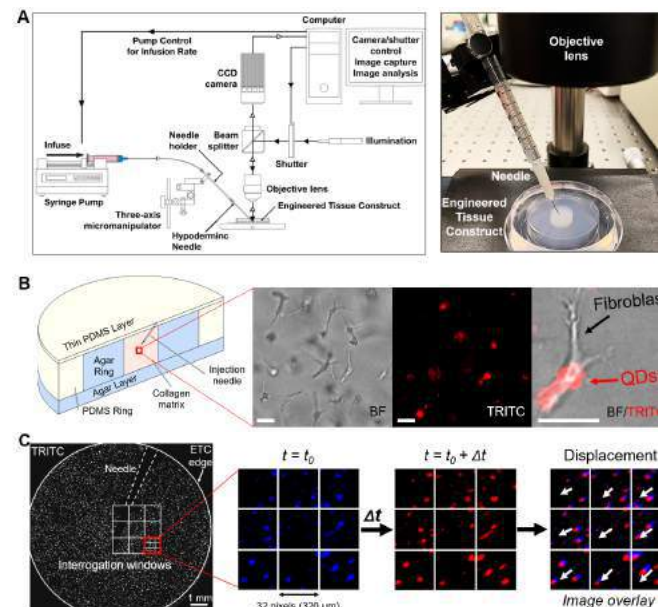

Figure 1: Engineered SQ injection model to mimic injection-induced tissue deformation.

injection system, an imaging system, and ETCs. The imaging system includes a fluorescence macro/microscope (MVX10, Olympus, PA) equipped with a CCD camera (Aqua, QImaging, CA). The injection system includes a syringe pump (NE 1000, New Era Pump Systems, NY) which controls the injection flow rates. The ETC was constructed by seeding and culturing quantum dot-labeled dermal fibroblasts at 2×10^5 cells/ml in type I collagen matrix (6 mg/ml), as shown in Fig. 1B. During the injection, the ETC was imaged under a fluorescence microscope to track the location of QD-labeled cells. These time-lapsed images were cross-correlated to determine the displacement rate first. These displacement rates were further integrated to determine total displacement, as shown in Fig. 1C.

Computational Methods

We used a multi-physics coupled computational framework to simulate the variation in the ETC microenvironment brought by the SQ injection and to further predict the surface and internal three-dimensional distribution of interstitial fluid pressure (IFP) and matrix stress fields. The tissue is considered as poroelastic biphasic material with nonlinear elastic deformable porous solid and interstitial fluid saturated pores. The framework integrates interstitial fluid flow, tissue deformation, and mechanics based on finite deformation hyperelasticity to model the nonlinear response. The computational domain is discretized using an unstructured 3D tetrahedral mesh with extremely fine elements close to the needle and injection location in the ETC. A transient study simultaneously numerically solves the governing equations using the MULTifrontal Massively Parallel sparse direct (MUMPS) solver in COMSOL Multiphysics 5.4.

RESULTS AND DISCUSSION

Fig. 2A shows the displacement rate vector field measured by the CID method when distilled water is injected at a rate of 1.2 ml/min into ETC. The injection site is noted with the dot, and the injection direction is indicated with the arrow. Notable tissue deformation occurred in the first 0.2 s since the start of injection, during which the local displacement rate reached above $800 \mu\text{m/s}$ in the region around the injection site. Although the magnitude of the displacement rate substantially reduced at 0.3 and 0.4 s, the size of the deformed tissue continues to enlarge. The total displacement field provided in Fig. 2B shows the localized deformation around the injection site with a displacement larger than $160 \mu\text{m}$. This result demonstrates the injection induces significant tissue deformation around the injection site.

Computational analysis of the injection-induced deformation of ETC is shown in Fig. 3. It simulates the water injection at 1.2 ml/min. The top view of the computational result can be compared with the experimental measurements. Similarly, significant tissue deformation occurred in the first 0.2 s around the injection site of the computational model, and the size of deformed tissue continues to enlarge at 0.3 and

Figure 3: Computational estimation of the injection-induced tissue deformation. Top and side views.

0.4 s. The side view of the computational result provides information on the tissue deformation at the vertical cross-section of ETC. The significant deformation beneath the needle tip, as well as the expansion of the deformed tissue area, is clearly exhibited by the side view. Both the experimental and computational results show larger tissue deformation along the injection direction than in the perpendicular direction. Further computational analysis on the interstitial fluid pressure and matrix stress suggests that both IFP and equivalent matrix stress fields are more localized close to the injection site. The maximum IFP and stress reach 68 and 90 kPa, respectively, at 2.5 ml/min (data not shown). The stress distribution in the tissue is mostly under 25 kPa.

The present study demonstrates that SQ injection causes distinct spatiotemporal changes in the mechanical microenvironment. This study suggests that the mechanical microenvironment changes are thought to activate nociceptors and induce pain, which can be compared with different types of mechanical stimuli studied on the responses of nociceptors.

INTRODUCTION

The application of excessive levels of mechanical loading has long been accepted as a cause of tendon pathology. More recently, however, evidence is emerging that inflammation also plays a critical role in the initiation and progression of tendinopathy [1]. It remains to be understood how mechanical and inflammatory environments of tendon disease interact with and affect one another; however, there is evidence that inflammatory cytokines such as *IL1 β* can regulate this interaction [2]. Macrophages have been shown, depending on their activation state, to regulate both inflammatory and anti-inflammatory activity of nearby cells, and to stimulate cell proliferation and matrix deposition [3,4]. Additionally, macrophages have been identified in early tendinopathy, abundantly after acute injury, and persistently throughout long-term tendon healing [5,6]. Recent studies have also shown that mechanical loading can regulate macrophage function, but the role of macrophages in tendon mechanoresponsiveness is unknown [7]. Therefore, we investigated the role of macrophage signaling in altering tendon fibroblast (TF) responses to mechanical loading using an *in vitro* loading model. We hypothesized that stimulation of TFs with conditioned media from M1-activated macrophages would cause TFs to be hyper-responsive to mechanical stimulus, accelerating intracellular injury response pathways in an effort to reinforce their cytoskeletal structure and ECM against further loading.

METHODS

Macrophage isolation and culture: Bone marrow was isolated from femur and tibia of 2-month-old C57BL/6 mice. Macrophages were differentiated by culturing bone marrow aspirate in RPMI complete medium with 10% FBS and 1% penicillin/streptomycin, supplemented with 20% L929-conditioned medium (LCM) containing M-CSF. After 5 days of culture, macrophages were seeded into 6-well plates. The following day, macrophages were polarized to M1 phenotype by LPS and IFN- γ stimulation for 24 hours. Then, stimulation media was

replaced with fresh cytokine-free macrophage media. 24 hours later, the media was harvested from the activated macrophages, to be added to TFs.

Tendon fibroblast isolation and culture: TFs were isolated from the tail tendons of 2-month-old C57BL/6 male and female mice by collagenase digestion in a shaking incubator. The cells were seeded on fibronectin-coated silicon elastomer PDMS stretch chambers (STB-CH-04, STREX Co., Osaka, Japan) at passage 2, and then serum starved with 1% fetal bovine serum (FBS) media to synchronize cell cycle phase 24 hours prior to conditioned media treatment and onset of loading. To assess the TF response to macrophage paracrine signaling, conditioned media (CM) harvested from M1-activated macrophages and filtered with a 0.2 μ m syringe filter. TFs were first washed with PBS, and then immediately received a media treatment of equal parts fibroblast medium (media with 10% FBS and 1% penicillin/streptomycin) and M1-macrophage CM. Control media treatment consisted of equal parts fibroblast culture medium and macrophage culture medium.

In Vitro Loading Model: Scaffolds were allowed to equilibrate for 1 hour prior to beginning of the loading protocol. Control scaffolds underwent a mock protocol of preparation for loading prior to being return to static culture in the same incubator. Loaded fibroblasts were subjected to 24 hours of cyclical tensile strain at a magnitude of 7% strain and a frequency of 0.5 Hz, using the STB-1400 STREX cell stretch system (STREX Co., Osaka, Japan).

Outcome measures: For gene expression results, cells were lysed and RNA was isolated immediately after the completion of loading. RT-qPCR was then performed for genes related to fibroblast mechanoresponse, inflammation, and tenogenesis. For imaging experiments, cells were fixed with 10% formalin for 15 minutes prior to immunostaining with alpha smooth muscle actin (α SMA), and DAPI (nuclei). Images were taken at 20x magnification using Zeiss Apotome.

RESULTS

TFs responded to treatment with M1 CM by upregulating *Il6* and *Cox2* gene expression after 24 hours (Figure 1). The increase in α SMA gene expression was not statistically significant, however, α SMA immunostaining was more intense and more homogenous 24 hours after M1-CM treatment (Figure 3).

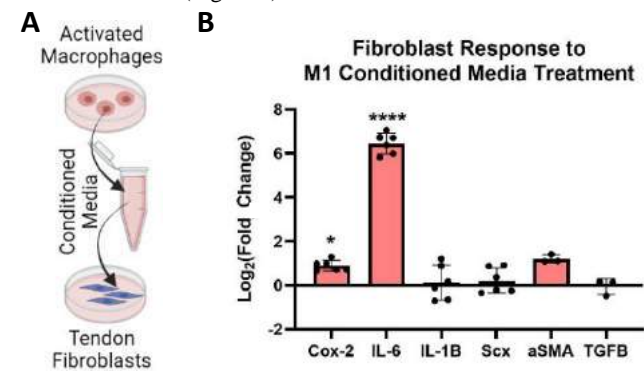

Figure 1: A) Schematic for M1-CM stimulation of tendon fibroblasts and B) Gene expression responses to treatment (*indicates $p<0.05$, ****indicates $p<0.001$, paired t-test with Holm-Sidak correction). Fold changes were relative to TFs with control media.

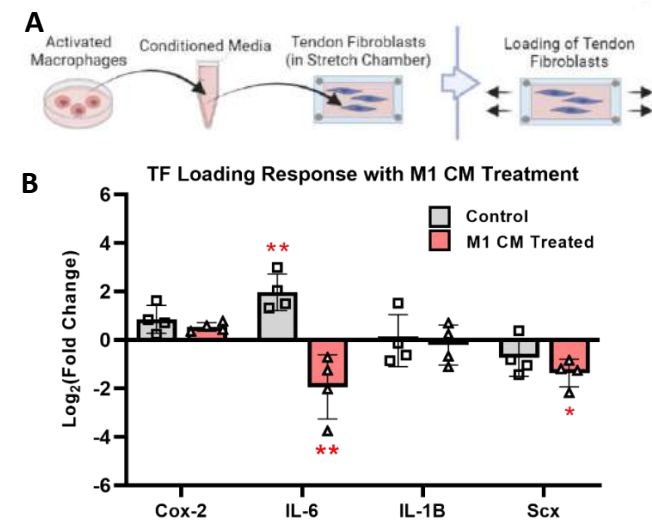

Figure 2: A) Schematic of experimental design (*indicates $p<0.05$, **indicates $p<0.01$, paired t-test with Holm-Sidak correction). B) IL-6 increased with loading in control TFs, but decreased with loading in M1-CM-treated TFs. Fold change is relative to unloaded control-media cells for the control group, and unloaded M1-CM treated cells for the M1-CM treated group.

When fibroblasts cultured in M1-CM were subjected to mechanical loading, they responded differently than fibroblasts in control media. Instead of upregulating *Il6* expression, as unstimulated fibroblasts did, M1-stimulated fibroblasts downregulated *Il6* expression in response to loading (Figure 2). In addition, *Scx* did not change in response to loading in fibroblasts with control media, but significantly decreased in response to loading in fibroblasts treated with M1 CM (Figure 2). α SMA staining revealed increased formation of stress fibers in response to loading compared to TFs in static culture (Figure 3). No clear

difference was noted between loaded TFs treated with M1 CM and loaded TFs in control media.

Figure 3: TFs were fixed and stained with α SMA (red) and DAPI (blue) after 24 hours of A) static culture with control media, B) static culture with M1 CM, C) loading with control media, and D) loading with M1 CM.

DISCUSSION

This study established the potential of M1 macrophage signaling for regulating TF responses to mechanical loading. Interestingly, treatment of TFs with M1 CM resulted in an opposite *Il6* response to loading, compared to control media-treated TFs. While this did not reflect the hyper-responsive reaction to mechanical loading that we expected, further studies will be necessary to determine the functional significance behind the change in *Il6* response. *Il6* has been reported to have either pro-inflammatory or anti-inflammatory effects in tendon, and its effects appear to be context dependent [8]. *Il6* has also been shown to regulate matrix deposition and increase collagen production, but can contribute to the formation of excessive scar [9,10]. Thus, negative feedback of *Il6* levels may be a protective mechanism by the TFs, in effort to maintain ideal expression levels for injury response and tissue homeostasis. Additionally, *Scx* was downregulated in the M1-CM-treated TFs, but not in the control-media TFs. Because *Scx* is known to initiate the expression of mechanically-activated genes, this may be further evidence of a protective response against overloading [11]. Future studies will investigate mechanoresponsive pathways in M1-CM treated TFs to determine the mechanism(s) behind the altered response to loading, as well as to investigate for altered patterns of ECM production. In addition, further investigations will be performed to identify the specific components present in the M1 CM that are responsible for inducing the altered mechanoregulation observed in this study.

INTRODUCTION

Each year, 2100 children are born with an atrioventricular canal (AVC) in the United States [1]. Among children with Down Syndrome, this defect is even more prevalent – 40% of those with cardiac disease have AVCs. Patients with complete atrioventricular canals (CAVC) have a single atrioventricular valve that spans across both ventricles. Surgical repair attempts to divide the single valve into two valves including a mitral-equivalent left atrioventricular valve (LAVV). With current repair techniques, LAVV failure requires reintervention in up to 40% of patients [2-4]. Further, reintervention results are poor with more than a quarter of patients who undergo reintervention requiring two or more reoperations [4, 5].

The development of 3D echocardiographic (3DE) based valve modeling tools have been used to make high quality analyses of cardiac structures, allowing precise, quantitative comparison of normal valves to dysfunctional valves, greatly improving the understanding of the 3D structural correlates of adult valve dysfunction [6]. The application of image-derived modeling for physical simulation has potential to allow investigators to better understand treatment options for patients with failing LAVVs. Therefore, there is a need for a platform to test and evaluate repair strategies before treatments are performed on a patient. Current 3D printed models are static and lack a dynamic component necessary for evaluating the success of repairs to these valves. Dynamic simulations have already been developed for mitral and tricuspid valves; therefore, it is the goal of this study to adapt these prior workflows for simulating and assessing different repair strategies for LAVVs [7,8].

METHODS

This study protocol was reviewed and approved by the Children's Hospital of Philadelphia institutional review board.

Patient Selection and Image Acquisition: Patients who had underwent AVC repair and high-quality (3DE) imaging were queried from an

existing institutional database. One case of a regurgitant LAVV was identified: a 21-year-old female with moderate LAVV regurgitation originating centrally from a residual cleft in the neo-anterior leaflet. 3DE images were previously existing and acquired via transesophageal 3DE on a Philips Epiq system (Philips Medical, Cambridge, MA).

Leaflet Segmentation and Mold Generation: The selected Digital Imaging and Communications in Medicine (DICOM) files were imported into 3D Slicer (www.slicer.org). The annulus was defined in mid-systole and late-diastole using Annulus Analysis module in SlicerHeart [9]. Mid-systole is defined as the median time frame between the first frame when the valve is closed and the last frame when the valve is closed in a cardiac cycle. Late-diastole is defined as the frame before systole where the leaflets have not yet coapted and individual leaflets are still visible. The leaflets are then manually segmented using the Valve Segmentation module. Lastly, a mold of the atrial profile of the leaflets is created and the locations of the papillary muscle tips are recorded.

Silicone Model Creation: We create a silicone model to emulate valve physiology that include leaflets, chordae, papillary muscles, and the surrounding myocardium. A composite of silicone (Ecoflex, Smooth-On Inc., Macungie, PA) and nonwoven gauze is painted onto the 3D printed valve profile to create the leaflets. Gauze is added to give the silicone tensile strength and to prevent sutures from dehiscing under hemodynamic loading. Additionally, six frayed Dacron threads are imbedded in the silicon to simulate the chordae tendineae. The Dacron thread then runs through a 3D-printed patient-specific papillary muscle post that is made using the papillary muscle data recorded from the 3DE. The ends of the threads attach to tunable keys that can be used to adjust the tension of the chordae. The myocardium is modeled using silicone (Dragonskin, Smooth-On Inc, Macungie, PA) that has been injected into a 3D printed mold containing a hinge-point-apparatus. The hinge-point-apparatus is used for defining the valve annulus and enforcing the hinge

point. Once the silicone has cured, the entire apparatus is fixed between two 3D printed flanges (Fig. 1a).

Figure 1: a) Silicone valve model schematic, b) silicone valve model in pulse duplicator.

Simulated Repair: Four identical silicone valves are constructed and presented to an attending cardiothoracic surgeon to perform a different surgical valve repair on each. The strategies employed were an annuloplasty where the annular circumference between the anterolateral commissure and the posteromedial commissure was reduced by 10%, a second annuloplasty where the circumference was reduced by 20%, an Alfieri stitch between the neo-anterior leaflet and the mural leaflet, and a closure of the residual cleft in the neo-anterior leaflet (Fig 2).

Pulse Duplicator: The assembled valve apparatus is then mounted in a two-chamber dynamic simulator (Archetype Biomedical Inc, London, Ontario, Canada) which can replicate patient heart rate, stroke volume, and pressures at the time of image acquisition (Fig. 1b). Performance and regurgitation of the simulated valve are visualized using a transesophageal echo probe with EKG gating and colored Doppler.

Analysis: Image data recorded from the pulse duplicator is imported into 3D Slicer, and the leaflets are segmented in mid-systole for analysis. The four different repair strategies are compared via common clinical metrics: billow height, tenting height, mean trans-valvar pressure gradient, and regurgitant orifice area. Billow height and tenting height are defined as the distance normal to the least-squares annular plane to the highest and lowest points on the leaflets, respectively. The regurgitant orifice area is calculated using a custom shrink-wrapping algorithm on the resulting leaflet segmentation [10].

Figure 2: Simulated repairs on four identical LAVVs.

RESULTS

The resulting valves were mounted in the pulse duplicator and patient physiological loads were applied. The 3DE measurements and segmentation data are provided in Table 1.

Billow height and mean gradient pressure were consistent across all models except for the Alfieri stitch repair which resulted in a stenotic valve. The tenting height is increased in all repaired models; this is a product of mural leaflet immobility. Overall, closure of the partial cleft in the neo-anterior leaflet produced the valve with the smallest regurgitant orifice area.

Table 1: Comparison of repair strategies

Valve Model	Tenting Height (mm)	Billow Height (mm)	Mean Gradient (mmHg)	Regurgitant Area (cm ²)
10% Annuloplasty	17.7	3.1	4	1.1
20% Annuloplasty	12.2	3.4	5	0.72
Alfieri Stitch	18.0	3.3	17	0.75
Cleft Closure	17.0	2.2	5	0.37

DISCUSSION

This study has provided a first approach to using dynamic physical modeling for comparing different repair strategies in patient-specific LAVV models. These methods provide powerful opportunities for medical training and preoperative planning. This is especially true for congenital heart diseases where anatomies are highly heterogeneous and treatment options are variable. The work of this study sets the groundwork for a platform for testing and evaluating treatment options for atrioventricular valves. With further development and experimentation using more samples, this system has the potential to simulate the function of complex valve morphologies under physiological loads. This workflow can also continue to be built out with more valves, including CAVCs, and more complex interventions in the future.

There is no concluded best repair method in this study as there is no comparison to a control model or a ground truth. Limitations in this work include variability in the manufacturing workflow. For example, the silicone may have been painted onto the leaflet with varying thickness between each valve model. Additionally, the valvar and sub-valvar apparatuses have been vastly simplified in this study. Future work includes research into enhanced manufacturing techniques that allow for much more precise control over leaflet thickness such as 3D printing in tissue mimicking materials. Further, the manufactured heart valves will need to be validated against a ground-truth patient 3DE.

INTRODUCTION

Right ventricular (RV) function strongly associates with mortality in patients with pulmonary arterial hypertension (PAH). Survival is associated with right ventricular function rather than pulmonary vascular resistance or PA pressure.^{2,3} Optimization of RV assessment is an identified priority in PH clinical research.^{1,4} Echocardiography and cardiac magnetic resonance (CMR) imaging are both used to quantify RV function but CMR can be used to reliably obtain quantitative information about RV shape, size, and remodeling.⁵ A current unmet clinical need is the identification of clinically meaningful imaging features that clearly distinguishes between normal and abnormal RV structure and function.

Right ventricle global longitudinal strain has been shown to associate with outcomes in PH and is typically measured via echocardiography⁶. Measures of strain help to provide insight into the biomechanics of the RV (diastolic stiffness) and function. Changes in ventricular dynamics during ejection and filling may associate with the biomechanics of the RV. We hypothesize RV strain will be different in advanced RV dysfunction and the aim of the study was to evaluate RV strain and instantaneous strain rates throughout the cardiac cycle from CMR images in patients with pulmonary hypertension.

METHODS

Participants were identified from The Ohio State University CMR PH registry and included if they had four chamber (4CH) CMR images and right heart catheterization (RHC) data (n = 85). Participants were split based on hemodynamics into PH groups: No PH (mPAP < 20mmHg), PH-LHD (mPAP ≥ 20 mmHg, PAWP ≥ 15 mmHg), and Pre-capillary PH (mPAP ≥ 20 mmHg, PAWP < 15 mmHg). Diastolic elastance (E_{ed}) was calculated by fitting the curve $P = \alpha(e^{V^{\beta-1}})$ using pressure and volume data from RHC and CMR. Participants were into low and high E_{ed} groups based on the median E_{ed} value (0.28).

From the 4CH cine images, the right ventricular area was manually segmented throughout the cardiac cycle using MATLAB (**Figure 1A**).

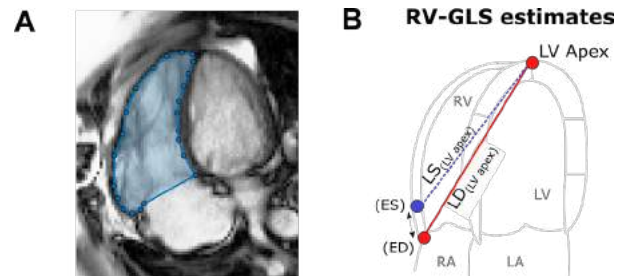

Figure 1: Methods to estimate RV strain. A) Segmentation of the right ventricle (blue area). B) The lateral tricuspid valve point and LV apex was used to estimate the length of the RV. RV global longitudinal strain was calculated as the difference between the end-diastolic length (LD) and end-systolic length (LS).

To estimate RV-GLS, the lateral tricuspid valve and LV apex landmarks were selected at end diastole and end systole (**Figure 1B**). RV-GLS was estimated as the difference in length from the lateral tricuspid valve point to either the LV apex or RV insertion point from end diastole (LD) to end systole (LS) (**Equation 1**).

$$RV_{GLS} = \frac{(L_D - L_S)}{L_D} \quad (1)$$

The segmented areas were plotted as a function of time and repeated a total of three cardiac cycles (**Figure 2A**). The derivative of the area was used to obtain ejection (linear decreasing area, negative derivative) and filling (linear increasing area, positive derivative) phases (**Figure 2B**). The filling phase was split into passive filling (early diastole) and active filling (late diastole). The ejection rate, passive filling rate and active filling rate were determined by fitting a linear line to the identified regions. Statistics were calculated in R. Pearson's correlations were used to obtain correlations. A p-value of 0.05 was used to determine significance.

Figure 2: Methods to estimate RV ejection and filling rates. A) Area as a function of time for three cardiac cycles. B) Area gradients were used to identify linear ejection (negative) and filling phases (positive). The filling phase was split into the passive filling (early diastole) and active filling (late diastole).

RESULTS

From the $n = 81$ participants, 56.8% had pre-capillary PH, 29.6% had PH-LHD and 13.5% had no PH based on RHC hemodynamics (Table 1). Participants with PH had increased RV end diastolic pressures (RVEDP) and systolic pressures (RVSP) compared with no PH. PH-LHD had increased RVEDP when compared to pre-capillary PH and no PH participants.

Table 1: Cohort characteristics

	No PH N = 11	PH-LHD N = 25	Pre-capillary PH N = 49
mPAP (mmHg)	16 ± 3	$45 \pm 12^*$	$38 \pm 13^{\dagger}$
PAWP (mmHg)	9 ± 4	$22 \pm 5^*$	$10 \pm 4^{\dagger}$
RVSP (mmHg)	30 ± 8	$71 \pm 22^*$	$61 \pm 21^*$
RVEDP (mmHg)	7 ± 3	$20 \pm 5^*$	$11 \pm 6^{\dagger}$
Ejection Rate (cm^2/s)	-39.8 ± 14.3	-32.2 ± 11.3	-33.4 ± 16.9
Passive Filling Rate (cm^2/s)	33.3 ± 12.4	32.05 ± 19.0	35.8 ± 21.7
Active Filling Rate (cm^2/s)	48.7 ± 20.3	36.2 ± 15.6	40.5 ± 24.0

* $P < 0.05$ vs No PH, $\dagger P < 0.05$ vs PH-LHD

In the PH-LHD and pre-capillary PH groups, PVR was increased, RVEF was decreased and RV-GLS was less negative (decreased movement) compared to no PH (Figure 3A-C). Despite similar RV-GLS and RVEF, PH-LHD group had increased diastolic elastance compared to pre-capillary PH (Figure 3D). There were no significant differences in ejection rate, passive filling rate or active filling rate between PH types (Table 1).

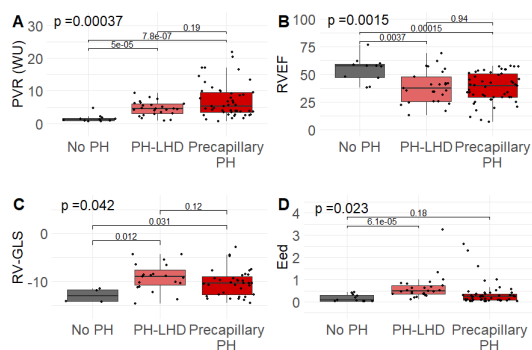

Figure 3: Increased RV diastolic stiffness in PH-LHD. Participants with pulmonary hypertension (PH-LHD and pre-capillary PH) have increased PVR (A), decreased RVEF (B) and less negative RV-GLS (C) compared to no PH. D) PH-LHD had increased diastolic elastance (Eed) compared to no PH and pre-capillary PH.

The RV ejection, passive filling and active filling rates significantly correlated with RV-GLS (Figure 4A&B). Eed correlated with active filling ($r = -0.27$, $p = 0.014$) but not ejection ($r = -0.18$, $p = 0.11$) or passive filling ($r = -0.16$, $p = 0.14$). When split based on high and low Eed, participants with high Eed had decreased ejection rates (Figure

4C), no difference in passive filling rates (Figure 4D), and decreased active filling rates (Figure 4E) compared to low Eed.

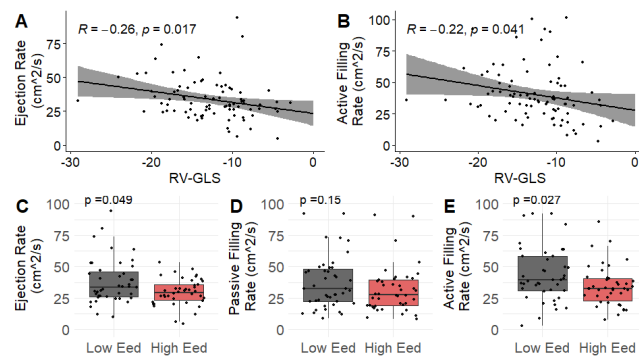

Figure 4: Ejection and active filling rates as a function of RV-GLS and RV diastolic elastance (Eed). RV-GLS significantly correlates with ejection rate (A) and filling rate (B) but not passive filling (not pictured). When split by median diastolic elastance (Eed: 0.28), participants with high Eed had decreased ejection rate (C), no difference in passive filling (D) and decreased active filling rates (E) compared to low Eed.

DISCUSSION

Right ventricular dynamics can be quantified from four chamber CMR images using RV ejection and filling rates. Participants with pulmonary hypertension (PH-LHD and pre-capillary PH) had less dynamic ventricles (less negative RV strain) and more RV dysfunction compared to participants with no PH. The PH-LHD group had increased end-diastolic elastance compared to the other groups but similar RV-GLS and RV function as the pre-capillary PH group. Ejection and filling rates did not associate with PH type but were correlated with RV End-diastolic elastance. The filling phase was split into passive filling (early diastole) and active filling (late diastole)⁷. RV diastolic stiffness might not be as much of driving factor for the passive filling rate because ventricular pressure and strain is less compared to late diastole and active filling. Patients with increased ventricular stiffness (high Eed) have increased end-diastolic pressure that could be contributing to decreased active filling rates compared to low Eed. More investigations into the changes in ventricular stiffness and the biomechanics of the ventricle are needed to understand the altered ventricular dynamics from pulmonary hypertension.

A THERMODYNAMIC FRAMEWORK FOR THE EVOLUTION OF SARCOMERES IN CARDIOMYOCYTES SUBJECTED TO DYNAMIC LOADING

INTRODUCTION

Identification of in-vitro protocols to develop mature cardiomyocytes (CMs) with sarcomeric structures and aligned myofibrils remains a key challenge in the field of cell and tissue engineering [1]. Physiologically sarcomeres consist of ordered actin-myosin (AM) bounded by Z-bands. Active contractility is generated through AM cross-bridge cycling. Titin proteins connect M-bands to Z-bands. Sarcomeres spontaneously beat in mature CMs [1, 2, 3].

Similar to sarcomeres, stress fibers (SFs) actively generate tension through AM cross bridge cycling. However, SFs are unstructured and do not contain Z-bands or titin, consequently SFs generate lower levels of tension than sarcomeres [4, 5]. SFs are found throughout the cytoplasm of naïve cardiomyocytes (CMs) and human pluripotent stem cells (hPSCs)-CMs. Sarcomeres evolve from highly aligned SFs during differentiation to a mature CM phenotype. The in vitro study of Dou et al. [6] shows that application of dynamic biaxial stretching significantly increases sarcomere formation in comparison to static controls. However, the mechanism by which dynamic loading leads to increased sarcomere formation and a mature CM phenotype is poorly understood. A new understanding of the role of mechanical loading in sarcomere formation would represent a significant contribution to the field of cardiac tissue engineering, in addition to advancing the current clinical understanding of the pathogenesis of cardiac hypertrophy.

In the current study we propose a novel dynamic theoretical formulation for the remodeling of sarcomeres and SFs. Our analyses uncover a thermodynamic basis for the relationship between dynamic loading and sarcomere formation, including the key energetic role of titin in this complex process. Our model is shown to correctly predict that application of 20% dynamic stretching at 1 Hz results in a three-fold increase in sarcomere density compared to static control, as observed in vitro [6].

METHODS

In our thermodynamic framework, evolution and remodeling of sarcomeres and SFs is driven by differences in chemical potential of bound proteins in sarcomeres and SFs, and that of unbound proteins. Enthalpies of proteins in their ground states are represented as μ_U , μ_{B0} , and μ_{H0} , with activation barriers μ_A , and μ_{Z0} highlighted in Figure 1.

Figure 1: Energy landscape for cytoskeletal unbound cytoskeletal proteins, SFs and sarcomeres, highlighting enthalpies in their ground state (solid curve), in their standard state (dashed curve), and activation barriers.

Through dynamic loading, standard enthalpy changes such that the enthalpy of SFs at any point is calculated as,

$$\mu_B = \mu_{B0}(1 + \beta \tilde{\epsilon}^2) - \Omega \sigma_F(1 + \tilde{\epsilon}). \quad (1)$$

Here, $\tilde{\epsilon}$ is strain within an SF, β is a non dimensional constant governing growth of in series SFs and sarcomeres, Ω is a constant representing volumetric density of functional units at a point, and σ_F is maximum isometric SF tension. The enthalpy of sarcomeres at any point is calculated as,

$$\mu_H = \mu_{H0}(1 + \beta \tilde{\epsilon}_S^2) - \Omega \sigma_S(1 + \tilde{\epsilon}_S) + (1 - \kappa)\Delta\mu_H + \Phi_T - W_T, \quad (2)$$

where, $\tilde{\epsilon}_S$ is strain within a sarcomere, and σ_S is maximum isometric sarcomere tension, κ is a normalized term representing level of alignment of the underlying SF network, and $\Delta\mu_H$ is the maximum penalty when the SF network is isotropic. The activation enthalpy, which affects the rate of sarcomere growth, is given as $\mu_Z = \mu_{Z0} - \kappa\Delta\mu_Z$. Under dynamic loading, titin is stretched between Z- and M-bands, resulting in an internal elastic strain. We assume a titin elastic modulus, κ_T , such that titin strain energy is given as $\Phi_T = \frac{1}{2}\kappa_T\Omega\tilde{\epsilon}_T^2$, and induced work due to titin stretching is given as $W_T = \frac{\partial\Phi_T}{\partial\tilde{\epsilon}_T}\tilde{\lambda}_T$, where $\tilde{\lambda}_T$ and $\tilde{\epsilon}_T$ represent titin stretch and strain respectively.

The evolution of unbound cytoskeletal proteins into sarcomeres, $\hat{\eta}_{SU}$, is given as:

$$\frac{\partial\hat{\eta}_{SU}}{\partial t} = \omega_{SU} \frac{\hat{N}_U + \hat{N}_{BF}}{\hat{n}_S} \left(1 - \frac{\hat{N}_{BF} + \hat{N}_{BS}}{\xi_1}\right) \exp\left(\hat{n}_S \frac{\mu_U - \mu_Z}{k_B T}\right) - \omega_{SU}\hat{\eta}_S \exp\left(\hat{n}_S \frac{\mu_H - \mu_Z}{k_B T}\right), \quad (3)$$

where ω_{SU} is a rate constant, \hat{n}_S is sarcomere concentration in series, ξ_1 is peak sarcomere concentration at a point, and $k_B T$ is Boltzmann's constant and absolute temperature respectively, noting that protein conservation is maintained between unbound functional units, SF, and sarcomeres respectively, where $\hat{N}_U + \hat{N}_{BF} + \hat{N}_{BS} = 1$.

Sarcomere formation in parallel, $\hat{\eta}_{SF}$, due to reorganization of bound aligned SF proteins, and is driven towards thermodynamic equilibrium such that:

$$\frac{\partial\hat{\eta}_{SF}}{\partial t} = \omega_{SF} \frac{\hat{N}_U + \hat{N}_{BF}}{\xi_1} \frac{\xi_1 - \hat{N}_{BF} - \hat{N}_{BS}}{\hat{n}_S} \left(\frac{\xi_0}{\hat{N}_U \xi_0 - \hat{n}_F \hat{\eta}_F}\right)^{\frac{1}{v_S}} \exp\left(\hat{n}_S \frac{\mu_B - \mu_Z}{k_B T}\right) - \omega_{SF}\hat{\eta}_S \exp\left(\hat{n}_S \frac{\mu_H - \mu_Z}{k_B T}\right), \quad (4)$$

where ω_{SF} is a rate constant, \hat{n}_F is the concentration of SFs in series, and ξ_0 is peak SF concentration at a point. Total generation of sarcomeres is then expressed as; $\frac{\partial\hat{\eta}_S}{\partial t} = \frac{\partial\hat{\eta}_{SU}}{\partial t} + \int_{-\pi/2}^{\pi/2} \frac{\partial\hat{\eta}_{SF}}{\partial t} d\theta$.

Aggregation of SFs in parallel, $\hat{\eta}_{FU}$, is solely motivated by available unbound cytoskeletal proteins, driven towards thermodynamic equilibrium of unbound and bound SF species such that:

$$\frac{\partial\hat{\eta}_{FU}}{\partial t} = \omega_{FU}\hat{N}_U \left(\frac{1}{\hat{n}_F} - \frac{\hat{\eta}_F}{\xi_0}\right) \exp\left(\hat{n}_F \frac{\mu_A - \mu_U}{k_B T}\right) - \omega_{FU}\hat{\eta}_F \exp\left(\hat{n}_F \frac{\mu_B - \mu_A}{k_B T}\right), \quad (5)$$

where ω_{FU} is a rate constant. It is also necessary to consider SF loss due to sarcomere recruitment, as highlighted in Eq.(4), thus total SF generation and disassociation is expressed as $\frac{\partial\hat{\eta}_F}{\partial t} = \frac{\partial\hat{\eta}_{FU}}{\partial t} - \frac{1}{v} \frac{\partial\hat{\eta}_{SF}}{\partial t}$, where v is a scalar relating optimal length of sarcomeres and SFs.

In our framework, we simulate a cardiomyocyte that spreads to a steady-state geometry and is then subjected to biaxial dynamic loading to a nominal 20% at 1Hz for a period of 10 hours. Results are compared directly to the in vitro observations of [6].

RESULTS

Figure 2A shows the evolution of SFs and sarcomeres in a cell subjected to 20% biaxial dynamic loading and a cell under static conditions. Dynamic loading leads to the reorganization of proteins in aligned SFs so that they form structured sarcomeres. This process occurs due to the stretching of titin during dynamic loading which reduces the standard enthalpy of sarcomeres. Under static conditions titin is not stretched and the energetic barrier to convert SFs to

sarcomeres is prohibitively high. Figure 2B shows the alignment and concentration of SFs and sarcomeres for static and dynamic cases. Figure 2C shows the computed chemical potential of SFs, sarcomeres and unbound species as a function of orientation. Again, positive differences in chemical potential due to titin stretching along the long axis of the cell drives the ongoing formation of sarcomeres. Figure 2D shows that model predictions of increased sarcomere concentration due to dynamic loading are in reasonable agreement with experimental measurements [6].

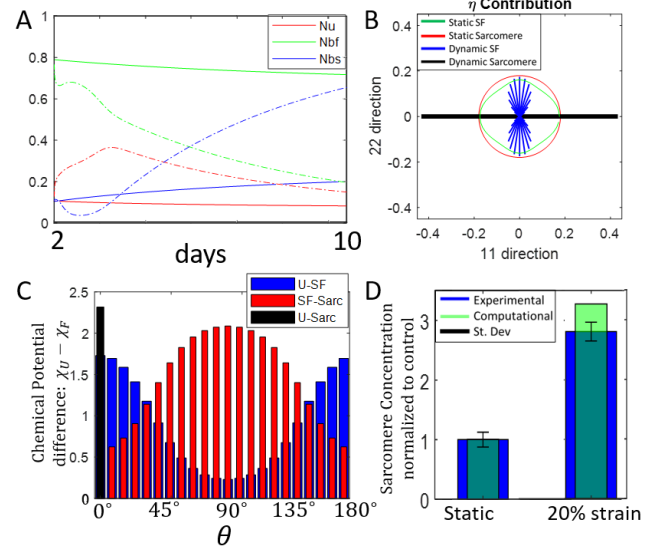

Figure 2: A) Dynamic evolution of protein concentration for static control (solid lines), and biaxial dynamic loading (dashed lines). B) Stress fiber and sarcomere orientation and concentrations following 10 days of cyclic loading. C) Difference in chemical potential between dynamic states after 10 days. D) Computed sarcomere concentration (normalized by static control level) following 10 days of dynamic loading, with comparison to experimental data [6].

DISCUSSION

The key finding that emerges from our novel thermodynamic framework is that stretching of titin during applied dynamic loading of CMs results in a reduction in the standard enthalpy of sarcomeres, which drives the remodeling of cytoskeletal proteins from SFs to sarcomeres. Our model predicts that application of a dynamic biaxial stretch of 20% at 1 Hz results in a three-fold increase in sarcomere concentration. This prediction aligns with the in vitro measurements of Dou et al. [6]. Our model suggests that titin knock-out experiments will lead to reduced sarcomere formation and increased SF formation under dynamic loading, as observed in vitro [7]. The dynamic remodeling framework will also be extended to simulate hypertrophy due to altered mechanical loading of the myocardium [8].

INTRODUCTION

Biological cells can be differentiated to have specialized functions to build realistic *in vitro* cell culture models. The methods to achieve this are typically based on chemical stimulation with multiple differentiation factors and steps^{1,2}, but can also incorporate biophysical cues such as subjecting cells to specific forces^{3,4}, or combinations of these signals by engineering specific tissue microenvironments.^{5,6} Air-liquid interface (ALI) is a well-established cell culturing method required to differentiate epithelial cells towards functional phenotypes, and allows scientists to generate realistic barrier-based tissue and organ models for research purposes.^{7,8} For example, ALI is used to differentiate tracheobronchial cells to closely mimic human airway architectures for drug screening⁹ or studying lung diseases.¹⁰ Despite common use of ALI for many applications, the precise drivers of differentiation that underlie this approach remains unknown. This lack of knowledge creates additional challenges: ALI differentiation typically requires long multi-week cultures, and the challenges of handling porous *Transwell* inserts make ALI culture less robust than required for industrially scaled-up high-throughput applications.¹¹ Hence, understanding the mechanism driving ALI epithelial differentiation could allow us to develop more flexible and robust tissue process control strategies, scale up the fabrication process of *in vitro* cell culture models, and potentially help reveal and target the mechanisms underlying epithelium formation during fetal development.

ALI consists of culturing cells on a porous membrane, while allowing them to access nutrient-containing culture media through the membrane and exposing the top surface of cells to air. When these ALI conditions were recreated by growing epithelial cells on a media-soaked hydrogel and exposed to air from the top surface, surprisingly the expected ALI differentiation did not occur. Therefore, we hypothesized that the innate hydrostatic biophysical pressure difference created by ALI across the epithelial barrier might play a critical role in epithelial differentiation

and its variability in regular ALI culture due to handlings and evaporation causes the current lack of reproducibility in ALI differentiation.

METHODS

A transepithelial hydrostatic pressure device was built to subject the cell layer to a pressure differential, while maintaining cells at standard submerged culture (Figure 1). This new culture setup removes the confounding effects of an air-liquid interface, such as differential oxygenation, while manipulating and precisely controlling the small hydrostatic pressure differentials that are often unintentionally created by ALI culture in a standard *Transwell* inserts.

Figure 1. Transmembrane hydrostatic pressure differential device. A raised media reservoir connected to the well induces a constant hydrostatic pressure to the basolateral surface of epithelial layer.

Primary human bronchial epithelium (HBE) and human intestinal organoid were cultured in this device to analyze the effect of pressure differential on different types of epithelial cells. HBE were cultured in 4 different conditions over 3 weeks: Control (regular submerged culture), ALI, pressure differential (5 cmH₂O), and double-sided pressure (increased pressured on both basolateral and apical surface). Epithelial histology sections were then used to compare HBE samples stained with hematoxylin and eosin (H&E).

RESULTS

Histology sections of HBEs are shown in Figure 2 and top views of intestinal organoid grown on *Transwell* inserts in Figure 3.

Figure 2. Human bronchial epithelial monolayers grown on *Transwell* inserts cultured for 3 weeks in 4 different conditions: (A) Submerged, (B) ALI, (C) Double-sided pressure, and (D) Pressure differential. Scale bar 50 µm.

Figure 3. Human intestinal organoid grown on *Transwell* inserts cultured in (A) regular submerged condition and (B) pressure differential device for 14 days. Red circle indicates potential lumen formation.

The observed thicker HBE membrane obtained from pressure differential device (Figure 2D) compared to control condition (Figure 2A) indicates the formation of pseudostratified columnar epithelium which was previously obtained only through ALI culture as shown in Figure 2B. HBE membrane under increased hydrostatic pressure on both apical and basolateral surfaces (Figure 2C) maintained its original thickness similar to control condition. Thus, the formation of pseudostratified columnar epithelium was due entirely to transepithelial pressure differentials rather than an absolute increase of pressure on basolateral surface. Interestingly, the formation of cilia, another marker of airway epithelium differentiation, was only observed in the ALI cultures.

Similarly, human intestinal organoids cultured in the pressure differential device drives heterogeneous growth (Figure 3B) compared to the regular submerged culture (Figure 3A). The heterogeneity of the pressurized tissue suggests differentiation towards specialized cell types and even possible formation of lumens as indicated by red circle. Differentiation profiles arising from various differential hydrostatic pressure treatments are currently being determined.

DISCUSSION

Preliminary results in using this device show significant improvements in phenotypes associated with differentiation for multiple cell lines including primary lung cells and miniature gut tissue. These initial results are very promising as it demonstrates how pressure differential underlies ALI differentiation and can be isolated to precisely control different differentiation features of epithelial cells such as thickening of the monolayer or formation of cilia. Thus, regulating hydrostatic pressure could be a good strategy to control epithelial cell differentiation as it provides an easier, more robust, and more consistent method and thus rendering possible the scale up of differentiation procedure as opposed to ALI cultures. Furthermore, this finding might thus be the key in determining the differentiation mechanism since it could be used as a “filter” condition during genetic analysis. Upon comparison with the full ALI condition, the specific and critical genes involved in differentiation will likely be more apparent compared to the existing genetic analysis of ALI differentiation. This differentiation mechanism behind pressure differential could even potentially play an important role during fetal development in which air is also absent.

INTRODUCTION

Many respiratory system pathologies can disrupt lung function by altering the mechanical properties of the parenchyma. Computational models can provide a non-invasive and patient-specific approach to understanding the mechanics of breathing and the effects of heterogeneous damage distribution on lung function. The geometry and spatial scale of *in silico* models are essential in creating realistic models that produce accurate and reliable results. Similarly, it is vital to consider the accuracy of the constitutive mechanical behavior used to model tissue behavior. Many computational models have been developed for the lung at various spatial scales, while morphological studies combined with increased computing power have allowed for model expansion to smaller length scales. Yet, the wide range of experimental techniques and reported constitutive models for lung tissue at different length scales can lead to uncertainty when utilizing such material properties in computer modeling. Hence, reliable alveolar stiffness values are essential when using multiscale models that incorporate the mechanical properties of the parenchyma.

To compare the mechanical properties of tissue reported across length scales from different studies, the differences in experimental protocols should be considered. Also, other factors, such as tissue preparation technique and loading rate, may affect the reported stiffness values. Thus, reconciling the reported stiffness values of lung tissue across spatial scales may give insight into how well the reported stiffness values represent lung tissue behavior across different scales. As the emergent mesoscale mechanical properties of the parenchyma depend on the microscale properties of the alveolar tissues, reported values at the microscale must be accurate before they can be used in meso- and macro-scale lung models.

Hence, this study aims to use *in silico* modeling to compare, reconcile, and resolve the differences reported in lung tissue mechanics at different length scales. Specifically, the objective of this research is to utilize computational modeling for the purpose of studying whether

the emergent mechanical properties of lung tissue at the mesoscale, based on micro-scale mechanical testing data, can be reconciled with the experimental data reported at the mesoscale.

METHODS

A finite element (FE) analysis was performed at the mesoscale by assigning microscale-based properties to alveolar septa based on previously reported *in vitro* and *in situ* experiments. The 3D geometry comprised an array of alveoli represented by truncated octahedra [1]. The geometry modeled the tissue slices used in the uniaxial tension testing of Birzle et al. [2]. SolidWorks 2022 (Dassault Systems, France) was used to build the geometry where each truncated alveoli had the average dimensions of a rat alveolus as measured by Cavalcante et al. [3]. The geometry was imported to COMSOL Multiphysics v6.0 for FE analysis (COMSOL Multiphysics, MA, USA). The entire structure had overall height, width, and depth dimensions equal to the average dimensions of lung tissue slices used for uniaxial tension testing in Birzle et al. [2], and was simulated for up to 80% strain. The FE model was meshed using 2.2 million quadratic tetrahedral elements.

Mechanical properties at the microscale were taken from the results reported by two different research groups that determined the mechanical behavior of rat lung tissue using atomic force microscopy (AFM) and *in situ* mechanical testing, respectively [4], [5]. The emergent properties from the FE analysis were then compared to mesoscale data from a study that utilized a comprehensive approach to determine the mechanical behavior of rat parenchyma [2] and reporting the strain energy density function below:

$$\varphi = c(I_1 - 3) + \frac{c}{\beta} \left(I_3^{-\beta} - 1 \right) + c_1 (I_3^{-\frac{1}{3}} I_1 - 3)^{d_1} + c_3 (I_3^{\frac{1}{3}} - 1)^{d_3} \quad (1)$$

Where I_1 and I_3 are invariants of the right Cauchy-Green deformation tensor, c_1, c_3, d_1 and d_3 are material constants that characterize the

isochoric and volumetric elastic response of the tissue, and c and β define Young's modulus E and Poisson's ratio ν as:

$$E = 4c(1 + \nu) \quad (2)$$

$$\nu = \beta / (1 + 2\beta) \quad (3)$$

Additionally, based on a study by Birzle and Wall [6], the standard linear solid viscoelastic model was added to the microscale hyperelastic constitutive models to account for the effect of rate of loading [6]. The viscoelastic stress (σ_q) of the standard linear solid model was determined by the equation:

$$\sigma_q = 2n_1\dot{\gamma}_1 \quad (4)$$

Where n_1 is the viscosity and is related to the stiffness (G_I) and relaxation time (τ_1) by $n_1 = G_I \tau_1$. Also, $\dot{\gamma}_1$ is the strain rate. This visco-hyperelastic model of the alveolar tissue was used to determine the emergent mesoscale behavior of the tissue.

RESULTS

The tensile test simulation results (Figure 1) from the visco-hyperelastic model [5] showed reasonable agreement with the reported mesoscale data [2] at strains between 0.0-0.3. Specifically, the simulated curve based on the work of Perlman and Wu [5] showed slightly lower stiffness compared to the reported mesoscale behavior model below ~28% strain. Above 30% strain, the disagreement between the simulated microscale-based curve and the mesoscale dataset increased.

The mean error was determined for each simulated case concerning the reported mesoscale data to quantify the difference in the resulting stress-strain curves. Overall, the visco-hyperelastic microscale model [5] showed the lowest mean error compared to the mesoscale data across all strains (error of 39%) with an even lower error (error of 26%) when only accounting for strains of up to 40%. Conversely, the AFM-based microscale model [4] resulted in a larger mean error overall (error of 61%) with a larger mean error in lower strain ranges (error of 94%) than over the whole strain range of the experiment.

DISCUSSION

In this study, we utilized computational modeling to investigate whether the emergent mechanical properties of lung tissue at the mesoscale, based on micro-scale mechanical testing data, can be reconciled with the experimental data obtained using mesoscale tensile testing. We picked two of the most comprehensive and high-fidelity mechanical testing datasets published by other researchers for the purpose of this study: the microscale data reported by Perlman and Wu [5] and the mesoscale multimodal data of Birzle et al. [2]. An additional comparison to a linear model based on the AFM experiments of Melo et al. [4] was also made for comparison purposes. Overall, the comparative study successfully reconciled the mechanical properties of lung tissue across micro- and mesoscales when comparing the microscale study of Perlman and Wu [5] to the mesoscale data reported by Birzle et al. [2]. By comparing the emergent properties of simulated microscale-based models to the material behavior reported at the mesoscale, this research further confirmed the reasonable accuracy of the mechanical behavior reported for lung tissue in both experimental studies. Furthermore, this study showed that FE modeling could be used as an informative and guiding tool to investigate and potentially resolve the differences in reported lung tissue mechanical properties across spatial scales.

THE ROLE OF THE POSTERIOR CRUCIATE LIGAMENT ON FEMORAL ROLLBACK IN MEDIAL CONGRUENT TOTAL KNEE ARTHROPLASTY: A COMPUTATIONAL STUDY

INTRODUCTION

Total knee arthroplasty (TKA) with medial congruent (MC) polyethylene designs has shown increased clinical utilization with satisfactory clinical outcomes over the last several years [1]. The goal of this design is to reproduce the medial pivoting behavior of the native knee through a more constrained medial compartment allowing posterior sliding of the lateral femoral condyle with flexion [2]. This design employs a standard cruciate-retaining femoral component with the option of retaining the posterior cruciate ligament (PCL).

The role of PCL and whether it should be retained in medial congruent TKA is controversial [3]. Arguments in favor of PCL retention cite more physiological knee kinematics [4]. One desired aspect in PCL-retaining TKA is achieving femoral posterior translation of the native knee, also referred to as femoral rollback, through a range of knee flexion [5]. In contrast, those who advocate sacrificing the PCL cite inconsistency in femoral rollback with retention of the PCL [6]. Therefore, we developed a computational framework to quantify the role of the PCL in the kinematics of medial congruent TKA. We posed the following research question: How does the absence of the PCL affect the posterior translation of the medial and lateral femoral condyles through a range of knee flexion from 0 to 90°? We hypothesized that resecting the PCL reduces posterior translation of the medial and lateral femoral condyles.

METHODS

Computational models derived from 10 independent cadaveric left knees (five male, five female; mean age: 63.7±10.5 years) were virtually implanted with an MC TKA tibial insert (12 mm) and cruciate retaining (CR) femoral component (Persona, Zimmer-Biomet, Warsaw, IN). The computational modeling pipeline utilized the multibody dynamics framework and has been published previously [7]. The tibial bearing surface of the MC design has a conforming feature on the anterior aspects of the medial and lateral compartments while the posterior

aspects are less conforming laterally than medially (Fig. 1a). The model development pipeline consists of the following four steps: (1) segmenting and reconstructing the entire femoral and tibial bony geometries in 3D from computed tomography scans (Fig. 1a); (2) creating an anatomical coordinate system for the knee joint [8] (Fig. 1b); (3) positioning implants according to manufacturer recommendations including 9 mm posterior-referencing femoral bony cuts, 9 mm of tibial bony cut with 5° of slope; and (4) incorporating ligament models based on their anatomical insertions (Fig. 1b).

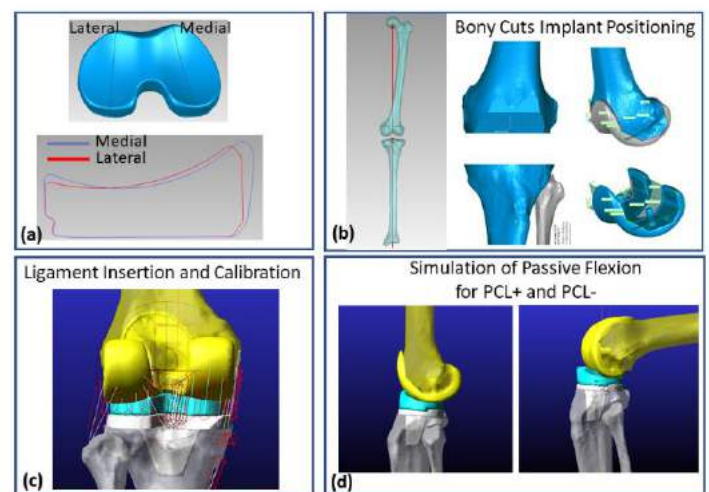

Figure 1: Computational workflow in modeling medial congruent TKA with simulated PCL retention (PCL+) and resection (PCL-).

The ligament models consisted of 33 line-elements describing the collateral and capsular ligaments and the PCL. The PCL consisted of seven line elements with three elements and four elements representing the posteromedial (PM) and anterolateral (AL) bundles, respectively. The nonlinear, tension-only force-elongation response of each ligament was represented with a power function and population mean structural properties taken from the literature. Slack lengths were defined using a previously published optimization algorithm [7].

We modelled two conditions: PCL-intact (PCL+) and PCL-deficient (PCL-). For both conditions, the knee was flexed through a range of motion from 0° to 90° under 500 N of compression representing a common clinical test of passive flexion. Simulations were conducted using a multibody dynamics software package (MSC Software; Adams 2021-4, Hexagon, Stockholm).

Outcome measures were the difference in anterior-posterior (AP) translation between 0° and 90° of flexion for both the medial and the lateral femoral condyles with anterior translation of the femoral condyle designated as positive. A Kolmogorov-Smirnov test ($p < 0.05$) revealed that our data were not normally distributed; therefore, we reported medians and quartiles. To compare the AP translation of the medial femoral condyle for the PCL intact and PCL deficient conditions and the lateral femoral condyles for these same two conditions, we used a nonparametric Wilcoxon signed-rank test ($\alpha = 0.05$).

RESULTS

AP translation of the medial femoral condyle for the PCL intact and PCL deficient conditions were small, differing by a median of 0.8 mm (Fig. 2a). In contrast, the AP translation of the lateral femoral condyle was a median of 4.1 mm greater for the PCL intact condition compared to the PCL deficient condition (Fig. 2b) ($p = 0.002$).

DISCUSSION

We found that the lateral femoral condyle translated posteriorly with the PCL intact but did not when the PCL was deactivated. In contrast, the PCL had minimal effect on the AP translation of the medial femoral condyle. Therefore, our hypothesis was partially accepted. Similar to our findings, Most et al. [9] reported greater rollback of the lateral femoral condyle compared to the medial femoral condyle in an in vitro robotic study of cruciate retaining TKA. They also reported femoral rollback of 10 mm on the lateral side with PCL retention, which corroborates our findings.

The design of the medial congruent bearing surface likely contributes to the greater posterior translation of the lateral femoral condyle compared to the medial femoral condyle when the PCL is retained. The less conforming lateral bearing surface with a larger radius of curvature than the medial bearing surface (Fig. 1a) provides less constraint to the lateral femoral condyle, allowing a higher range of AP translation.

The magnitude of rollback of the lateral femoral condyle was variable even with retention of the PCL. Thus, medial congruent TKA does not guarantee rollback even with retention of the PCL. In contrast, posterior femoral translation was always minimal in absence of PCL.

Although there was femoral rollback laterally with the PCL retained, the femoral rollback varied among knees ranging from -9.9 to 16.2 mm. This variability in femoral rollback agrees with previous findings [5]. Like standard cruciate retaining implant designs, soft tissue balance and PCL anatomy can have a substantial effect on femoral rollback. Possible anatomical explanations for this heterogeneity are variations in the femoral insertion of the PCL. Since the PCL is highly anisometric through a range of flexion [10], small variations in femoral insertion anatomy may have a strong influence on the magnitude of force carried

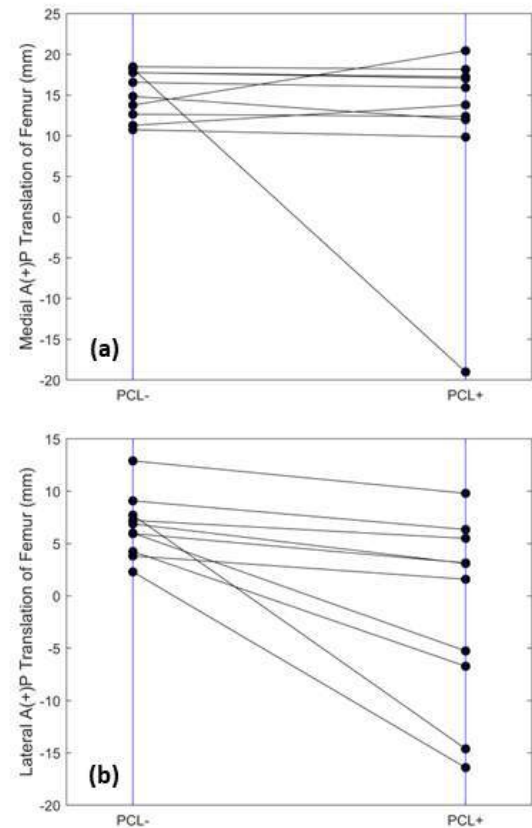

Figure 2: The AP translation of the medial (a) and lateral (b) femoral condyles from 0° to 90° of flexion with PCL intact (PCL+) and PCL deficient (PCL-). Each pair of black dots connected by a solid black line represents an individual knee model.

by the PCL as the knee flexes, which will, in turn, impact the amount of femoral rollback.

In conclusion resection of the PCL has minimal impact on rollback of the medial femoral condyle in MC TKA, likely due to the greater conformity of the medial tibial bearing surface. In contrast, resection of the PCL abolishes rollback of the lateral femoral condyle, while retention of the PCL leads to variable femoral rollback. Our findings support clinical observations of difficulty in achieving predictable femoral rollback with retention of the PCL in MC TKA.

CHARACTERIZING NATURAL FREQUENCIES OF THE HYBRID III AND NOCSAE HEADFORMS

Kristin J. Dingelstedt and Steven Rowson

Biomedical Engineering and Mechanics
Virginia Tech
Blacksburg, VA, USA

INTRODUCTION

Anthropomorphic test device (ATD) headforms are used to study different head impact scenarios. Two popular ATD headforms are the Hybrid III and the National Operating Committee on Standards for Athletic Equipment (NOCSAE), though they have structural differences [1-2]. The Hybrid III headform was developed for automotive safety testing, modeled after an average American man. It consists of an aluminum shell with a hollow brain cavity for instrumentation and is covered with a vinyl skin. The NOCSAE headform was designed for the evaluation of protective athletic gear, modeled after an American football player. It is constructed with a nylon shell, filled with glycerin, and covered with urethane [2]. Both headforms have been shown to have biofidelic biomechanical responses, and each has been used extensively to study sports-related head impacts, where they perform very similarly in impact scenarios typically seen in helmeted sports [1].

While these headforms are used to understand the behavior of the human head in different impact events, little research has been done on fully understanding their dynamic properties, especially the natural frequencies. All systems have natural frequencies at which they vibrate in the absence of any driving forces. If a time-varying external load is applied to a system, and its frequency is equal to any of the system's natural frequencies, resonance will occur. This causes the system to oscillate at high amplitudes, causing abnormally large deflections of the system. Understanding the natural frequencies of headforms used in impact testing is important because the head will behave differently depending on the characteristics of the impact [1]. Gurdjian et al. [3] hypothesized that awareness of natural frequencies is useful for shorter-duration impacts ($t < 5$ ms), because these impacts have a broader frequency spectrum which can cause resonance frequency excitation and skull deformation, potentially due to relative motion between the brain and the skull. Therefore, in impact testing, it is important to consider frequency content, since the results from these types of impact

scenarios can be influenced by the dynamic response of the headform [3].

In previous attempts to characterize the dynamic properties of the human head, various modal testing techniques have been done to identify the natural frequencies using different methods to vibrate human cadaver skulls [3-4], polymer skull models [5], and human skulls *in vivo* [6]. Many of these tests used modal impact hammers to excite the skulls. However, there are no data describing the dynamic responses of the Hybrid III and NOCSAE headforms. By determining the natural frequencies of these headforms in a similar manner, they can be compared against published values [3-6] to determine which one captures the most accurate vibrational response.

METHODS

Experimental modal analysis uses excitation and response signals to identify natural frequencies and other dynamic characteristics of a structure, so modal testing methods were used to identify the natural frequencies of the two headforms. A 50th percentile male Hybrid III headform and a medium NOCSAE headform were attached to a 50th percentile Hybrid III neck and mounted to a stationary plate. To collect linear acceleration data, which served as the response signals, the headforms were instrumented with 3 linear accelerometers at their respective centers of gravity. An Impulse Force Test Hammer (PCB Piezotronics, Model 086C04 (Depew, NY)), hereafter referred to as simply an impact hammer, was used to provide the excitation force to the headforms. A stainless-steel tip of hard stiffness was used on the impact hammer, as it was capable of providing impacts up to 400 N and covered a broad frequency range of 0-5 kHz.

A “roving hammer” test approach was used, where the accelerometers remained fixed and the headforms were struck with the impact hammer at several locations, ensuring that the impact durations were between 1-3 ms. Five locations were identified for frontal impacts, with each location being impacted a total of 4 times. The same was done

for temporal impacts (Figure 1). Multiple locations were selected in an effort to excite various possible modes in the headforms, as natural frequencies can vary with location. The data were not filtered to avoid the possibility of missing any important frequencies. A custom-written MATLAB (MathWorks, Natick, MA) code was used to calculate the desired metric of natural frequency. The force signal from the impact hammer and the acceleration signals from the headforms' accelerometers were transformed from the time domain into the frequency domain using a Fast Fourier Transform (FFT). Then, the Frequency Response Function (FRF) was calculated, which is the ratio of the response signal to the excitation signal in the frequency domain. When the FRF is plotted, the frequencies that correspond with each peak are the natural frequencies. The results for the Hybrid III and NOCSAE headforms were compared with each other and against published values [3-6].

Figure 1. Experimental setup of the Hybrid III headform (left) and the NOCSAE headform (right), which were each marked with 5 frontal and 5 temporal targets to impact with the tip of the impact hammer.

RESULTS

In both the Hybrid III and the NOCSAE headforms, most of the natural frequencies were observed between 1000-2000 Hz. For certain impacts, there were natural frequencies as low as 700 Hz. More research needs to be conducted to determine the potential effects of impact duration and location on natural frequencies to gain a fuller understanding of the dynamic characteristics of different headforms.

DISCUSSION

The natural frequencies of both headforms fall within the ranges seen in existing published values (Table 1). This is an encouraging result, as it suggests that these headforms behave similarly to the human head regarding their dynamic behaviors.

Table 1. Published natural frequency values associated with various modes in different types of skulls.

	Human cadaver skull filled with silicon gel [3]	Dry human cadaver skull [4]	Polystyrene skull model [5]	Human skull <i>in vivo</i> [6]
1 st Mode (Hz)	313	1385	1410	972
2 nd Mode (Hz)	600	1777	1790	1230
3 rd Mode (Hz)	880	1883	1888	1532

When performing impact testing, it is important to be aware of these characteristics, because when resonant frequencies occur due to the head experiencing a loading at or near one of its natural frequencies, it can be more easily deformed. This makes the head more vulnerable to certain impacts, regardless of their magnitudes. By understanding the intrinsic characteristic of two popular ATD headforms, informed decisions can be made in test environments to determine which one will best capture the frequency response of the head depending on the impact scenarios.

INTRODUCTION

Narrowing or stenosis in the coronary arteries, the vessels that supply blood to the heart, can lead to serious adverse effects such as heart attack and death. Fractional flow reserve (FFR), a measure of stenosis severity, is the pressure gradient across a stenosis under maximum flow. This metric is determined via an invasive and technically challenging procedure. Developing a computational method to estimate FFR avoids risks associated with this procedure; however high-fidelity (3D) models (e.g., Navier-Stokes) are computationally expensive and impractical for real-time diagnosis. An alternative is to use low fidelity models such as those based on 1D nonlinear theory that are computationally inexpensive.

In previous studies, 1D nonlinear theory was shown to produce relatively low errors compared to 3D theory for multiple types of pulsatile flows in non-stenosed vessels. [1] However, the 1D theory assumes that the pressure is constant over a tubular cross section and that the velocity is an average over the cross-section. Therefore, the lateral velocity components and contributions from the in-section pressure gradient of the 3D model are lost. In scenarios where lateral velocity components are triggered by the stenosis, making the flow patterns more complex, 1D theory is not equipped to capture these complexities and thus the parameter of interest for diagnosis, the axial pressure gradient (a surrogate of the FFR) is not accurate, as shown in Figure 1. In this project, we aim to develop a reduced order model (ROM) capable of accurately describing the complexities of flow across a coronary stenosis.

METHODS

In this study, we consider an analysis-based discovery of a ROM by applying assumptions to the 3D Navier-Stokes equations. High-fidelity data is required to verify the results of this approach. The high-fidelity results are generated using the CRIMSON software. [2] We start with idealized pipes with a constant circular cross-section and a single

cosine shaped restriction defined in Equation 1, a schematic representation is in Figure 2. This specific stenosis profile has often been used in studies of pressure gradient models. [3] Multiple boundary value problems were generated with varying degrees of restriction, stenosis half lengths, and inlet flows. A small sample of these boundary value problems is shown in Figure 3.

Figure 1: The inaccuracy of existing low dimensional models (1D) in capturing the pressure drop across a mild stenosis; this discrepancy is highlighted in gray.

$$R = R_0 - \frac{\delta}{2} \left(1 + \cos\left(\frac{\pi z}{z_0}\right) \right) \quad (1)$$

Figure 2: An idealized stenosis geometry with a cosine profile.

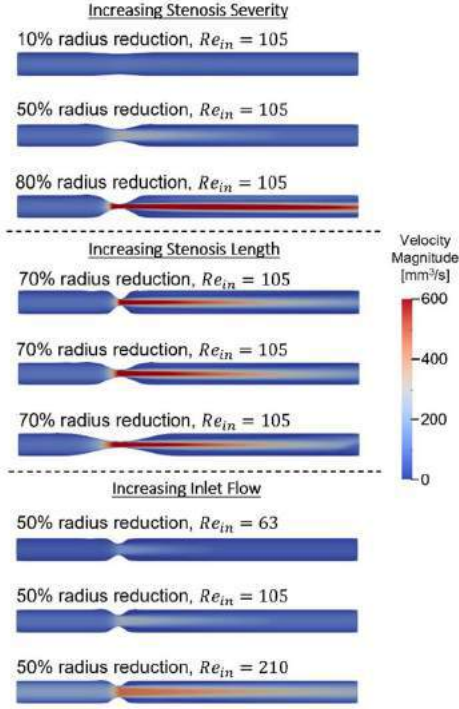

Figure 3: A sampling of the data generation of idealized stenoses. Examples are presented for increasing stenosis severity by increasing the percent diameter reduction, the length of the stenosed region, and increasing the inlet flow.

While our model does not rely on a specific profile, it can be useful to have an explicit mathematical expression for the geometry when developing a reduced order model. We develop a reduced order model by simplifying the full 3D incompressible Navier-Stokes equations in cylindrical coordinates using axisymmetric assumptions. The area averaged form of these equations may be used to relate the pressure gradient to the changes in the axial velocity as shown in Equation 2.

$$\frac{\partial \bar{p}}{\partial z} = \rho \frac{\partial \bar{u}_z^2}{\partial z} + \frac{2\mu}{R} \frac{\partial u_z}{\partial r} \bigg|_R + \mu \frac{\partial^2 \bar{u}_z}{\partial z^2} \quad (2)$$

As a modeling approximation, we assume that the axial velocity as a function of radial and axial positions, r and z , satisfies separation of variables, as shown in Equation 3.

$$u_z(z, r) = \hat{u}_z(z, \hat{r}) = W_z(z)W_r(\hat{r}) \quad (3)$$

We proceed to identify a reduced order model for these area averaged. When substituting in this separation and averaging over the area, we consider the normalized radial position, \hat{r} and expand the radial component of the separation, $W_r(\hat{r})$, in terms of a basis. We apply this to Equation 2 as well as the constant flow rate, Q . From this flow rate equation, we can solve for the separated function $W_z(z)$ and substitute it back into Equation 2 to achieve the final ROM shown in Equation 4.

$$\frac{\partial \bar{p}}{\partial z} = -\frac{2\rho Q^2}{\pi^2 R^5} \frac{\partial R}{\partial z} \gamma_1 + \frac{\mu Q}{\pi R^4} \gamma_2 + \frac{6\mu Q}{\pi R^4} \left(\frac{\partial R}{\partial z} \right)^2 - \frac{2\mu Q}{\pi R^3} \frac{\partial^2 R}{\partial z^2} \quad (4)$$

In this model, the data from multiple boundary value problems may be combined into a linear system and regression is used to solve for the scalar coefficients γ_1 and γ_2 . Data used for this model may have varying geometries and inlet flows, however, there cannot be a laminar separation bubble in the diverging section of the stenosis. This would change the shape of the velocity profile, invalidating our assumption that the axial velocity satisfies separation of variables.

RESULTS

Table 1 shows best fit values for the scalar coefficients γ_1 and γ_2 found using 90 boundary value problems where there was no laminar separation bubble.

Table 1: Coefficients of Equation 5 determined from the data

γ_1	-2.46
γ_2	-54.13

A sample comparison of pressure gradients for two different boundary value problems using these coefficients in Equation 4 is shown in Figure 4. The pointwise error along z was determined between the CFD solution and the ROM. The average error across all problems in the dataset was 0.012.

Figure 4: Prediction of the ROM compared to CFD results for a geometric profile not used to fit the model (BVP 1 is a 30% diam. reduction, $Z_0 = 15$ mm, and $Q_{in} = 250$ mm³/s, BVP 2 is a 10% diam. reduction, $Z_0 = 5$ mm, and $Q_{in} = 750$ mm³/s).

DISCUSSION

The model we have discovered is similar to existing models for the pressure drop across a stenosis. However, in our approach, no assumptions were made in deriving our ROM regarding a specific geometric profile for the stenosis. This is an improvement on existing models; however, it is still limited by the assumption that the velocity profile satisfies separation of variables along radial and axial directions. Therefore, this model is only applicable to non-separated flows.

Further exploration is required, relaxing the separation of variables assumptions to obtain a model in which the radial velocity profile can change along the length of the vessel. Alternatively, several data-driven approaches could be used to discover new ROMs. For instance, system identification could be used on a library of candidate operators, inspired by our analytical model, to discover a new ROM. A key component in this approach is stepwise regression, which is used to eliminate terms until the Pareto front is reached. Traditional surrogate modeling approaches like neural networks may also be considered, however, these do not provide an interpretable model.

ADAPTIVE CHANGES IN THE BAT'S SHOULDER ANATOMY ALLOW FOR REPETITIVE OVERHEAD MOTIONS

INTRODUCTION

In humans, the glenohumeral joint enables the greatest mobility in the human body, at the expense of its stability. The bony anatomy between the proximal humerus and glenoid cavity of the scapula has minimal constraints, thus humans are able to perform a wide range of overhead motions. Stability in the joint is largely provided by soft tissues such as the rotator cuff and the labrum. Unfortunately, repetitive overhead motion leads to rotator cuff injuries that affect millions of people in the US each year [1,2]. Bats, however, have evolved to perform repetitive overhead motion in order to achieve flight. Their survival depends on performing these motions across a relatively long lifespan without injury [3,4]. To gain insight into strategies that might inform improved treatment, we therefore investigated the structure and function of the bat rotator cuff. In this study, we performed comparative anatomy to better understand the functional advantages of the bat shoulder versus that of the mouse, a similarly-sized quadrupedal animal. We hypothesized that the anatomy of the bat glenohumeral joint would differ from that of the mouse in ways that are consistent with improved stability.

METHODS

Sample preparation: All animal procedures were approved by the Columbia and Brown University Institutional Animal Care and Use Committees. Shoulders harvested from adult (12 weeks) C57BL6/J mice (n=5) and *C. perspicillata* bats (n=5) were dissected then fixed in three different positions: full shoulder extension ("P1"), intermediate ("P2"), and full shoulder flexion ("P3"). To consistently identify the angle between the scapular spine and the humerus for each fixation position, gait (mouse) and flight (bat) analyses were used. **MicroCT Imaging:** Samples were scanned at 55 kV peaks with 145 mA intensity, and 19.3 μ m resolution (Skyscan 1272, Bruker). **Anatomical Measurements:** Images were reconstructed (NRecon, Skyscan), and bone parameters measured (Skyscan CT Analyzer). The scapular linear

index was determined as the ratio of scapular width to length. Supraspinatus and infraspinatus linear indices were calculated using the length from the medial aspect of the spine to the superior or inferior angle. Glenoid retroversion was measured via the anterior facing angle between the body of the scapula and the glenoid face on the axial cross section. Supraspinatus outlet area was measured as the area posterior to the coracoid, inferior to the acromion, and within the acromial arch. Supraspinatus clearance, measured as the vertical distance between the humeral supraspinatus insertion and the bottom face of the acromion, was measured for each sample at each of the three positions. Glenoid curvature was measured using the circle tool in ImageJ to create the best fit circle. The arc length of the glenoid was calculated using the angle from the superior to the inferior glenoid rim. **Modeling:** Using a mathematical model based upon our imaging of the enthesis of mouse and bats, we predicted how strength, stiffness and toughness of the tendon enthesis would vary with loading direction and the bony ridge abutting the enthesis [9]. Simulations considered 20 linear elastic, brittle fibers of thickness $w = 10 \mu$ m and spacing $s/w = 1.5$ abutting a cylindrical bone ridge of aspect ratio $B/A=1$ (mouse) or $B/A=0.4$ (bat). Strength, stiffness, and toughness were normalized against idealized scenario where tightly packed fibers ($s/w = 1$) were pulled to failure uniaxially at 90° (Fig. 3). **Biomechanics:** Humerus and supraspinatus muscle and tendon units were dissected from adult (8 weeks) C57BL6/J mice (n=10) and *C. perspicillata* bats (n=5). To determine cross-sectional area of the tendon, microCT scanning was performed at 55 kV peaks with 145 mA intensity, and 6.5 μ m resolution (Skyscan 1272, Bruker). Following scanning, samples were preconditioned by being sinusoidally loaded from 0.05 to 0.2 N for 5 cycles then allowed to rest for 2 minutes, before being strained until failure in tension at 0.1 %/s. **Statistical Analysis:** All data are shown as mean \pm standard deviation. Statistical analysis was performed for all experiments using unpaired t-tests with Welch's correction (GraphPad Prism 7). The threshold for statistical significance was defined at $p < 0.05$.

RESULTS

Bony Anatomy: The scapular index and infraspinatus index were both significantly larger in bats than in mice, while the supraspinatus index did not differ (Fig. 1a). Supraspinatus-acromion clearance increased when moving from full shoulder flexion to extension (i.e., from P3 to P2 to P1) in both bats and mice. However, the supraspinatus outlet area was significantly greater in bats compared to mice (Fig. 1b). The glenoid was retroverted in bats and anteverted in mice. Glenoid curvature and arc length were significantly higher in bats than in mice. **Tissue level mechanics:** The supraspinatus tendon cross-sectional area was significantly larger in bats compared to mice (Fig. 2). Mechanical testing revealed that mouse supraspinatus tendons were significantly stronger (i.e., higher maximum failure stress) and significantly stiffer (i.e., higher modulus) compared to bats (Fig. 2). There was no difference in toughness between the two groups (Fig. 2). **Modeling:** Simulations suggested that the strength and stiffness of the supraspinatus tendon attachment are greater for the bat's flatter humeral head than for the mouse's more circular humeral head (Fig. 3). The higher strength associated with the bat was maintained over a broad range of loading angles, while toughness was slightly reduced, particularly at very low abduction angles.

Figure 2. Material properties of supraspinatus tendons

Figure 3. Modeling suggested that the flatter bat humeral head may increase strength and stiffness relative to the mouse.

DISCUSSION

Comparison of the glenohumeral joints of two similarly-sized species (i.e., bats and mice) suggested functional adaptations of bat shoulder anatomy in relation to the demands of flight.

Bony anatomy adaptations: The bat's enlarged scapular and infraspinatus indices imply changes to muscle size and orientation. The supraspinatus index, however, was conserved across species. Because the infraspinatus and supraspinatus stabilize quadrupedal gait, the bat's

enlarged infraspinatus index suggests a larger role for the infraspinatus in the bat's glenohumeral stability. This also hints at adaptation to relieve stress on the supraspinatus. Similarly, the larger supraspinatus outlet in the bat provides more space for the supraspinatus to pass under the coracoacromial arch to prevent supraspinatus shoulder impingement commonly seen in overhead-throwing athletes [5]. Although the glenoid was anteverted in mice, it was retroverted in bats, analogous to the retroverted glenoids reported in high-level overhead-throwing athletes [6]. This may enable more rotation of the joint while limiting capsular tension. The bat glenoid was more concave, encapsulating more of the humeral head when compared to mice. In addition, the bat had a larger glenoid arc length and articulating surface area with the humeral head, thus providing more stability while maintaining mobility.

Tissue level adaptations: Bat supraspinatus tendon cross-sectional area was significantly larger than that of mice, consistent with previous measurements of supraspinatus-acromion clearance and outlet area. While bat supraspinatus tendons were weaker when compared to mice, as indicated by significantly lower maximum failure stresses and significantly lower stiffness, resilience and toughness was similar between the two groups. In bats, the supraspinatus attachment (i.e., the greater tuberosity of the humerus) protrudes laterally to the humeral head, seemingly forming a secondary articulation with the acromion. Due to this enlarged tuberosity, the supraspinatus tendon forms an L-shape as it inserts into the scapular fossa. This adaptation may be to optimize strength over a wider range of motion, as seen by the large energy absorption experienced relative to its lower maximum failure stress and modulus values.

Modeling: The idea of the bat's deeper glenoid providing more stability is consistent with shoulder instability patients, who present with loss of glenoid concavity and a flatter glenoid morphology [8]. Our modeling revealed potential reasons why the humeral head shape at the supraspinatus tendon attachment may affect stability. The models suggested that flatter attachment in bats relative to mice leads to increased strength over a wide range of motion, enabling bats to perform high stress flight by optimizing strength over a wider range of motion than needed for walking. The mechanical energy needed to dislocate the humeral head increases with concavity of the glenoid and stiffness of the rotator cuff tendons: compression of the convex humeral head into the concave glenoid fossa stabilizes the shoulder. Dislocation requires displacing the humeral head laterally over the glenoid lip, with a force that increases with tendon stiffness. The energy required for this displacement is thus directly related to the shape of the glenoid. In the case of the bat, where the glenoid is deeper and more concave, more energy is required for shoulder dislocation.

Implications for rotator cuff repair. From the clinical perspective, adaptations in the bat provide insight into reshaping of the anatomy in surgical repair. Future studies of the bat rotator cuff muscles will further test these hypotheses about passive stabilization of the shoulder and rotator cuff repair techniques to decrease supraspinatus stresses.

INTRODUCTION

The uterus plays a critical role in establishing and maintaining pregnancy, undergoing dramatic growth and remodeling from embryo implantation to labor and birth [1]. In order to support these basic reproductive processes, the uterus is composed of three tissue layers that are structurally and functionally distinct: (i) the endometrium-decidua, the innermost layer that forms the maternal-fetal interface (ii) the myometrium, the thickest layer composed of smooth muscle interwoven with collagen fibers, and (iii) the perimetrium, the outermost serosal layer [1]. Although the uterus performs critical biomechanical functions, few studies have investigated the mechanical properties of the gravid uterus [2-3]. A complete absence of data exists for mid-gestational time points due to ethical limitations surrounding human uterine tissue collection. Therefore, we propose using a nonhuman primate model (Rhesus macaque) to assess mid-gestation uterine changes given known similarities in anatomy and pregnancy physiology [4]. The purpose of this study is to characterize the time-dependent micro-mechanical properties of the nonhuman primate (NHP) uterus at nonpregnant (NP) and three pregnant (PG) time points: early 2nd (E2), early 3rd (E3), and late 3rd (L3) trimesters.

METHODS

NHP uterine tissue was collected from Rhesus macaques following a total hysterectomy for the following groups: NP (n = 2), E2 (n = 2), E3 (n = 2), and L3 (n = 2). Uterine specimens contained all three tissue layers and were sampled from the anterior region (Fig. 1A). Samples were flash-frozen on dry ice and stored at -80°C until testing. This protocol was approved by the University of Wisconsin Institutional Animal Care and Use Committee (IACUC). To investigate the qualitative distribution of smooth muscle and collagen in all three uterine layers, uterine cross-sections were fixed in 10% formalin, paraffin-embedded, sectioned to a thickness of 5 µm, and stained for Masson's trichrome.

Prior to mechanical testing, samples were sectioned into separate tissue layers, swelled at 4°C overnight in PBS solution, and equilibrated at room temperature for 30 min. Spherical nanoindentation (Piuma, Optics11Life, Amsterdam, NL) was utilized to determine the time-dependent material properties of the NHP uterine layers. Using an indenter with a probe radius of 50 µm and cantilever stiffness of 0.19 N/m,

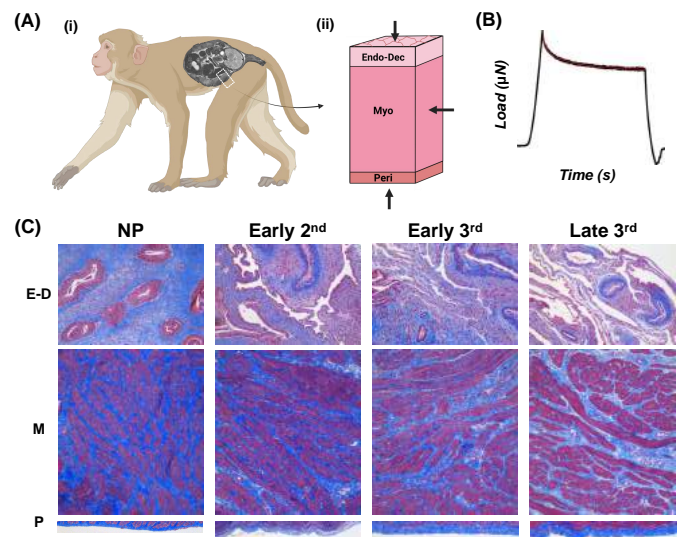

Figure 1: (A) Schematic of a (i) pregnant Rhesus macaque and (ii) uterine cross-section containing all three tissue layers. Arrows indicate the directionality of nanoindentation testing. (B) Representative load relaxation curve (black line) generated from nanoindentation testing fit with the PVE model (red line). (C) Histology (Masson's trichrome) of uterine layers (E-D = endometrium-decidua; M = myometrium; P = perimetrium) for NP, E2, E3, and L3 groups (blue = collagen; red = smooth muscle). Scale bar = 200 µm.

samples were indented to a fixed depth of 4 µm for 15 s, corresponding to a 5% strain, to achieve a load relaxation curve approaching equilibrium (Fig. 1B). The distance between indentation points was fixed at 200 µm. At least 150 indentation measurements were taken for each sample. Load relaxation curves were fit in MATLAB with a combined poroelastic-viscoelastic (PVE) model based on established methods [5-7]. Parameters of stiffness (E), viscoelastic ratio (E_{∞}/E_0), and intrinsic permeability (k) were determined. Statistical analysis was performed in GraphPad Prism 9.4.0 using a nested one-way ANOVA with significance set at a 95% confidence level. P-value symbols follow a standard GraphPad (GP) style (* $p \leq 0.05$, ** $p \leq 0.01$, *** $p \leq 0.001$) with an added

distinction for trends ($^{\#}p \leq 0.1$).

RESULTS

Distinct structural changes are evident for all uterine layers as a result of pregnancy (Fig. 1C). The endometrium-decidua exhibits the greatest degree of remodeling, marked by a shift in collagen content, an increase in the number and size of blood vessels, and the transformation of glandular epithelium morphology into a saw-toothed appearance in pregnancy. Similarly, the myometrium undergoes a significant increase in size during pregnancy through hyperplasia and hypertrophy of smooth muscle fibers. Lastly, the perimetrium, a layer exclusively composed of collagen, appears to thicken in pregnancy, with clear differences observed across all gestational time points.

Differences in the material properties of the NHP uterus are demonstrated for NP and PG tissue layers across gestation (Fig. 2). Notably, the endometrium-decidua is the least stiff layer of the uterus, by nearly one to two orders of magnitude, regardless of PG state (Fig. 2A). Relative to the myometrium, the perimetrium exhibits variable trends within each gestational time point and nonpregnancy, with the greatest differences detected for E2 and L3 trimesters (Fig. 2A). The perimetrium is the only layer of the uterus that stiffens in pregnancy, with tissue in the L3 trimester demonstrating increased stiffness relative to NP, E2, and E3 groups. No change to myometrium stiffness is observed as a result of pregnancy (Fig. 2A).

For all uterine layers, regardless of PG state, viscoelastic ratio ranges from 0.4 to 0.6 (Fig. 2B). For all PG time points, the endometrium-decidua exhibits a decreased viscoelastic ratio relative to both the myometrium and perimetrium, a trend not observed in nonpregnancy (Fig. 2B). No changes in viscoelastic ratio are observed for and between the myometrium and perimetrium in pregnancy (Fig. 2B). Permeability shows variable trends for all tissue layers across NP and PG groups, ranging from 10^{-15} to 10^{-17} m^2 (Fig. 2C). The NP endometrium-decidua appears less permeable than the NP myometrium, yet this difference is not statistically significant for any PG time points (Fig. 2C).

DISCUSSION

Here, we uncover the transformation of structural and material properties for the NHP uterus in pregnancy with the unique inclusion of mid-gestational time points. This robust dataset collected via nanoindentation contributes to a key knowledge gap in pregnancy biomechanics due to insurmountable ethical boundaries in humans. Specifically, this dataset, together with qualitative histology results, highlights drastic differences in structure, composition, and stiffness across the endometrium-decidua, myometrium, and perimetrium in pregnancy. Surprisingly, the perimetrium is the only uterine tissue to exhibit clear stiffening relative to NP and early gestational time points, mirroring changes in thickness to this layer.

A key limitation of this study is the relatively small sample size per group ($n = 2$), making it difficult to conclude whether differences, or lack thereof, are truly representative of each NP and PG group or are subject to individual animal variability. Moving forward, we plan to address this by including additional samples. It is also important to note that the NP endometrium-decidua and perimetrium exhibit the greatest degree of individual variability in stiffness values amongst all tissues tested, a likely product of menstrual cycle fluctuations. Yet, despite these limitations, the data presented here yield key insights into mid-gestational changes that occur for all three uterine layers. Characterizing baseline changes that occur throughout pregnancy in a physiologically comparable animal model is foundational to better understanding and predicting healthy and disordered alterations in human gestation.

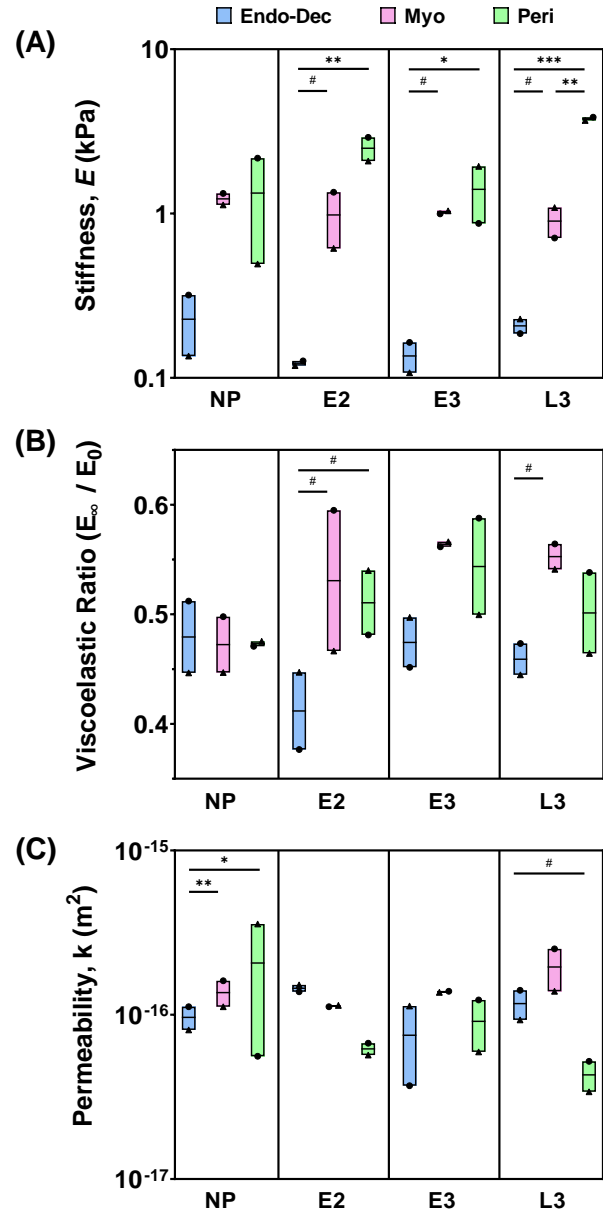

Figure 2: (A) Stiffness, (B) viscoelastic ratio, and (C) permeability of NP, E2, E3, and L3 NHP uterine layers. Each symbol represents the median value of all indentation points ($10^1 - 10^2$) for a given sample, with triangles and circles indicating different animals.

DEVELOPMENT OF A FINITE ELEMENT BIRTHING MODEL TO ASSESS PELVIC FLOOR BIOMECHANICS

M. Mounzer (1), A. Singh, Ph.D. (2), S. Balasubramanian, Ph.D. (1)

- (1) School of Biomedical Engineering, Science and Health Systems, Drexel University, Philadelphia, PA, USA

INTRODUCTION

Due to ethical constraints of conducting birthing injury studies in pregnant women, computational birthing simulations have been developed to assess the involved structures and forces [1]. However, current models suffer from oversimplified pelvic floor geometry. Therefore, the objective of this study was to create detailed finite element (FE) models of a female bony pelvis with pelvic floor muscles, and a fetal head to simulate birthing.

METHODS

Retrospective MRI images from a female subject (age 25-39 years) was obtained from an open-source database [2]. The geometry of the pelvic floor muscles, namely puborectalis, pubococcygeus, iliococcygeus, coccygeus, and obturator internus were segmented using 3D Slicer (Slicer), an open-source medical image processing software (Figure 1.). Post-processing of these segmented geometries was done in Fusion 360 (Autodesk, San Rafael, CA) to promote uniformity in order to generate quality meshes. Hexahedral meshes of the segmented geometries were created using HyperWorks (Altair Engineering, Troy, MI), and integrated with an existing hexahedral FE model (1031 elements) of the female bony pelvis. A fetal head and skull model was adapted from an open-source license: Position and Personalize Advanced Human Body Models for Injury Prediction (PIPER) project. The 1.5-year-old PIPER head and skull FE model (available at piper-project.org/downloads) was meshed into a hexahedral FE model (3144 elements) and scaled down to the dimensions of a 50th percentile fetus. Material properties and ligamentous structures for the pelvis will be added to create a more biofidelic model for birthing simulations, and therefore can properly assess pelvic floor stresses and strains on muscles and connective tissues.

Figure 1: Segmented pelvic floor from MRI-scan slices using 3D Slicer. (Red: Puborectalis, Orange: Pubococcygeus, Yellow: Iliococcygeus, Green: Coccygeus, Blue: Obturator Internus).

RESULTS

High-quality FE model of the pelvic floor muscles were created (271 out of 294 elements have a Jacobian greater than 0.7) and integrated with the FE model of the female bony pelvis (Figure 2). The FE model of the fetus head was positioned within the pelvis to simulate birthing (Figures 3, 4). The Jacobian matrices for bony structures such as the fetal skull and pelvis can be ignored due to the rigidity of bone as compared to soft tissue structures (total element size: 5491).

Figure 2. Hexahedral meshed FE models of the bony pelvis and pelvic floor muscles using HyperWorks (Red: Puborectalis, Orange: Pubococcygeus, Yellow: Iliococcygeus, Green: Coccygeus, Blue: Obturator Internus, White: Bony Pelvis, Yellow: Pubic Symphysis).

Figure 3. Hexahedral mesh of the fetal head (turquoise) and fetal skull (blue).

Figure 4. Combined hexahedral FE models with fetal head and skull placed in the occipito-posterior position.

DISCUSSION

Maximum stretch ratios can range from 1.6 to 3.5 and occur at the inner posterior-medial portion of the puborectalis [3]. Furthermore, occipito-posterior (OP) fetal positions result in a greater stretch of the

levator ani than compared to occipitio-anterior position. However, due to variability between muscles and connective tissue comprising the pelvic floor, birthing simulations are necessary to validate appropriate locations of maximum strain of the levator ani muscle. Therefore, parametric simulations are needed to correlate fetal position to maximum stretch ratios of specific pelvic floor muscles.

INTRODUCTION

Meniscal Traumatic Injury is the most prevalent orthopedic injury among adults with approximately 700,000 procedures performed annually in the United States alone according to AAOS data. Further the economic impact of such injury is a multi-billion-dollar annual economic market. As such significant research efforts are being undertaken to improve upon the surgical repair and regeneration of menisci[3].

Current techniques to repair the menisci involved arthroscopic surgical intervention using sutures to reintegrate the torn tissue to the intact tissue. However given the interior avascular nature of the menisci white zone tears offer little in the way of regeneration. As such said injuries are dealt with via meniscectomy are partial or complete in which the tissue is excised and removed. However as the menisci plays a crucial role in maintaining joint function, via lubrication, load bearing, and joint congruency, these procedures are incomplete in restoring joint health and function[3].

As such meniscal alternatives have been developed to offer improved post-surgical outcomes. Implantable devices such as the Menaflex and CMI have been developed. These devices are porous collagen type1 based implants impregnated with GAGs that are trimmed to fit the current defect. These implants are resorbable and typically integrate and resorb into the body over a period of 8-12 weeks post-surgery.

Collagen based meniscal implants have seen varied success within the field. However further improvement upon the properties of Collagen based implants relative to native meniscal tissue is still desired regarding structural integrity, hydraulic permeability, bio composition, and aggregate modulus.

Previous efforts at our lab have been taken to characterize and assess the various properties of native meniscal tissue in relation to transport properties, tissue composition, micro and macro architecture, and viscoelastic behavior under compression, tension, and shear loads.

Utilizing data previously gathered our goal is to begin to recapitulate the behavior of native meniscal tissue. In the development of a composite biomaterial for meniscal tissue engineering.

METHODS

Hydrogel Formation

A 15% Gelatin A wt/vol solution (Sigma-Aldrich 300 Bloom) was prepared by dissolving GelA in PBS at relevant concentrations and dissolving the solution in a heated water bath at 80C. The solution was then cross-linked utilizing a Glutaraldehyde solution diluted with PBS to maintain consistent osmolarity. To achieve varied molar ratios of GelA:GA, various concentrations of GA solution were used, and all samples were cross-linked for 1 hour prior to being thrice rinsed in distilled water and then allowed to swell for 12 hours to reach osmotic equilibrium. Following the swelling period, the samples were removed, patted dry to remove excess moisture and weighed, yielding wet weight. The samples were then placed in a fume hood uncovered and allowed to completely dehydrate for a period of 24 hours and weighed again, yielding dry weight.

Degree of Swelling was then calculated using the following formula.

Equation 1:

$$\frac{Wt_{wet} - Wt_{dry}}{Wt_{dry}} = \text{Degree of Swelling}$$

Stress Relaxation

Unconfined compression stress relaxation was performed on a hydrogel sample utilizing a UniVert Uniaxial testing machine by CellScale. Hydrogel samples were prepared using the protocol in a 6 well plate. Volume was controlled to ensure the total sample height would not exceed 3mm, while molar ratios of GelA:GA were maintained. Samples were allowed to swell to osmotic equilibrium for a period of 12 hours prior to testing. Samples were excised using a 10 mm hole punch and measured for thickness. Samples were then placed on the center of the UniVert platen above an affixed piece of sandpaper (800 grit) to prevent slippage of the sample. The sample was then preloaded to 0.1N and PBS was filled into sample holder. The sample was then compressed at a rate of 0.003 mm/s to 10% and held for a period of 4 hours. Following this hold phase, the sample was compressed and held at 20% using the same protocol.

3D Printing

PCL filament was utilized on a FDM 3D printer at a nozzle temperature of 140C and a bed temperature of 33C. Various patterns and configurations will be utilized and assessed for mechanical properties.

DISCUSSION

While our research and development is still in its’ early phases, initial tests show statistically significant control of swellability in hydrogel formation. Allowing for the fine tuning of osmotic behavior in the hydrogel portion of the composite material. Allowing for control of the matrix portion of the composite material.

Further the stress relaxation behavior of the hydrogel alone follows the behavior exhibited by native meniscal tissue in that, a steep decrease followed by a gradual leveling off to equilibrium force. Consistent with stress-relaxation behavior exhibited by Standard Linear Solid Models.

In turn the integration of PCL printed reinforcement grids will need to be tested under similar protocols to determine the overall enhance effect of the composite material. As well as the relative mechanical properties too native meniscus tissue.

When assessing PCL on its’ own it is found to have a Young’s Modulus of 3.89 MPa with native Meniscus tissue being on the order of 2-5 MPa. While PCL alone exhibits good stress-relaxation behavior our goal is to determine if the composite of PCL and the hydrogel matrix can improve upon the properties relative to native tissue[4].

Figure 3 Composite BioMaterials using GelA hydrogels and PCL 3D prints.

Further as such this could provide the basis for generating tissue engineered articular cartilage scaffolds to replace static synthetic materials while improving the efficacy of natural materials alone.

CHANGES IN VISCOELASTIC MECHANICAL PROPERTIES AND GENE EXPRESSION IN RAT ACHILLES TENDON DUE TO TREADMILL RUNNING DEPEND ON EXERCISE INTENSITY AND DURATION

INTRODUCTION

Despite high prevalence of Achilles tendinopathy,¹ the effect of exercise on tendon properties that influence prevention, development, and treatment of Achilles tendon pathology remain unclear. Clinically, patients with a variety of exercise histories, ranging from sedentary individuals to elite athletes, present with Achilles tendon pathology.² In animal models, where exercise can be investigated as a controlled variable, effects of exercise on tendon range from anabolic effects including improved tendon mechanical properties³ and increased collagen type I gene expression⁴ to catabolic effects including reduced mechanical properties and damaged collagen fibrils.⁵ Accordingly, to leverage exercise as a tool for Achilles tendinopathy treatment and prevention, the contributions of exercise intensity and duration to exercise-induced tendon changes must be better understood. Using an *in vivo* rat Achilles tendon model, our objective was to define intensity- and duration-dependent effects of treadmill running exercise on mechanical properties, cell morphology and density, and gene expression. We hypothesized that exercise would induce tendon changes in an intensity-dependent manner whereby increased exercise intensity would increase: resistance to mechanical fatigue, tenocyte density, and expression of genes associated with tendonous anabolism with changes most notable after prolonged exercise duration.

METHODS

Study Design: Sixty Sprague Dawley rats ~10 weeks of age (300-350 g) were randomized into six groups (n = 10/group) corresponding to exercise duration (4 or 8 weeks) and intensity: Low (cage activity), Moderate (running 1 hour/day 5 days/week at 10 m/min, 0° incline), or High (running 1 hour/day 5 days/week at 20 m/min, 10° incline). Rats assigned to Moderate and High groups participated in two weeks of treadmill acclimation prior to initiation of the exercise protocol.

Following sacrifice at either 4 or 8 weeks, tendons were harvested bilaterally and randomly assigned to mechanical, histological, and gene expression analyses. All analyses were performed blinded to experimental group. **Mechanical Analysis:** Tendons were prepared, and cross-sectional area was measured as described⁶ (8 mm gauge length). Mechanical assessment was performed with a viscoelastic testing protocol (preconditioning, stress relaxation at 9% strain, and sinusoidal frequency sweep at 0.1, 1, 5, and 10 Hz) followed by a ramp (1% strain/s) to 30 N with subsequent fatigue cycling (5 N to 30 N at 1 Hz). Images were captured during the ramp for optical strain measurement. **Histological Analysis:** Ankles were fixed, decalcified, and embedded in paraffin using standard techniques.⁶ Tendons were sectioned sagittally at 7 μ m, stained with Hoechst 33342, and imaged at 20X magnification. Three regions (1000 x 2000 pixels, 1 at the insertion, 2 in the midsubstance) per tendon were analyzed with a custom thresholding protocol to quantify cell density and nuclear circularity (0 = line, 1 = circle, ImageJ, Bethesda, MD). **Gene Expression:** RNA was isolated from Achilles tendons using TRIzol (ThermoFisher, Waltham, MA). RNA was converted to cDNA (WT PLUS Kit, ThermoFisher), run on a ClariomTM S Rat Transcriptome Array 1.0 (ThermoFisher), and assessed with Transcriptome Analysis Console Software (ThermoFisher, ≥ 1.5 -fold change, 0.1 false discovery rate). **Statistics:** For histological and mechanical analyses, outliers, identified with the ROUT method (Q = 0.1%), were excluded, and differences were assessed for each timepoint with one-way ANOVAs for exercise intensity and Tukey's post hoc tests.

RESULTS

Mechanical Analysis (Fig. 1): After 4 and 8 weeks of exercise, no significant differences were observed in stiffness or modulus for tendons exercised at different intensities (Fig. 1A-B). However, after 4

weeks, viscoelastic mechanical properties were different between tendons in Moderate and High groups. Tendons from the High group demonstrated increased stress relaxation, decreased dynamic modulus at all frequencies, and increased phase shift at 0.1, 1, and 5 Hz compared to tendons from the Moderate group (Fig. 1C-I, 10 Hz data not shown). After 8 weeks, differences between Moderate and High groups resolved but differences between Low and Moderate and Low and High groups emerged. Compared to tendons from the Low group, Moderate and High group tendons had decreased percent relaxation (Fig. 1C). While there were no differences in dynamic modulus at any frequency, Moderate group tendons had decreased phase shift at 0.1, 1, and 5 Hz compared to Low group tendons (Fig. 1D-I). Similarly, compared to Low group tendons, High group tendons demonstrated decreased phase shift at 0.1 Hz and a trend toward decreased phase shift at 1, 5, and 10 Hz. There were no changes in fatigue properties due to exercise intensity (data not shown).

Histological Analysis (Fig. 2): Changes in cellular density and nuclear circularity at the tendon insertion (data not shown) and midsubstance (Fig. 2A-E) were not detected between intensity groups.

Gene Expression (Table 1): With 4 weeks of exercise, differences in gene expression were observed between Low and High groups, including differential expression of several ribosomal RNA transcripts. After 8 weeks of exercise, differences in gene expression occurred between all groups. The highest number of differentially expressed genes was observed between Low and High groups, including genes involved in the regulation of inflammation (Table 1).

DISCUSSION

This study demonstrated dose-dependent changes in mechanics and gene expression of the rat Achilles tendon in response to treadmill running as a form of mechanical loading. Specifically, results indicate that the tendon exercise response is intensity- and duration-dependent; in this model, exercise-intensity induced viscoelastic mechanical changes manifest at 4 weeks and resolve by 8 weeks. Mechanical changes in rat Achilles tendon after treadmill running are known to vary based on exercise duration,⁷ and our results suggest that the nature and time course of such changes is exercise intensity-dependent. Exercise intensity did not influence fatigue properties, but resistance to fatigue at higher load limits should be explored as this may better resemble repetitions of challenging physiologic loading scenarios, such as jumping and landing, which are high risk for Achilles tendon injury. Surprisingly, exercise did not impact tendon cellularity or nuclear shape which may indicate an ability of existing resident tendon cells to maintain homeostasis at the intensities examined. Gene expression was impacted by exercise intensity, concordant with findings in mouse Achilles tendon.⁸ Despite mechanical differences between Moderate and High groups at 4 weeks, gene expression differences were only detected between Low and High groups, which may indicate that early matrix changes are not driven by gene expression changes, additional gene expression changes occur transiently before 4 weeks, or a combination thereof. Gene expression differences at 8 weeks may reflect compensatory adaptations to exercise-induced cell and matrix changes. Future studies of gene expression will incorporate unbiased approaches to continue to elucidate the impact of exercise intensity and duration on the rat Achilles tendon transcriptome. Moreover, to further clarify the relationship between exercise and tendon health, future work will include additional exercise durations and intensities as well as exercise in pre- and post-injury contexts.

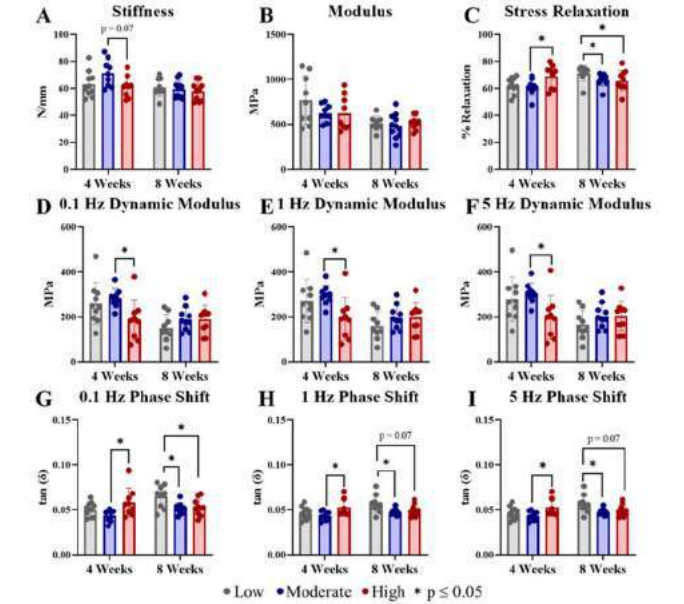

Figure 1: Exercise intensity does not influence tendon stiffness (A) or modulus (B). Differences between Moderate and High intensity exercise groups emerge in viscoelastic properties after 4 weeks but resolve after 8 weeks (C-I). Differences between Low and Moderate as well as Low and High groups emerge after 8 weeks of exercise in percent relaxation (C) and phase shift (G-I).

Figure 2: Cellularity (A) and nuclear circularity (B) in the midsubstance region were not altered by exercise (C- Low, D- Moderate, E- High at 8-week timepoint).

Table 1: Intensity (L-Low, M-Moderate, H-High) and duration of treadmill running exercise influence gene expression. Lower intensity exercise is considered baseline for fold change.

UNDERSTANDING CILIARY WAVEFORMS THROUGH OPTIMIZATION

Louis G. Woodhams (1), Philip V. Bayly (1)

(1) Mechanical Engineering and Materials Science
Washington University in St. Louis, St. Louis, MO, USA

INTRODUCTION

Cilia and flagella are slender organelles that move fluid or propel cells through fluid. Proper ciliary function in human beings is essential for clearing mucus in airways, circulating cerebrospinal fluid in brain ventricles, and transporting eggs along fallopian tubes. Those with ciliopathies such as primary ciliary dyskinesia suffer from chronic infections of the sinuses and bronchi, male and female infertility, and a 50% chance of *Situs inversus* – a condition which affects organ locations in the body due to improper function of embryonic nodal cilia, which establish asymmetry in the embryo through fluid flow.

Though the internal structure of cilia and flagella is now well known – the microtubule-based axoneme consisting of 9 outer doublets and a central singlet pair interconnected by radial spokes and circumferential links – the exact mechanism of beating remains poorly understood [1]. The motor protein dynein hydrolyzes ATP to drive a one-way sliding force between adjacent outer doublets, but the question remains as to how these nanomotors are coordinated, or if they are coordinated, to create the propulsive waveforms observed in cilia. Are the activation patterns prescribed by a signal (like spark distribution in an internal combustion engine)? Is there a feedback mechanism based on curvature or sliding? Or is the beating driven purely by mechanical instabilities [2]? Finally, it has been shown that dynein distributions along the length of the axoneme are not uniform, so how do these distributions affect ciliary function.

To answer questions about ciliary beating, there is a long-established practice of mathematical modeling dating back to Machin [3]. This approach typically involves the creation of a hypothetical model and comparing the behavior of that model with observed ciliary behavior to establish the plausibility of the model. In the current work, we approach the mathematical model as an optimization problem – given an objective and a set of constraints, how would the cilium evolve to be as effective and efficient as possible?

METHODS

We applied kinematic optimization to the waveform using resistive force theory. The tangent angle as a function of arclength, $\tilde{\theta}(s)$, was represented as a complex polynomial:

$$\tilde{\theta}(s) = a_1 s + ib_1 s + a_2 s^2 + ib_2 s^2 + \dots \quad (1)$$

A beat cycle is created by rotating the complex tangent angle function through 2π radians in complex space and projecting the complex function values onto the real plane:

$$\theta(s, t) = \text{real}(\tilde{\theta}(s) \cdot e^{i2\pi\omega t}) \quad (2)$$

The beat shape $x(s)$ and $y(s)$ coordinates are reconstructed by integrating the cosine and sine of the tangent angle, respectively, along the arclength of the cilium. The forces along the length of the cilium are calculated using resistive force theory with tangent and normal components taken from experimental values [4]. Total forces in the x -direction (parallel to the undeformed cilium) and y -direction (perpendicular to the undeformed cilium) as a function of time were calculated by integrating the x and y components of the force along the cilium, respectively. To calculate the effective propulsion during one cycle, the impulse of the stroke was calculated by integrating the force with respect to time [5].

For the optimization, the objective function was taken to be either the impulse in the x -direction ('flagellar' beating) or y -direction ('ciliary' beating). Optimization of the polynomial coefficients a_i, b_i of Eq. 1 was carried out in Matlab using the function *fminsearch()* (2021b, Natick, Massachusetts: The MathWorks Inc.). A penalty term was added to avoid excessive curvature in the optimized waveforms.

RESULTS

Optimizing the waveform for transverse propulsion yields asymmetric shapes that bear striking resemblance to those observed in cilia (Fig. 1). This waveform is optimized to propel fluid horizontally to the right. It should be noted that running the optimization multiple times with randomized initial parameters led to different optimized results as the algorithm is attracted to local optima. Without a penalty term associated with curvature, unrealistically contorted shapes emerge (not shown). Excessive curvature penalties lead to shapes that are insufficiently propulsive (not shown). A polynomial order of 3 (for the complex tangent angle function) was found to be sufficient to capture complicated beat shapes. In many cases, increasing polynomial order has minimal impact on the optimized waveform.

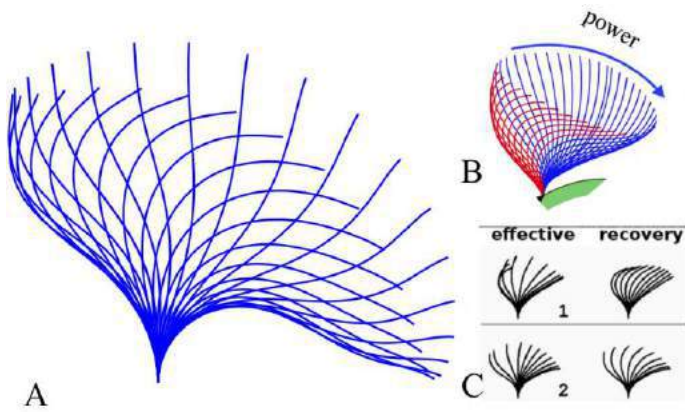

Figure 1: Waveform optimized for transverse propulsion
(A) Waveform produced through optimization. (B) *Chlamydomonas* waveform in Newtonian fluid [6] (C) Effective and recovery waveforms traced from human airway cilia [7]

Optimizing the waveform for axial propulsion yields symmetric shapes such as that shown in Fig. 2A. This waveform is optimized to propel fluid horizontally to the right. There is a wide variety of shapes observed in sperm propulsion. The current process is capable of producing results similar to some of these shapes, such as the one shown in Fig. 2B.

Figure 2: Waveform optimized for axial propulsion
(A) Waveform produced through optimization. (B) Human sperm waveform traced using computer-aided sperm analysis [8]

DISCUSSION

We find that kinematic optimization yields waveforms similar to those observed in cilia, especially for transversely propulsive beating shapes of short (5-15 μ m) cilia such as those of *Tetrahymena* [5], *Chlamydomonas* [6], and human airway cilia [7]. The current work leverages highly-simplified models of fluid behavior and cilia shape; added complexity may be necessary to capture the beating shapes of longer or more intricate structures, such as sperm flagella.

A limitation of the current work is that it is an optimization only of the beat shape, without taking into account a physical model of the mechanics of ciliary beat generation. We are currently working on incorporating this type of optimization into a model of ciliary beating that accounts for bend generation by inter-doublet sliding forces. We hope the results of such an optimization could lead to a better understanding of dynein activity and distribution within the axoneme.

Another future application of this work is extending the optimization to arrays of cilia. Arrays of cilia are known to beat with a temporal propagation pattern known as a metachronal wave [9]. This work could lead to a better understanding of not only why cilia beat with the shapes that they do, but what gains in efficiency and effectiveness might be gained from fine-tuning the metachronal propagation rate.

ACKNOWLEDGEMENTS

The work was supported by NSF grant no. CMMI-1633971 and the Children's Discovery Institute.

INTRODUCTION

Chronic wounds and ulcers often set off a cascade that culminates in amputation of a limb. This is particularly common in patients with diabetes mellitus: 6% of diabetes patients suffer from foot ulcers [1-2]; 65-75% of these heal, but the majority of the rest require amputation [3].

Many efforts to improve these poor healing outcomes focus on tissue engineered scaffolds that promote ingrowth of the myofibroblast cells needed for wound healing and the repair of microvasculature that, in the case of diabetic patients, is damaged by hyper-glycemia. To overcome the latter, angiogenic factors such as KLT peptide are of interest in the literature [4]. However, assisting the ingrowth of myofibroblasts onto a chronic wound from the surrounding diabetic tissue remains a critical challenge [5-6]. Our objective was therefore to develop tissue engineered technologies to facilitate the ingrowth of myofibroblasts over a diabetic wound.

The healing grafts we focused on fibrin gels, which have been studied for some time in the literature [7]. Based upon recent observations of the role of mechanical anisotropy on activation of myofibroblasts [8], we hypothesized that fibrin gels could be structured to facilitate myofibroblast ingrowth by providing cells with anisotropic mechanobiological cues.

METHODS

To test our hypothesis, we developed isotropic and aligned electrospun fibrin gel scaffolds, and tested them in an animal model of chronic diabetic wound healing. Results were interpreted through a random walk model of cell ingrowth.

Fibrin scaffolds: Aligned fibrin scaffolds were synthesized by electrospinning and compared to isotropic fibrin scaffolds. To separate mechanobiological and angiogenic factors, KLT peptide was engrafted onto the fibrin in some experiments using the KLT has self-assembly motif (Fig. 1a).

Characterization: scanning (SEM) and transmission (TEM) electron microscopy (TEM) was used to verify alignment of the fibrin in the

scaffolds. Human umbilical vein endothelial cells (HUVECs) cultured on each type of scaffold were imaged using confocal immunofluorescence microscopy to ensure that scaffolds supported angiogenesis.

Animal model: Animal protocols were approved by Institutional Animal Care and Use Committee (IACUC) at Tsinghua University. Adult (36 week) male Sprague-Dawley rats were treated with streptozotocin for 3 days to induce diabetes, then subjected to a square or rectangular wound (20x20 or 25x15 mm²) on the back. Immediately afterwards, isotropic or aligned fibrin gels, with or without KLT peptide were applied and healing results compared to controls (no scaffold). To model the human wound contracture (weak relative to the rat), contracture was restrained by a poly(methyl meth-acrylate) frame sutured beyond the wound periphery. Wound ingrowth was monitored as a function of time by computing the dimensions of the outer wound boundary as delineated by hand from the steepness of the color gradient. Wound height and width time courses were computed from these data.

Mathematical model: We developed a two-dimensional random walk model of cell migration to interpret experimental data and quantify the effects of scaffold alignment and KLT peptide. In the model, the spatial concentration $\varphi(\vec{r}, t)$ of healed wound area was dominated by migration of myofibroblasts and thus followed a diffusivity equation:

$$\frac{d\varphi(\vec{r}, t)}{dt} = \vec{\nabla} \cdot [\mathbf{D}(t)\vec{\nabla}\varphi(\vec{r}, t)] \quad (1)$$

where the migration coefficient tensor $\mathbf{D}(t)$ is diagonal in the axes of the fibers, with components $D_{\parallel}(t)$ and $D_{\perp}(t)$ parallel and perpendicular to the fibers, respectively, including both activation and steadily increasing terms:

$$D_{\parallel}(t) = a_{\parallel} \tanh(t/t_0) + b_{\parallel}t \quad (2)$$

$$D_{\perp}(t) = a_{\perp} \tanh(t/t_0) + b_{\perp}t \quad (3)$$

Dirichlet boundary conditions were used on the borders of the wound.

Hypothesis testing: We estimated $D_{\parallel}(t)$ and $D_{\perp}(t)$ from the experimental data using finite difference approximations if Eq. (1) and

a genetic algorithm. We hypothesized that the model would predict the data, and that the time constants for activation would be independent of healing scaffold, while the wound healing constants a_{\parallel} , b_{\parallel} , a_{\perp} , and b_{\perp} would vary with scaffold type.

RESULTS

SEM images (Fig 1b) analyzed using ImageJ (Fig 1c) revealed that fibrin in “aligned” scaffolds had a tighter orientation distribution than fibrin in “isotropic” scaffolds. KLT treatment roughened fiber texture (Fig. 1b). TEM images (Fig 1d) revealed that the cross-sections of isotropic gel fibers were varied due to their skew with respect to the sectioning plane, and that KLT treatment resulted in a porous structure and increased fiber diameters, likely indicating that KLT peptide was distributed not only on the surface but also within the interior of fibers.

Figure 1: Material Synthesis and Characterization. a. Material synthesis protocol. b. SEM images of scaffolds (top scale bars: 1 μ m; bottom: 200 nm). c. Analysis of fiber orientation based on SEM images. d. TEM images of scaffolds (scale bars: 0.5 μ m).

Confocal microscopy images showed HUVECs cultured for two days on aligned scaffolds to be more uniformly distributed than HUVECs cultured for two days on isotropic scaffolds. After five days of culture, HUVECs formed the expected lumen-like structures needed for eventual vessel formation (Fig 2). These were more prominent and numerous in scaffolds treated with KLT, indicating that KLT had angiogenic effects *in vitro*.

In diabetic rat models *in vivo*, wound healing was fastest in aligned fiber scaffolds, with speed greatest along the fiber direction (Fig 3a-b). The dimensions of the wound parallel and perpendicular to the fiber directions were measured and their evolution over time was fit to the wound healing model.

From the parameters of the fitted model, the effects of the scaffolds on wound healing could be deduced. The migration coefficients for all scaffolds reached activation within one week, and the time constant was insensitive to the scaffold type (Fig. 3c). For isotropic scaffolds, the migration coefficients reached a plateau that did not change with KLT treatment. For aligned scaffolds, the migration coefficients were higher parallel to the fibers than they were perpendicular to the fibers, and

increased steadily over two weeks. KLT treatment accelerated wound healing on these scaffolds.

Figure 2: Confocal immunofluorescence images of HUVECs cultured on scaffolds for 2 or 5 days (scale bars: 100 μ m).

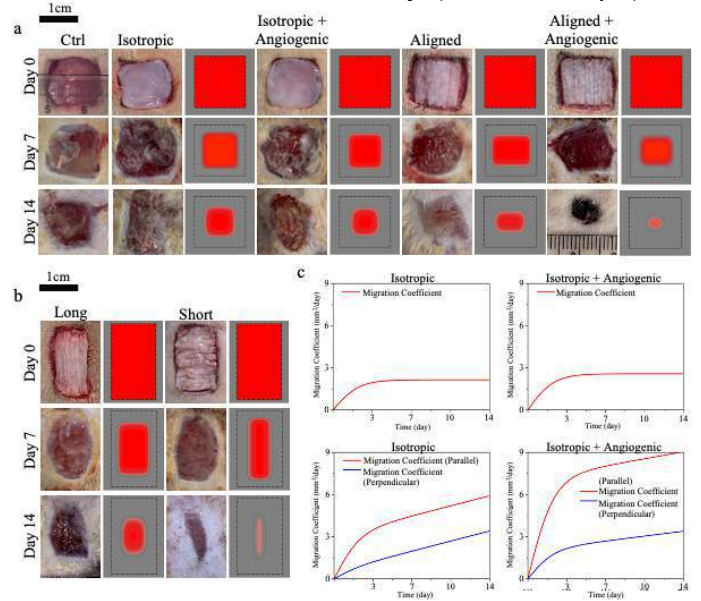

Figure 3: Wound healing model and *in vivo* experiments. a. Square wound. b. Rectangular wound. c. Fitted migration coefficients.

DISCUSSION

Consistent with the results of others, cells migrated faster parallel to fibers [11-12]. Results indicate that this effect can be used to enhance healing on large wounds in diabetic rat models. Consistent with our hypothesis, effects of anisotropy and KLT angiogenic factors were synergistic, with anisotropy leading to an increase in migration coefficient over time, and KLT leading to an increase in migration coefficient immediately following the onset of activation. Results point to a promising technique for enhancing healing of large-scale wounds.

INTRODUCTION

Articulating joints are susceptible to injury and degenerative diseases like osteoarthritis (OA), which afflicts millions of people in the United States [1]. High-throughput testing of disease pathogenesis and new therapeutics is essential to eliminate excessive animal testing and reduce failure in clinical trials of treatment candidates. While there has been recent progress in the development of *in vitro* models, such as tissue-on-chip technology, there is still a need for a reliable miniaturized joint model that can be used to advance new disease treatments.

A critical first step in producing realistic joint models is the recapitulation of tissue-specific cell and extracellular matrix (ECM) behavior. ECM-derived biomaterials can be utilized as they contain essential components that influence cell behavior. In contrast to solubilized ECM, which consists of enzymatically-digested ECM in liquid form [2], particulated ECM preserves both the biochemical and structural micro-architecture of ECM. Tissue particles can be packed into a hydrogel base to achieve a biomaterial with both practical and biomimetic macro-scale properties [3].

The inclusion of ECM microparticles increases viscosity without compromising extrudability, resulting in an ideal biomaterial for 3D bioprinting. Extrusion bioprinting is the most common type of 3D bioprinting due to its versatility and affordability [4], and can produce complex multi-ink structures for various *in vitro* models. The packing density of microparticles and choice of hydrogel base material enables tuning of macro-scale biomaterial properties, such as stiffness. For *in vitro* joint models, the ability to apply physiologically-relevant load is essential in recapitulating joint movement.

In this study, we present hyaluronic acid-based particulated ECM biomaterial inks for both bone and cartilage tissue, with rheological and mechanical characterization. Furthermore, 3D extrusion bioprinting of our ECM inks is demonstrated to produce two proof-of-concept osteochondral *in vitro* models, including applied compression.

METHODS

Bone tissue was sourced from human donors under 35 years old (AlloSource, Centennial CO). Cartilage tissue was sourced from porcine animals within 48 h of slaughter. Tissues were pulverized using a liquid nitrogen cryo-mill and sorted via a micro sieve stack to isolate microparticles 40-100 μm in diameter (Electron Microscopy Sciences, Hatfield PA). Cartilage microparticles were decellularized in 2% sodium dodecyl sulfate (SDS) for 8 h at 37°C, and in 0.1% DNase for 3 h to remove xenogeneic cellular and genetic material. Microparticles were flash frozen in liquid nitrogen, and lyophilized. Biomaterial ink formulations consisted of 10mg/mL hyaluronic acid (HA) (~20% thiolation) packed with either 0.72g/mL bone microparticles or 0.2g/mL cartilage microparticles to achieve equivalent consistency/extrudability. Biomaterial inks were thoroughly mixed between two syringes attached by a custom luer lock connector with cross hairs. HA and particles crosslinked via disulfide bonding [5].

Rheological properties were measured using a Flow Procedure with a steady state flow step setting on a Rheometer (AR-G2, TA Instruments), with 8mm diameter plates in stiff bearing mode and a gap distance of 800 μm . A room temperature shear sweep was performed within 5 mins of mixing, with shear rates from 0.01 to 250 s^{-1} with no normal force, a pre-shear rate of 10 for 10 s, and zero velocity (**Fig 1C**).

Mechanical properties were assessed using unconfined compression testing on a Bose ElectroForce 5500 system. Molded cylindrical biomaterial ink constructs were polymerized for 30 min at 37°C and compressed to a strain of 40% of the initial height (0.1% per second) for quasi-static loading following 0.1 N pre-load. Compressive modulus was calculated by measuring the slope of the linear portion of the stress strain curve, between 30% and 40% strain (**Fig 1D, Fig 1E**).

Biomaterial inks were 3D printed on a multi-nozzle pneumatic extrusion printer with 20 G or 18 G nozzles (BioX, Cell Ink Life Sciences). Bone ink was extruded with 45-65 kPa pressure at a rate of

12 mm/s, and cartilage ink with 60-80 kPa at 12 mm/s (**Fig 2A**). An osteochondral plug scaffold was printed with 50% infill density (**Fig 2B**). Pre-stained particle inks were 3D printed into a molded Sylgard 184 polydimethylsiloxane (PDMS) tissue-on-chip model (**Fig 2C**) and imaged using confocal microscopy (**Fig 2D**). A cartilage ink construct was loaded on the PDMS chip, and the cross section was imaged via confocal microscopy during compression with a micro-actuator. Deformation microscopy was used to compute construct strains using deformed and undeformed images (**Fig 2E**) [6].

RESULTS

We achieved extrudable and particulated ECM biomaterial inks for both bone and cartilage tissue, and demonstrated 3D printability of these inks suitable to create osteochondral *in vitro* models. Rheological measurements indicate shear-thinning behavior of bone and cartilage biomaterial inks (**Fig 1C**). Unconfined compression testing demonstrated a compressive modulus of 741 kPa for the bone ink and 39 kPa for the cartilage ink (**Fig 1D, Fig 1E**).

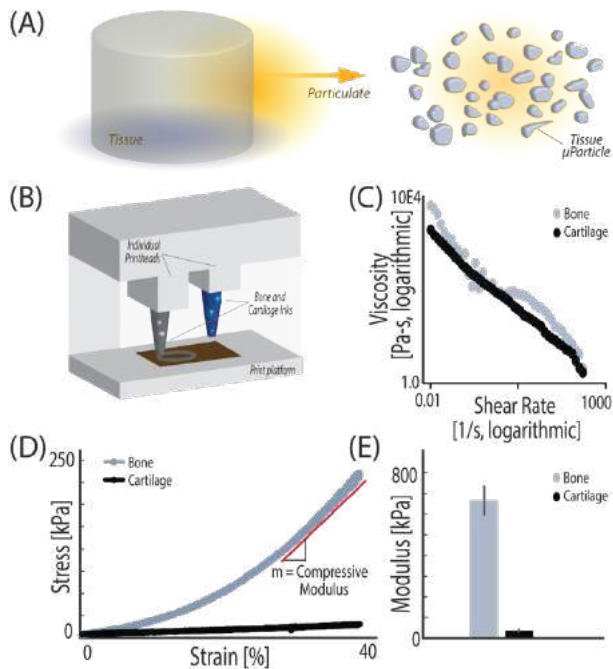

Figure 1: Particulated ECM inks demonstrate shear-thinning and biomimetic mechanical properties. (A) Tissue is cryo-milled into microparticles. (B) Particulated ECM inks can be extrusion 3D bioprinted. (C) Rheological data (n=6) demonstrates shear-thinning behavior. (D) Compressive modulus was calculated from the slope of the linear portion between 30% and 40% strain. (E) Compressive modulus (n=6) for bone and cartilage inks.

Both bone and cartilage inks were easily extruded through pneumatic-based bioprinting (**Fig 2A**). A proof-of-concept osteochondral plug was successfully printed with sequential bone and cartilage inks (**Fig 2B**). Bone and cartilage inks were also 3D printed side-by-side into a proof-of-concept PDMS chip (**Fig 2C**), in which two types of media could flow past the bone versus cartilage ink. The osteochondral chip was imaged using confocal microscopy, revealing a distinct interface between pre-stained bone (DAPI) and cartilage (Ghost Dye) particles (**Fig 2D**). Finally, strain calculated via deformation microscopy showed spatially-dependent mechanical signaling within a compressed cartilage ink construct loaded into a PDMS chip (**Fig 2E**).

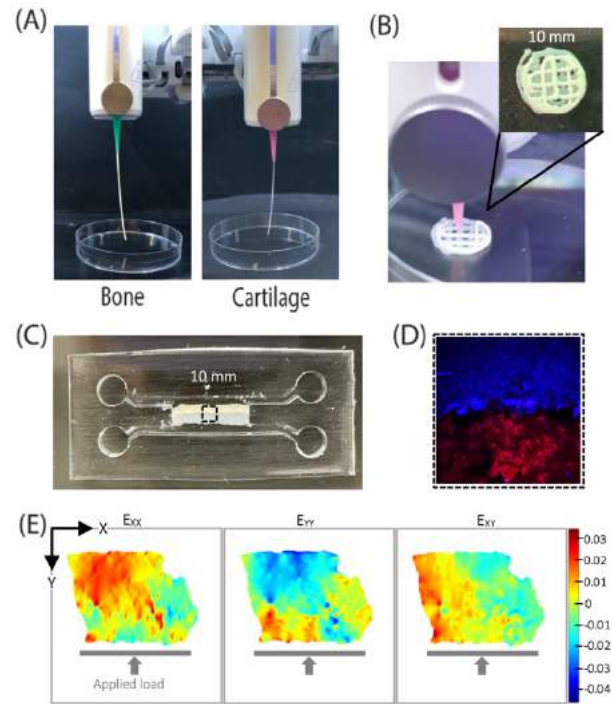

Figure 2: Bone and cartilage inks can be 3D printed to form osteochondral *in vitro* models. (A) Extrusion of bone and cartilage inks. (B) 3D printed osteochondral plug with top layer bone and bottom layer cartilage. (C) Bone (top) and cartilage (bottom) inks printed into PDMS chip. (D) Confocal imaging of tissue-on-chip interface showing bone (top, blue) and cartilage (bottom, red) particles. (E) Deformation microscopy of cross-section of compressed cartilage ink construct.

DISCUSSION

This work provides macro-scale rheological and mechanical characterization and 3D printing demonstrations of novel bone and cartilage particulated ECM biomaterial inks. Previous work showed that as packing density increased in the microparticle cartilage ink, compressive modulus rapidly increased up to 300 kPa [3]. As such, it is expected that this cartilage ink could reach physiologically relevant stiffness under load. Furthermore, we have seen a similar relationship between packing density and compressive modulus of the bone ink (not shown). We have previously shown that cartilage microparticles preserve ECM micro-architecture and biochemical factors, promoting infiltration of chondrocytes and chondrogenic phenotype [3]. Additional studies further support microparticle-guided cell differentiation [7]. Follow-up studies will assess cellular interaction with bone microparticles and explore cellular responses to biomaterial inks. Ultimately, we aim to recapitulate the structure and function of osteochondral tissues to produce realistic *in vitro* joint models.

INTRODUCTION

There are an increasing number of anterior cruciate ligament (ACL) injuries in pediatric athletes compared to adults [1]. While some call for conservative treatment for younger patients, nonoperative treatment leads to knee instability and low return to sports rates [2]. Furthermore, an increased number of meniscal injuries and tears are found with delayed ACL reconstruction even by 6 weeks after surgery [2,3]. These meniscal injuries in the pediatric population could occur at the time of ACL injury or occur over time due to altered joint motion and loading. A previous *ex vivo* study in skeletally mature human cadavers found ACL transection (ACLT) increased joint laxity and force contribution of secondary stabilizers in the knee, such as the medial collateral ligament (MCL)[4]. Previous work in the skeletally immature porcine model also demonstrated similar results in laxity and tissue force changes after ACLT, with the medial meniscus also acting as a stabilizer under injured biomechanics [5]. Long-term degenerative changes, such as radiographic knee osteoarthritis, have also been linked to joint instability and meniscal hypertrophy [6]. However, there is little *in vivo* data detailing long-term degenerative changes in the knee after ACL injury in skeletally immature patients. Therefore, the objective of this study was to evaluate the long-term impact of ACLT on knee function and meniscus structure remodeling in a juvenile porcine model. We hypothesized that joint laxity would increase after ACL injury, along with in altered tissue loading and remodeling of the menisci.

METHODS

Seven female juvenile (3-months) Yorkshire crossbreed pigs underwent a unilateral arthroscopic ACLT and a sham incision on the contralateral joint. All animals were bred at the North Carolina State University Swine Education Unit, and all experimental protocols were approved by the NC State IACUC. Twelve weeks after surgery, hind limbs were imaged using a 3.0-T Siemens MAGNETOM Skyra MRI system (T2 SWI sequence, voxel size 0.5x0.5x0.8mm). Meniscal

measurements were then taken for both medial and lateral menisci from the MRI scans. Specifically, the height and width of the anterior and posterior regions of the meniscus near the attachment sites and the height and width of the central region of the meniscus were recorded. Anterior and posterior heights were recorded in the sagittal plane and the central height and width was recorded in the frontal plane. The animals were euthanized, hindlimbs collected, and stifle (knee) joints stored at -20°C in saline-soaked gauze.

Then, stifle joints were biomechanically tested using a robotic testing system (Kuka, SimVtro) with a universal force-moment sensor. Anterior-posterior loads (80 N) and compressive loads (120 N) were applied at 60° of flexion in force control mode and the kinematic paths were recorded. The kinematic paths were then repeated for the intact joint and after removing the capsule, ACL (or any scar remaining), medial collateral ligament (MCL), lateral collateral ligament (LCL), posterior cruciate ligament (PCL), medial meniscus (MMEN), lateral meniscus (LMEN), medial femoral condyle (MCON), and the lateral femoral condyle (LCON). Each tissue contribution to maximum anterior and compressive loading was determined by the principle of superposition. Joint laxity was recorded as the anterior-posterior tibial translation (APTT) during anterior loading and the anterior tibial translation (ATT) during compressive loading. Differences in APTT and ATT were compared between sham and injured legs using paired t-tests. Multiple paired t-tested were used to detect differences between tissue forces with Holm-Sidak correction. Linear regression analysis was performed to compare interlimb differences in posterior horn height and central width to interlimb differences in axial compressive force in the medial meniscus. Significance was set to $\alpha=0.05$ overall for each analysis.

RESULTS

Total ACL transection led to significant destabilization of the knee joint during applied anterior drawer and axial compression. APTT

(Figure 1A) and ATT (Figure 1B) of the joint increased by approximately 3-fold ($p<0.0001$) and 7-fold ($p<0.0001$) in ACLT joints compared to the sham-operated joints, respectively.

Figure 1: ACL transection (ACLT) led to joint destabilization 12 weeks after injury. (A) Anterior-posterior tibial translation (APTT) under applied AP drawer. (B) Anterior tibial translation (ATT) under applied compression. Bars indicate $p<0.0001$.

In the sham-operated joints, the ACL was the primary stabilizer during anterior loading (Figure 2A). However, in ACLT joints, the ACL resultant force dropped by 99% (adj $p<0.0001$) and the load was distributed across several different tissues. Most strikingly, the capsule anterior force increased by 23 N (adj $p=0.01$) and the medial collateral ligament increased by 57 N (adj $p=0.0002$). Changes in the medial and lateral meniscus were minor (<10 N). Under compressive loading in the sham-operated joint, the compressive forces were largest in the medial and lateral femoral condyles, followed by the medial and lateral menisci (Figure 2B). ACLT joints had drastic shifts in forces during compressive loading, mainly between direct cartilage contact of the femoral condyles on the tibia and the forces transmitted through the menisci. The compressive forces in the medial and lateral menisci increased by 50 N and 22 N in the ACLT joints compared to sham controls (adj $p=0.004$ and adj $p=0.10$, respectively). An opposite shift occurred in the medial and lateral condyles, where the force decreased by 29 N and 45 N (adj $p=0.03$ and adj $p=0.01$, respectively).

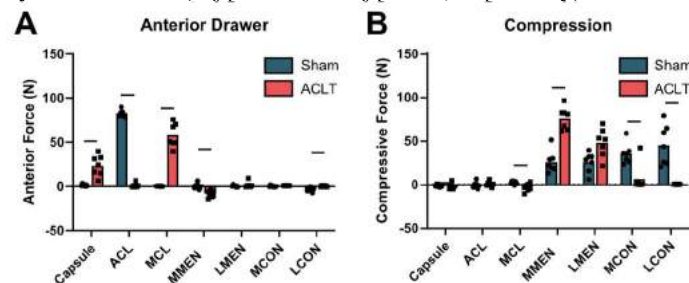

Figure 2: ACL transection (ACLT) impacted the loads carried by tissues under applied joint loading. (A) Anterior force carried by tissues under applied anterior drawer in sham and injured joints. (B) Compressive force carried by the tissues under the applied compression. Bars indicate $p<0.05$ between sham and ACLT.

Meniscus anatomical features were also impacted by ACLT, with a 22% increase in the posterior height in the medial meniscus ($p=0.02$), but not the lateral meniscus ($p=0.79$) (Figure 3A). The medial and lateral central width increased by 14% and 13% in the ACLT joints compared to the sham-operated contralateral joints ($p=0.02$ and $p=0.01$, respectively) (Figure 3B). The interlimb difference in medial meniscus central width was positively associated ($r^2=0.71$; $p=0.02$) with the interlimb difference in axial compressive force carried by the medial meniscus under compressive loading (Figure 3C). However, the change in medial meniscus central width was the only factor that associated with the change in medial meniscus axial compressive force. Changes in medial meniscus posterior height ($p=0.73$) and width ($p=0.80$) did not associate with compressive force changes, despite the statistically significant increases in posterior horn height.

Figure 3: ACL transection (ACLT) led to structural remodeling of the menisci. (A) Posterior height of the medial and lateral menisci. (B) Central width of the medial and lateral menisci. (C) The difference in medial meniscus central width versus the difference in compressive force (relative to sham-operated controls) under compressive loading. Statistical results from the linear regression are shown in the graph corner. Bars indicate $p<0.05$.

DISCUSSION

This study confirmed our hypothesis that ACLT led to a major increase in joint laxity and shift in tissue forces under biomechanical loads as well as an increase in meniscal hypertrophy in the skeletally immature knee joint. The increase in APTT nearly 3-fold between injured joints and sham-operated joints in this study is consistent with previous *ex vivo* findings of an increase (2.7-fold) in APTT in a 6-month pig immediately following ACLT [5]. The shift in tissue function during anterior loading in ACLT joints indicates that the medial collateral ligament acts as the primary stabilizer under an applied anterior load, which is similar to other *ex vivo* findings in human cadavers [4]. While under compressive loads, the medial and lateral menisci become primary stabilizers instead of the cartilage-cartilage contact of the condyles, likely due to the excessive ATT. The meniscal hypertrophy described in this work is similar to meniscal hypertrophy found in an adolescent guinea pig model after ACLT [7]. Meniscal hypertrophy has also been linked to knee osteoarthritis and cartilage degeneration, which is known to be more likely in a patient who has torn their ACL and undergone ACL reconstruction [8]. Therefore, the medial meniscus hypertrophy and shift in compressive forces could be indicative of a higher risk of long-term cartilage degeneration and incidence of post-traumatic osteoarthritis (PTOA). Effect sizes were large between sham and ACLT joints, but larger sample sizes could uncover more subtle changes. Having longer-term data would also prove beneficial for looking at cartilage degeneration and associating early and late degenerative changes. Overall, ACL injury in the skeletally immature joint results in instability, which in turn, causes abnormal meniscus remodeling. Identifying the impact of ACL injury on tissue forces and structural remodeling in growing subjects can lead to a better understanding of secondary tissue injury rates and inform clinical treatments for ACL injuries in young patients.

INTRODUCTION

Glioblastoma (GBM) is the most aggressive, invasive, and lethal form of cancer in the CNS of adults, carrying a median survival of 15 months and a 5-year survival of ~5%. This poor prognosis is due in part to its resistance to standard treatment – surgical resection followed by radiation and oral chemotherapy. Recent work has demonstrated that intratumor heterogeneity plays a critical role in therapy resistance by mediating tumor adaptation through biophysical and microenvironmental cues¹⁻⁴. Within this heterogeneous tumor, GBM can be separated into two distinct regions: a core and a rim. The core is hypercellular and hypoxic while the rim is sparse and permissive to cell invasion. Further, within these two regions are a diverse set of biomolecular and biophysical signals that underlie GBM evolution and therapy resistance. As recent work has focused on the biomolecular changes in these regions, much less attention has been paid towards the biophysical differences, which have been shown to be significant regulators of GBM malignancy. The elucidation of these factors is critical to identify the key biophysical regulators of GBM progression, adaptation, and therapy evasion. In this work, we investigate the mechanical and ultrastructural characteristics of the tumor ECM in patient matched GBM core and rim tissue. We hypothesize that tumor core and rim exhibit unique mechanical and ultrastructural signatures that correlate with patient prognosis.

METHODS

AFM was performed on 50 μm sections of GBM patient-matched tissue in order to quantify their mechanical stiffness. 20

$\mu\text{m} \times 20 \mu\text{m}$ force maps with 16x16 pixel resolution (256 force curves) were generated across three regions of each section. The Hertzian model, with a Poisson's ratio of 0.5, was then applied to determine the elastic modulus of the samples. SEM was used to characterize tissue ultrastructural differences of control and decellularized tissue. Histological quantification methods were employed using ImageJ. Combination treatment with ionic detergent (0.1% SD) and nuclease (DNase I) was utilized for removal of cellular material with adequate retention of the ECM constituents⁵ hyaluronic acid (HA) and tenascin-C, which was confirmed with immunofluorescence (IF) imaging. Chemical fixation with 1% glutaraldehyde and osmium tetroxide and subsequent sputter coating as SEM preparation.

Porosity Index Equation

$$\text{Porosity Index} = \frac{\text{Void Area}}{\text{Total Area}} \quad (1)$$

RESULTS

The AFM analysis of various patient matched samples provided results in the range of expectation for GBM tissue stiffness⁶. Our sample pool included a non-neoplastic, epileptic control and non-GBM gliomas as metrics for the prognostic implications of the study. Additionally, our prognostic metrics for each of these patients show that the overall survival of GBM patient 1723 was 235 days and our neurofibromatosis patient was 1199 days, thus providing an approach to determine mechanical and ultrastructural signatures that may be present in poor prognosis patients. AFM revealed (Figure 1: A/B) that the GBM patient 1723 exhibited a stiff core (384.8 Pa) and a soft rim

(177.8 Pa) while the neurofibromatosis patient showed a surprising opposite trend with the rim being stiffer (core: 553.5 Pa; rim: 679.8 Pa). Porosity analyses showed an intuitive trend with stiffer regions having lower porosity and softer regions having increased porosity (Figure 1: C/D). IF quantification showed that in GBM, there is more hyaluronic acid (HA) in the core when compared to the rim, while tenascin-C is more prominent in the rim. In the neurofibromatosis patient, there is higher HA and tenascin-C content in the rim. These changes suggest a role for HA in stiffening the matrix.

Figure 1: AFM quantification of GBM patient 1723 (A) and Neurofibromatosis patient 1707 (B) core and rim sections alongside a benign non-neoplastic control with porosity quantified. SEM imaging of 1723 (C) and 1707 (D) core and rim sections.

Figure 2: IF imaging of GBM patient 1723 (A) and Neurofibromatosis patient 1707 (B) for the common ECM proteins, hyaluronic acid and tenascin-C with quantification of mean intensity per unit area.

DISCUSSION

In this work, we have provided evidence of a unique biophysical profile in GBM core and rim. This, when taken with the rest of our patient cohort, has demonstrated implications for prognostic outcomes. The mechanical stiffness of the extracellular matrix in these samples have indicated that a hypoxic, hypercellular, necrotic core of greater stiffness is providing a pro-malignant environment that may promote

phenotypic shifts that lead to increased invasiveness and therapy resistance. This, coupled with more compliant rim mechanics, allows for enhanced migration potential and thus seeding of new tumors elsewhere, leading to the poor outcomes of these GBM patients. Regarding the improved survival for the neurofibromatosis patient, we speculate that this is due, in part, to the reduced permissiveness of its rim, limiting the migration potential invasive cells and preventing them from leaving the tumor as effectively. Our results represent the first study of GBM mechanical heterogeneity with patient match tissue to our knowledge and provide a novel connection for tumor biophysics and prognosis.

Currently, through our collaboration with our university hospital, we have acquired 30 patient samples, 9 of which have succumbed to disease, and plan to evaluate additional samples to strengthen the prognostic connections of our study. With a more cohesive look at the progression of this disease from a mechanical standpoint, new therapeutic interventions may be unveiled. From our data, it is suggested that one method may be to soften the core and explore potentially reduced mesenchymal phenotypic changes. Moreover, due to the lowered rim porosity shown here for GBM, allowing for avenues of escape for infiltrating cells, another treatment option may be to target matrix degrading processes in the rim region. We recognize our sample size is expanding, and due to the dismal prognosis of GBM, we expect it to increase in the coming months and provide further evidence for this mechanical connection to tumor mechanics and outcomes.

IN SILICO INVESTIGATION ON STROKE RISKS FROM LEFT VENTRICULAR ASSIST DEVICE

INTRODUCTION

Left ventricular assist device (LVAD) is a key treatment modality for advanced heart failure (HF) patients. Circulation support using LVAD can improve overall quality of life and reduce mortality for HF patients. However, post implant complications such as ischemic stroke, pump thrombosis, and aortic insufficiency adversely impact the efficacy of LVAD treatment. Prior studies [1] report post-LVAD implant stroke occurrence chances in the range of 10-40%. There can be numerous factors contributing to this complication, originating from altered state of hemodynamics and coagulation due to attachment of LVAD [2]. Prior works have studied LVAD-driven hemodynamics with varying graft angles, and estimated thrombotic risks [3]. In a previous work, we have reported hemodynamics as function of LVAD outflow graft angles and flow pulsation [4]. However, a lack of understanding about factors involving actual embolus transport to the brain by the flow driven by an LVAD hinders comprehensible understanding of post-implant stroke risks in these patients. To address this challenge, here we present an in silico approach to generate a stroke risk descriptor based on computational thromboembolus transport analysis. We use this approach to investigate stroke risk variation with LVAD outflow graft surgical anastomosis.

METHODS

Image-Based modeling of anatomy: A patient-specific vascular network comprising the aortic arch and branch arteries extending up to the iliofemoral arteries was obtained from computed tomography (CT) images [4, 5]. An image-based geometric modeling procedure was devised for virtual surgical placement of an LVAD outflow graft. The angle between the final pathline for the graft, and the pathline for aorta, were varied across a set of 9 different parametric graft anastomoses, referred to as: (1) perpendicular to the aorta (*Inc90*); (2) 45° towards the aortic valve (*Inc45*); and (3) 45° towards the aortic arch (*Inc135*) together with graft anastomosis angled: (1) 45° right of the heart (*AziNeg45*); (2) perpendicular to the coronal plane (*Azi0*); and (3) 45° left of the heart (*Azi45*). These 9 configurations are noted in Figure 1.

Figure 1: Generating a virtual family of LVADs [4]

Hemodynamics simulation: Hemodynamics across the 9 LVAD outflow graft models was simulated using a stabilized finite element method for incompressible Navier-Stokes equations using SimVascular. Blood was assumed to be a Newtonian fluid with a bulk density of 1.06 g/cc, and viscosity of 4.0 cP. Three-element Windkessel boundary conditions at each outlet of the computational domain were computed based on assumed target flow distribution across each outlet obtained from existing literature [4, 6]. Flow was driven by assigning a uniform (over time) flow-rate of 4.9 l/min at the LVAD outflow graft inlet face, mapped onto a parabolic profile across the face.

Embolus transport: Embolus transport was modeled using a custom modified version of the Maxey-Riley equation [7], leading to a one-way coupled fluid-particle interaction model. The emboli were assumed to be spherical particles, with diameter 1.0 mm. Embolus interactions with vessel wall were resolved using a custom algorithm based on signed distance fields, using a contact restitution of 0.75. The resulting simulations were used to obtain the distribution of emboli entering the aortic arch from the LVAD outflow graft. Two sets of embolus distribution fraction were computed: (a) distribution towards the cervical vessels leading in to the brain; and (b) accumulation at the aortic root near the dysfunctional aortic valve.

RESULTS

Figure 2: Fraction of embolic particles moving through the LVAD to the cervical vessels for each variation.

Figure 3: Fraction of embolic particle accumulation near aortic root for each variation.

We present data from $\approx 5,000$ different thromboembolism scenarios for each of the 9 LVAD anastomosis models as described earlier. For each model, the distribution fraction for 1 mm thromboemboli reaching the cervical vessels leading towards the brain are presented in Figure 2. From the data, we observe that LVAD graft anastomosis angle towards/away from the valve has a notable influence on embolus transport towards the brain, with graft angle 45° towards aortic valve transporting a higher percentage of emboli towards the cervical vessels, followed by 90° and 135° . Moreover, the anastomosis angle right/left of the heart on the coronal plane (*Azi* angles) is also observed to have a smaller but notable influence on embolus transport towards the brain. This anastomosis angle has been less commonly investigated in prior studies. Figure 3 presents the fraction of emboli accumulating below the outflow graft anastomosis site at the aortic root for each of the 9 LVAD graft models considered. The results indicate that the fraction accumulation at the root is significantly lower compared to the distribution to the cervical vessels. However, we note that out of the thromboemboli reaching the cervical vessels, a fraction of these actually make it further to the cerebral arteries. When compared accordingly, the accumulation of emboli at the aortic root as shown in Figure 3 is a significant number. We further observe that unlike in Figure 2, the extent of thromboembolus accumulation increases with increasing values of *Inc* angles, with the highest accumulation being for *Inc135*. These distributions are further illustrated by comparing the embolic particle ensemble transport against the flow patterns generated by the LVAD outflow graft jet impingement against the aortic wall [4]. In Figure 4, we present two time instances which show the initial and final embolus locations in the LVAD models with the three *Inc* and 45° right of the heart (*AziNeg45*). The higher velocity profile of model *Inc45* in the aortic root region pushes the particles towards the cervical region whereas the development of flow stasis in the aortic root for *Inc90* and *Inc135* causes accumulation of particles near the aortic root.

Figure 4: Snapshots of initial and final particle trajectory and velocity profiles for LVAD models with the three inclination angles and *AziNeg45*.

DISCUSSION

Here we have characterized thromboembolus dynamics in the aorta with an attached LVAD outflow graft, towards developing an in silico stroke descriptor. The jet impingement from the LVAD graft at different inclination angle informs aortic hemodynamics, and subsequent embolus transport and stroke risk. The minimum potential for embolic ischemic stroke is when the LVAD attachment is at an angle *Inc135Azi0*, and maximum at an angle *Inc45AziNeg45*. Transport of emboli entering from the LVAD outflow graft towards the cervical vessels enhances stroke risk. Additionally, the development of a stasis region for higher inclination angles can cause embolus accumulation in the aortic root. Due to intermittent opening of aortic valve (not considered here), these accumulated particles can reach the brain causing stroke. Prior works have reported that stasis in the aortic root region is prone to thrombogenicity, leading subsequently to stroke. Our work presents initial data showing a second mechanism by which the aortic root region influences stroke - embolus accumulation originating from LVAD flow. This can lead to significant advancements in accurate pre-surgical assessment of stroke risks as function of LVAD anastomosis. One limiting factor is the small number of cases considered, and more patient/anastomosis cases need to be considered for further statistical analysis and hypothesis testing

INTRODUCTION

Osteoarthritis (OA) is a degenerative joint condition commonly found in the knee joint that is triggered by events (e.g. mechanical insult) that lead to a cascade of cartilage degradation. OA is difficult to treat with current biomaterials and eventually leads to total joint arthroplasty. The specific composition of cartilage layers – primarily comprised of type II collagen, proteoglycans, and water – enables the tissue to provide excellent joint lubrication and facilitate load transmission during normal movement^[1]. The loss of cartilage due to disease or overuse leads to an inability for the remaining tissue to lubricate joints properly when exposed to mechanical loading. The lack of blood flow, nano-scale pore size, and the inability of the joint to heal on its own make articular cartilage a important example of the need for native structure to provide proper function in engineered scaffolds.

To treat cartilage defects, a variety of interventions exist, but each have limitations and drawbacks, and successful cartilage regeneration remains an unmet need in medicine. Microfracture is one surgical treatment for cartilage defects, and involves creating small fractures in the underlying subchondral bone to access progenitor cells in the marrow and fill the defect with a blood clot leading to a fibrocartilaginous repair^[2]. Allografts are a gold-standard treatment for cartilage repair^[3,4], but are unfortunately highly limited on the availability of donor tissue.

To address the donor availability limitations, we previously studied the use of full-thickness acellular porcine grafts in an *in vivo* cartilage defect model, and found that the implants suffered from poor recellularization^[5]. To improve integrative cartilage repair, we developed a new granulated extracellular matrix-based biomaterial where acellular tissue is first ground into a powder, and then combined with a unique chemistry to enable crosslinking at body temperature. The polymerized scaffold contains highly-packed particles near or

exceeding a percolation threshold, where the particle network dictates the modulus under compression, approaching native tissue mechanics^[6]. Here, we adapted the technology into a syringe delivery device to evaluate efficacy *in vivo*. Our device – *NatruLage* – is ‘flowable’ to deliver densely-packed ECM tissue particles, which enables forming and shaping after delivery before a temperature-induced crosslinking via thiol-functionalized hyaluronic acid. Here, we show proof-of-concept efficacy in a large animal (goat) model of a critical-sized cartilage defect, compared to microfracture, at 12 months post-surgery. The work presented here uses extensive cartilage and bone structural- and cell-level analyses to evaluate repair functionality, efficacy, and integration.

Figure 1: *NatruLage* (shown on the right) is applied to one knee in the surgical suite after mixing. The contralateral limb is left untreated as microfracture control (shown on the left).

METHODS

Decellularized Tissue Particles: Porcine tissue was sourced from a local butcher within 48 hours of slaughter. The articular cartilage was

collected from the knee with a scalpel, taking care not to include calcified tissue. Tissue was pulverized in a liquid nitrogen freezer mill (Qiagen), decellularized in 2% SDS for 8 hours at 37°C plus 0.1% DNase for 3 hours, rinsed, lyophilized, and size sorted to 100-250 μ m using a vibrational sieve. **Thiolating hyaluronic acid:** Glucuronate carboxyl groups on hyaluronic acid (HA) were replaced with thiol groups following previously established protocols [7]. Briefly, HA (MW 100 kDa) was dissolved at 10 mg/ml in degassed milliQ water. DTP was added to the solution, the pH was lowered to 4.5 and then EDC was added. The pH was maintained between 4.5-5 for 50 minutes. Next, DTT was added, and the pH was raised above 8.5 to stir overnight. After 24 hours, the pH of the solution was lowered and the solution was dialyzed (10 kDa membrane cutoff, Spectrum Labs) in an HCl solution +/- 100 mM sodium chloride for 12 changes in a sealed chamber with continuous nitrogen gas. HA thiolation was 20% (thiolated mmols/unthiolated mmols). **NatruLage Formation:** Lyophilized HA was dissolved in sterile DPBS (Hyclone) to make a 20 mg/ml HA solution, neutralized and loaded into a 1 mL syringe, then sealed. In a separate syringe, prepared tissue particles were mixed with DPBS at a ratio of 0.4 g/ml and sealed. **Surgical Protocol:** We created a critical-sized chondral defect in the load-bearing region of the medial condyle (6 mm diameter, 2.5 mm deep) of 11 goats. After drilling 4 holes in the bone marrow, syringes were attached to each other using a custom luer lock connector and mixed back and forth ~30 times until the material ran smoothly. The final mixture had an HA concentration of 10 mg/ml and particle concentration of 0.2 g/ml. The *NatruLage* material was injected into the defect region in one knee, smoothed to match the cartilage surface, and the joint was immediately closed (Figure 1). In the contralateral knee, the joint was closed following drilling of the defect. 12 months later, the goats were sacrificed for analysis.

Joints were opened and 10 mm plugs extracted (including repair tissue with surrounding native tissue). Matrix deposition, structural repair efficacy, integration and cellular migration is assessed using histology where half of the extracted tissue was fixed and embedded in PMMA. Sections were stained with Goldner's trichrome and Toluidine Blue (Indiana University).

A Keysight 5500 atomic force microscopy (AFM) system was used to evaluate the surface roughness, friction coefficient, compressive modulus, and to map the topography of surface structures in repair and native cartilage. All measurements were taken on the articular surface. A cantilever with known geometry was used (silicon nitride pyramidal tip, 20 nm radius), and the cantilever stiffness was calibrated to 0.12 N/m. High resolution contact mode scan was collected at 0.5 ln/s with an applied normal force of 20 nN to generate detailed topography, raw deflection, and lateral voltage signals of surface features in each region. From the averaged topography image of each region, surface roughness was obtained using Gwyddion software. Finally, independent force-spectroscopy curves were acquired with a setpoint force of 12.6 nN and a speed of 5 μ m/s. Force-displacement curves were fit to the Hertzian linear elastic model.

RESULTS

Structural analyses using histological staining indicates full defect filling in joints treated with *NatruLage*, compared to microfracture (Figure 2). Additionally, we observe lateral (structural) integration between the native tissue and the repair material in both bone and cartilage layers. A fibrous integration zone that is often observed at the boundary between a repair (graft) tissue and surrounding cartilage was not observed. Furthermore, cells migrated within and populated throughout the entire *NatruLage* repair material by 12 months. Initial macroscale evaluation and ICRS II scoring parameters indicate evidence of improved tissue organization and defect fill in the

NatruLage repair (n=5), and additional analysis is ongoing to evaluate repair efficacy of *NatruLage* compared to microfracture.

We measured lower adhesion in the *NatruLage* repair, as compared to microfracture and native tissue (n=5 in each treatment). Surface roughness was increased between native tissue and both repair groups, but the *NatruLage* surface roughness was slightly lower compared to microfracture. Using AFM, we measure frictional values similar to the surrounding native cartilage in the *NatruLage* repaired joints (n=5 of each treatment).

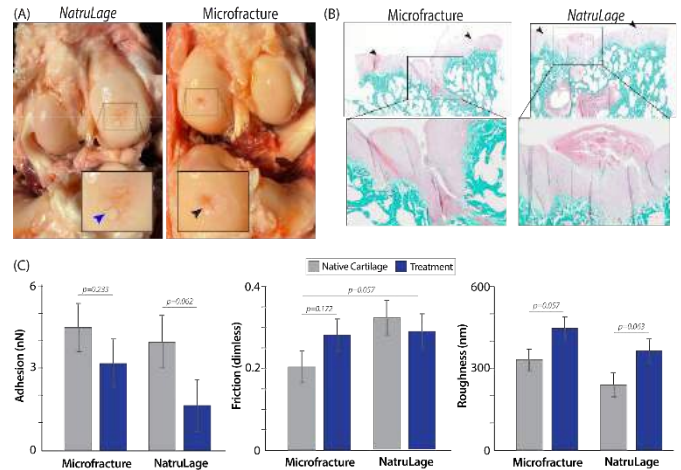

Figure 2: Acellular ECM powder contributes to improved structural integration and surface mechanics. (A) Repair and surrounding tissue is removed for analysis after 12 months. (B) Histological repair shows lateral integration (arrows indicate repair margins) and structural repair in each treatment. (C) *NatruLage* had lower adhesion than native or microfracture tissue, similar frictional profile to the surrounding native tissue, and slightly increased surface roughness.

DISCUSSION

In this work, we evaluated a new ECM particle-based articular cartilage repair material by applying the material to a critical-sized defect in the medial condyle of goats, and evaluating the repair efficacy 12 months later, compared to native tissue and the contralateral microfracture repair. We demonstrate that *NatruLage* is able to adhere to and integrate with native tissue without the use of an adhesive such as fibrin glue. While analysis and evaluation is ongoing, in a subset of 5 animals, we observe that the material enables cell migration throughout the repair, promotes cartilage tissue organization, facilitates smooth lateral integration in both bone and cartilage zones, and demonstrates evidence of improved surface functionality (friction and adhesion) from the microfracture repair. *NatruLage* promotes integration to surrounding tissue, cell migration into the construct, and previous *in vitro* work has shown that the material promotes tissue-specific cell phenotypes.

COMPARING FIVE METHODS TO IDENTIFY FRACTURE TOUGHNESS OF SOFT TISSUES

Matthew J. Lohr (1), Manuel K. Rausch (1,2,3)

INTRODUCTION

Modeling the behavior of soft tissues is challenging in general. Even more challenging is modeling the *fracture* behavior of soft tissues, as the field of soft tissue fracture is still evolving and includes obstacles that exceed the capabilities of linear fracture theory. There are some methods available to quantify the fracture toughness of materials, which is a measure of a material's resistance to fracture; however, there is no agreed-upon method that is ideal for quantifying this measure for soft tissues. The objective of our current work is to compare five methods of extracting fracture toughness from mode-I fracture experimental data. First, we will use an energetic approach (E1) that goes all the way back to Rivlin [1]. Second, we will use a modified version of this approach that supplements Rivlin's method with finite element (FE) simulations in Abaqus (E2). Third, we will calculate the J-integral that, in this context, is equivalent to fracture toughness, also from FE simulations in Abaqus (J1) [2]. Fourth, we will calculate the J-integral directly from experimental data collected via digital image correlation (DIC) images of mode-I fracture experiments (J2) [3]. Lastly, we will use a FE approach using a cohesive zone (CZ) in Abaqus [4].

METHODS

To collect the data needed to calculate the fracture toughness of blood clot, we performed pure shear and mode-I fracture tests on blood clot samples. An illustration of pure shear and mode-I loading is shown in Figure 1. We collected force-displacement data from both samples and identified the critical displacement (u^*) at which crack propagation began for the mode-I samples. The energetic approach (E1) we use comes from [1], viz.

$$G_c = W(u^*)H, \quad (1)$$

where G_c is the sample's fracture toughness, W is the strain energy density for a pure shear sample of blood clot at the critical displacement u^* , and H is the height of the sample. For this method, we averaged nine

sets of pure shear force-displacement data. We calculated the strain energy density of this averaged data set using the u^* for each mode-I sample to calculate G_c for each mode-I sample.

Figure 1: (A) Undeformed and deformed configurations for pure shear loading of blood clot. (B) Undeformed and deformed configurations for mode-I loading of blood clot.

An alternative approach to this energetic method (E2) is to create pure shear data using sample-specific material parameters to create sets of force-displacement data that are more representative of a specific mode-I sample, rather than using averaged data from pure shear tests of other clots. To this end, we performed an inverse FE analysis to fit hyperelastic material parameters to each mode-I clot sample in its elastic regime, which we assume to be 90% of its critical displacement. Specifically, we used a one-term Ogden model, which we have found

to be suitable for blood clot [5]. The methodology for identifying Ogden parameters for blood clot is given in [6]. After identifying the Ogden parameters, we created FE models in Abaqus of the pure shear experiment with sample-specific Ogden parameters for each mode-I experiment. We then calculated W from the force-displacement data and calculated G_c for each sample using Equation (1). Figure 2A illustrates our approaches E1/E2 and shows exemplary force-displacement data as used to calculate G_c .

For methods (J1 and J2), we computed the J-integral as a path-independent contour integral defined as

$$\int_{\Gamma} (W dy - \mathbf{t} \frac{\partial \mathbf{u}}{\partial x} ds), \quad (2)$$

where \mathbf{t} is the traction vector, $\frac{\partial \mathbf{u}}{\partial x}$ is the spatial derivative of the displacement vector with respect to the x-direction, and ds is the differential arc length of the contour. To calculate the J-integral (J1) using Abaqus's built-in function, we created a 2D FE mesh of the mode-I experiment with a highly refined region ahead of the crack tip to capture the nonlinear deformations of the clot. This allowed us to perform contour integration along multiple paths to calculate G_c and ensure the J-integral was path independent. Illustrated in Figure 2C is a FE mesh with a stress field typical of a mode-I sample as well as multiple J-integral contours. We also calculate the J-integral directly from DIC data fully forgoing the use of FE simulations (J2). Here again, we computed the J-Integral along multiple contours, see Figure 2D. Finally, for the CZ approach (CZ), we used the same geometry as in the Abaqus J-integral approach, but we modified the mesh to contain a single layer of cohesive elements along the crack path as seen in Figure 2B. To identify parameters of the bilinear traction-separation law for the cohesive elements, we ran forward simulations of the CZ model and minimized the error between the force-displacement curve and critical displacement of the experiment and simulation using a least squares approach in MATLAB. For all methods, we used plane stress and incompressibility assumptions and sample-specific Ogden parameters previously identified in our inverse analysis. [6].

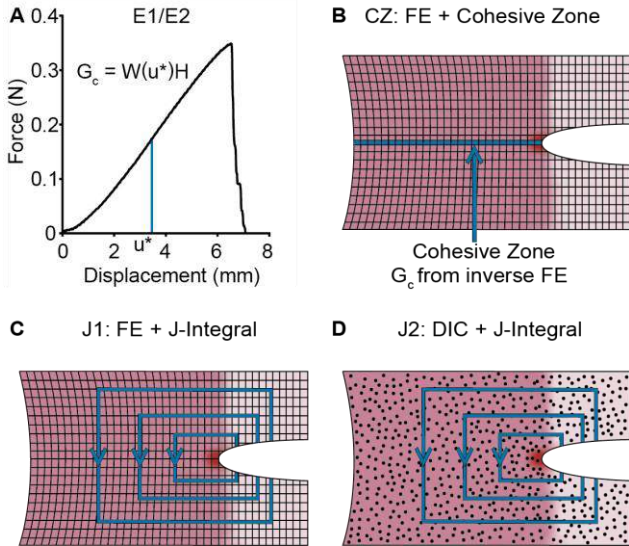

Figure 2: Illustrations of our five methods. (A) E1/E2: A exemplary set of force-displacement data and critical displacement (u^*) used in calculating G_c for a mode-I sample. (B) CZ: Illustration of a FE cohesive zone mesh and a depiction of a stress field typical of mode-I samples, with a stress concentration located at the crack tip. (C) J1: Illustration of a FE mesh and contours used in calculating the J-integral in Abaqus. (D) J2: Illustration of a speckled sample used in DIC, along with J-integral contours.

RESULTS

Figure 3 shows force-displacement data for three pure shear and mode-I samples, along with DIC images of stress fields corresponding to the black circles on the force-displacement plots. Figure 4 shows the calculated G_c for each method. The CZ method, energetic approaches, (E1) and (E2), and Abaqus J-integral (J1) give similar results for G_c , unlike the DIC J-integral (J2).

DISCUSSION

There is no gold standard in measuring G_c for soft tissues, but the fact that four of the five methods give values in similar ranges is promising. A limitation of the current work is that many assumptions went into building the models used, namely the plane stress assumption and the use of 2D models. Future studies should explore the discrepancies between methods and identify a method that is consistent across various fracture experiments for blood clot and other soft tissues.

DYNAMIC RESPONSE CHARACTERIZATION OF SHEEP LYMPHATIC PUMPING DURING GROWTH AND REMODELING

Young Jae Ryu (1), Sophia Mavris (2), Zhanna Nepiyushchikh (2), Rudolph L. Gleason, PhD (1,2), J. Brandon Dixon, PhD (1,2),

INTRODUCTION

The lymphatic system provides vital physiologic functions by maintaining fluid and protein homeostasis through a network of conduits, actively transporting interstitial fluid from tissues and organs back to the venous system^{1,2}. Interstitial fluid is collected and transported by collecting lymphatics vessels, which contract to drive lymph through one-way valves embedded in the channel¹. Lymphatic dysfunction results in excessive and debilitating fluid build-up in the extremities, known as lymphedema². Lymphedema that results from acute damage to the lymphatic system is deemed secondary lymphedema (SL) and affects 1 in 1000 Americans². SL puts patients at risk of extenuating sequelae including cardiovascular diseases if left untreated or undertreated.

Treatment of SL is informed by our limited understanding of basic structure-function relationships that govern lymphatic physiology. Our group and others have demonstrated remarkable insights to features (i.e., contractile dynamics and passive vessel stiffness) that influence lymphatic pumping across vessel networks^{3,4}. However, there is less data regarding growth and remodeling (G&R) of the lymphatic vasculature in development, growth, wound healing, and disease. These adaptation processes are strongly implicated in the delayed onset of lymphedema after cancer treatment⁵.

In this study, we employed a large-animal experimental model relevant to human physiology to encapsulate the growth and remodeling of lymphatic vasculature in an injury. In humans, gravity is the primary mechanical load that the lymphatic system must overcome⁵. Such load is absent in small animal model. The study of lymphatic remodeling in large animals is an essential step to translate small-animal findings to species more influenced by gravitational effects. We implemented our novel ligation model on sheep subjects where the influence of gravitational loading is greater especially in the hind limbs. The aim of this study is to validate a model that captures the dynamic response to growth and remodeling of lymphatic networks post-acute injury.

METHODS

12 sheep subjects were randomly assigned to three groups with separate termination times, defined as two, four, and eight weeks (n=4 for each group) post-surgery. Prior to the surgical procedure, each sheep underwent initial near infrared (NIR) functional lymphatic imaging of lymphatic vessels in both hind limbs. After imaging, ligation of the collecting lymphatic vessel was performed in a randomly selected hind limb. The ligation surgery was performed approximately 5cm above the hock between the proximal and distal aspects of the limb where a vein is located. During the surgery, one of the two parallel lymphatic vessels was transitively occluded with an ~1cm long excision of the vein, while the other hind limb received a sham surgery with no excision. The limb that received ligation surgery is hereafter termed the remodeled leg, while the leg with the sham operation is the control. Follow-up NIR functional imaging was conducted on each sheep immediately prior to takedown at the assigned group endpoint.

During each imaging session, an NIR lymphatic tracer (IRPEG40), a fluorophore dye conjugation developed in manner similar to a previously described method⁵, suspended in 0.5ml of sterile saline was injected over the course of 10 seconds into the lateral aspect of the mid hind limb centered 10cm proximal to the hock. A second injection of the same dose of IRPEG40 was given in the dorsal aspect of the hind limb 5cm distal to the hock. A 300 mW 785nm laser diode (Thorlabs) provided excitation light to the hind limb about 10cm above the surgical site. A Pixis 1024B back-illuminated charge coupled device camera (Princeton Instruments) with bandpass filter was positioned over the surgical site to capture fluorescence emission from the dye transported by the lymphatics from the site of injection. NIR images of dynamic fluorescence transport were captured at a rate of one frame per second for five minutes.

Two distinct metrics of lymphatic function were evaluated from the images using our previously developed method⁶: packet frequency (PF) and packet transport (PT). PF was evaluated by tracking the

average time between fluorescence peaks within a region of interest traced over lymphatic vessels during imaging. PF correlates to frequency of lymphatic contraction. PT was calculated by integrating the average intensity from the start to end of each fluorescence peak. PT denotes transport by intrinsic contraction and is given in relative peak fluorescence units (RFUs).

The significance of differences between control and remodeled limbs was determined using the paired t test for each time point with $P < 0.05$ indicating statistical significance. Additionally, separate paired t tests were conducted to compare pre-surgery and takedown values from the two-, four-, and eight-weeks groups.

RESULTS

At two weeks post-surgery, PF significantly increased in remodeled limbs relative to pre-surgery values and PT significantly decreased in remodeled limbs relative to control limbs. Mean PF increased from 1.657 min^{-1} to 2.899 min^{-1} (Figure 1a). Mean PT in the control limb was 42248 RFUs whereas the mean packet transport in the remodeled limb was 8371 RFUs (Figure 2a). It is important to note that three sheep data was collected due to unquantifiable PT measurements for one sheep trial in the two-weeks cohort. No further statistical significance was found in the two-weeks group. At four weeks post-surgery, no significant differences were observed either between control and remodeled limbs or between pre-surgery and takedown values. The four-week group demonstrated high variability in PF, packet amplitude, and PT. The eight-week group saw significant increase in mean PF from a pre-surgery value of 1.929 min^{-1} to 3.142 min^{-1} (Figure 1c). High variability of the packet amplitude was noted throughout the entire scope of the experiment, limiting the statistical significance of results.

DISCUSSION

In the two-weeks cohort, the increase in PF in conjunction with a significant decrease in PT demonstrates that lymphatic vessels are contracting more frequently but with less efficiency. Reduced PT is indicative of less fluorescent tracer traveling through the lymphatic vessel, which strongly suggests a compensatory response to the injury. Post-injury, lymphatic vessels sustain a higher load. Increased contractile frequency is expected because increased loads have previously been shown to increase frequency³. While a decrease in PT was observed, the exact mechanism remains uncertain; we hypothesize that it may be driven by a decrease in ejection fraction and lymphatic pumping efficiency.

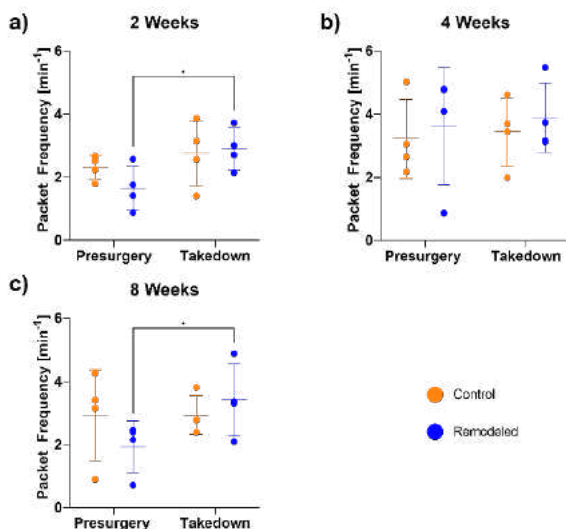

Figure 1: Packet frequency plots comparing the control and remodeled legs over three termination times

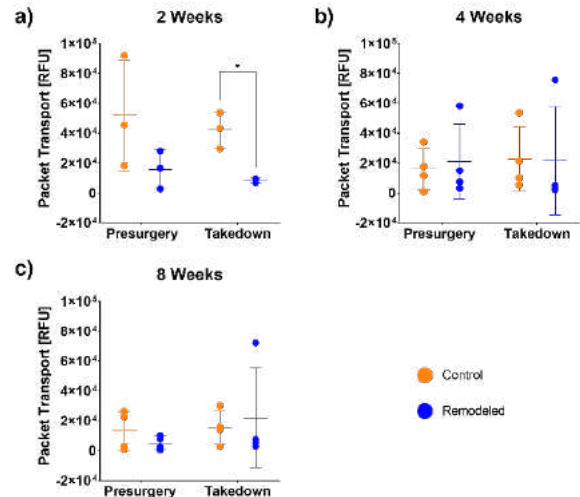

Figure 2: Packet transport plots comparing the control and remodeled legs over three termination times

After sustaining an injury, the lymphatic system must compensate for the barrier to lymph flow to the veins. In this study, we observe lymphatic pump dynamic changes to show that unique physical adaptation processes occur post-trauma. As the load on the lymphatic vessel increases and a barrier to lymphatic flow is in place, the rate of lymphatic pumping increases to maintain fluid balance. An increase in contractile frequency in injured leg at eight weeks post-surgery may suggest longer-term contractile response to the altered physiology.

Functional response to injury is important in maintaining fluid homeostasis, and thus the compensatory mechanisms of growth and remodeling are critical. While our experiment demonstrates that there exists a unique response to injury to compensate for altered lymphatic loads, further study is required to ascribe volumetric insights from changes in contractility. Nevertheless, a comprehensive study of lymphatic contractility through NIR imaging is indispensable tool to study growth and remodeling.

INTRODUCTION

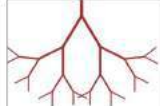

Pulmonary arterial hypertension (PAH) is a complex disease associated with a chronically elevated pulmonary arterial pressure. The onset and early progression of PAH can be traced to changes in the morphometry and structure of the distal vasculature. Coupling hemodynamics with vessel wall mechanics is crucial for understanding pathology at distal vasculature to study PAH. Accordingly, the goal of this study is to provide a multiscale modeling framework that embeds the essential features of arterial mechanics coupled with the PAH hemodynamics within an arterial network characterized by an extension of Murray's law. This framework will be used to establish the homeostatic baseline characteristics of a pulmonary arterial tree in a normotensive and hypertensive case. An iterative homeostatic optimization, which integrates a metabolic cost function minimization, the stress equilibrium, and hemodynamics, is performed. The results are compared with diverse literature data on morphometry, structure, and hemodynamics of pulmonary arteries for normotensive and hypertensive cases. The developed framework demonstrates a potential for advanced parametric studies and future pathophysiological modelling of PAH.

METHODS

The arterial network is assumed to be symmetric in the radial direction with constant mass fractions of the wall constituents. The two cases studied are the normotensive arterial network and hypertensive arterial network. A slow timescale is used to formulate the long-term vascular adaptations and homeostatic maintenance, while a fast timescale is used to formulate the hemodynamics over a cardiac cycle [1]. The slow-time hemodynamics in the arterial tree is computed using Poiseuille flow for each vessel, the flow conservation and pressure continuity for each bifurcation, and boundary conditions at the tree inlet and outlets. These two timescales are then coupled to formulate fluid-

solid growth (FSG) governing equations. The fluid solid interaction solution for one vessel is then extended for the entire geometry to solve for hemodynamics of the open arterial network with the given inlet and outlet boundary conditions. We estimate the baseline homeostatic optimization characteristics by using an extension of Murray's law for an individual normotensive vessel. The total metabolic energy consumption is optimized for the entire arterial network, while mean hemodynamics variables are computed by iteratively updating the geometries from the metabolic optimization. For the hypertensive case, then the cost optimization function (Eq. 1) is modified by incorporating data of PAH arterial thickness and clinically measured inlet hemodynamics. The effect of altering the metabolic cost function on hemodynamic response is studied and compared to normotensive case.

Table 1: Summary of the two cases of the arterial tree framework.

Parameter	Case 1	Case 2
Geometry	Symmetric Arterial Tree Inlet BC: Mean Flow  Outlet BC: Terminal Pressure	Symmetric Arterial Tree Inlet BC: Mean Flow  Outlet BC: Terminal Pressure
Mass Fraction of the Wall Constituents (Elastin, Smooth Muscle Cells and Collagen)	Constant across the Arterial Tree	Constant across the Arterial Tree
Tension	Normotensive	Hypertensive

$$C(R; \bar{p}^s, q^s) = \vartheta^{blood} \pi R^2 + \frac{8\mu q^s}{\rho_f \tau_{iud} \pi R^4} + 2\pi(1 - \phi_f) \bar{p}^s R^2 \frac{\sum_i \vartheta_i v_i^i}{\sum_i v_i \sigma_\theta^i} \quad (1)$$

RESULTS

Hemodynamics and morphometric results of the two cases are presented below for 19 bifurcations, considered here as generations starting at the third bifurcation from the main pulmonary artery. Input flow & terminal pressure are compared for normotensive and hypertensive arterial network (Fig. 1 & 2). Diameter distribution compared to reported data of large vessels (Fig. 3 & 4) in normotensive and PAH case [2,3,4].

Figure 1: Input flow across arterial tree for the two cases.

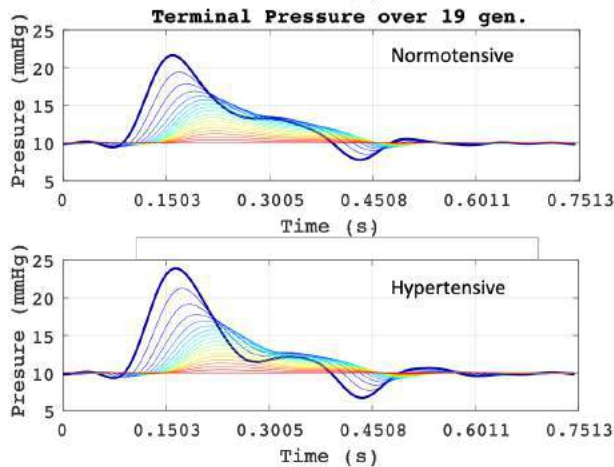

Figure 2: Terminal pressure across arterial tree for the two cases.

Figure 3: Normotensive homeostatic optimization diameter results plotted against generation number.

Figure 4: Hypertensive homeostatic optimization diameter results plotted against generation number.

DISCUSSION

We illustrated the utility of our homeostatic optimization framework on examples of normotensive and hypertensive pulmonary trees representing small- to intermediate-size vessels (0.01 to 0.5 cm) of the pulmonary vasculature. The results were presented in terms of the morphometric, and hemodynamics characteristics of the vessels in the tree. Employing our time-scale separation framework, the results of the homeostatic optimization were used to obtain the pulsatile hemodynamics using Womersley's analytical solution.

The morphometric results of the optimization have a direct impact on the pulsatile hemodynamics of the pulmonary tree. Using the developed framework, we demonstrated the impact of metabolic cost optimization on hemodynamics (Fig. 1 & 2). Although the input flow has minimal change, the terminal pressure has a significant change, replicating the hemodynamics of PAH. The increase in diameter of arterial vessels for hypertensive case (Fig. 4) is incoherent with the theory that homeostatic optimization thickens the vessels in PAH.

INTRODUCTION

Current methods to evaluate the lower urinary tract (LUT) are invasive but more importantly, do not offer dynamic anatomical evaluation of the LUT and specifically the bladder during filling and voiding^[1-3]. The dynamic study of the LUT, through MRI, has been shown in previous studies, which have demonstrated that MRI can provide both static and dynamic high fidelity 3D images of the bladder^[1,3]. Therefore, the aim of this study is to implement an MRI protocol that allows the comprehensive assessment of the bladder biomechanics during filling and voiding.

METHODS

In this HIPAA compliant, IRB-approved study, a healthy male was equipped with a condom catheter prior to the MRI scanning session. All scans were performed on a clinical 3T scanner (Premier, GE Healthcare, Waukesha, WI), using a high-density flexible surface coil array (AIR Coil, GE Healthcare). A dynamic acquisition was performed using Balanced Steady State Free Precession (BSSFP) imaging with a temporal resolution of 1.66 seconds, generating a total of 100 time steps per scan. A total of 9 scans were taken for filling (approximately 30 minutes worth of MR images) and a single scan for voiding (approximately 3 minutes). 15 minutes prior to the MRI scans, 1/3 of a single weight-based dose (0.1 mmol/kg) of gadolinium-based contrast was hand injected intravenously to enhance the visualization of bladder deformation during filling and voiding as well as volumetric displacement and bladder sphericity over time. Images were imported into MIMICS (Materialise, Leuven, Belgium), where the bladder lumen was segmented to obtain 3D renderings (Figure 1 and 2).

Bladder lumen volumes were then used to calculate volumetric flow rate throughout the whole filling and voiding event by calculating the volume change over time. For filling, data from 9 scans was analyzed. Due to the low filling rates, one time phase from each scan was taken to analyze volumetric changes of the bladder. For voiding,

the entirety of the scan was analyzed but only the phases where emptying of the bladder was observed were segmented.

The bladder can be approximated as a sphere where the largest radius can be measured from dome to bladder neck (base). The surface area of the bladder lumen was acquired from the bladder renderings at each time point. This was later compared to the surface area of a perfect sphere with the same volume as the bladder lumen using equation (1). This ratio is the sphericity index where values approaching 1.0 indicate an approximation to a perfect sphere^[4].

$$\text{Sphericity Index} = \frac{\text{Surface Area of Perfect Sphere}}{\text{Surface Area of Bladder Renderings}} \quad (1)$$

Figure 1: Contour lines of bladder lumen segmentations at different time points during A) filling (t_0 = red, t_1 = green, t_2 = blue, t_3 = light green, t_4 = cyan, t_5 = pink) and B) voiding events on a sagittal view.

Alongside the sphericity index the distance from the center of pubic symphysis (PS) to the dome, trigone, and lateral portions (left and

right) of the bladder were measured to determine the axes of eccentricity of the bladder while filling.

RESULTS

A methodology to evaluate and characterize biomechanics of the entirety of bladder during filling and voiding in a human subject was successfully implemented. Figure 2 shows the filling rate, voiding rate, volume measurements over time alongside analytics for filling and voiding. Filling analytics include total filled volume (TFV), post filling volume (PVF), and maximum and average filling rates (Q_{max} and Q_{avg} respectively). Voiding analytics include total voided volume (TVV), post void residual (PVR), as well as maximum and average voiding rates (Q_{max} and Q_{avg} respectively).

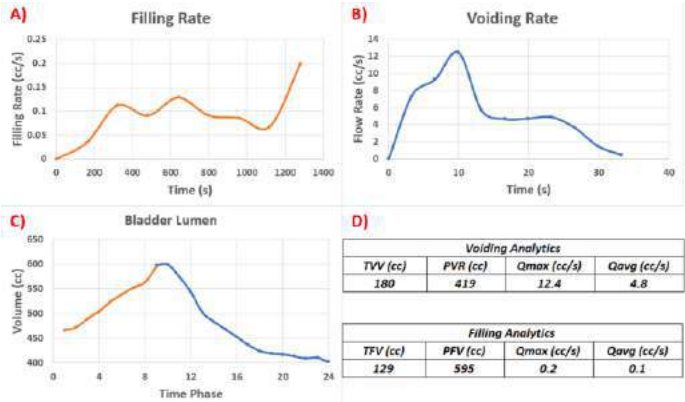

Figure 2: Filling and voiding rates (A and B respectively), bladder lumen volumes (C) during filling (orange) and voiding (blue), and filling and voiding analytics (D).

Figure 3: Sphericity Index measurements (A) during filling (orange) and voiding (blue) along with the distance between the center of the PS to the dome during filling (B).

Bladder lumen volumes increase constantly during filling as shown in figure 2C. Filling rates are displayed in figure 2A, displaying variations that range from 0.025 cc/s to 0.05 cc/s but with an average filling rate of 0.1 cc/s as shown in figure 2D. As voiding commences the bladder volumes decrease following voiding rate trends, displaying Q_{max} 10 seconds after the subject started voiding as shown in figure 2B. Bladder lumen volume before filling imaging started is 498 cc and reaches 595 cc after 1280 seconds (21.3 minutes) for the last time phase in the filling scans. During the voiding scan, bladder lumen volumes range from 598 cc to 419 cc and the slope of the bladder volume curves can be directly related to voiding rates.

Sphericity Index was calculated for filling (orange) and voiding (blue). The sphericity index shows different behaviors in filling and voiding but are not disjointed as shown in figure 3A where both seem to join in phase 9. The sphericity index displayed general asymmetry in the bladder during filling as shown in figure 3A having a maximum value of 0.903 right before the voiding scan and a minimum value of 0.864 at time phase 4. During filling, the PS distance to the dome

increases constantly while the sphericity index varies significantly. This indicates changes in the other axes of the bladder. During voiding, the sphericity index increases and reaches a maximum value (0.918) close to the time phase of Q_{max} and then decreases to pre-void values.

DISCUSSION

This non-invasive, novel MRI-based technique, allows for the quantitative assessment of the bladder biomechanics during filling and voiding during a single scanning session under an hour. Current diagnostic methods fail to completely characterize bladder biomechanics. Correspondingly, measurements of volumetric flow rate, TVV, TFV, PVR, PFV and sphericity index were able to be obtained during in a single session in the scanner. Sphericity index provides insight on bladder shape and how uniformly the bladder deforms during filling and voiding. When filling scans began, the bladder was partially filled. As the scans progressed, the dome of the bladder showed the first signs of displacement as shown in figure 3B. Afterwards, the sphericity index decreased which means the bladder became less spherical. This indicates that the bladder did not fill uniformly for that period. This occurs again during time phase 3 and 4 where the distance between the PS and the dome of the bladder stayed the same but the sphericity index curve displays an inflection point. This inflection point may indicate that other regions of the bladder were expanding during these time phases. During voiding, the sphericity index matches the behavior of the voiding rates until reaching Q_{max} , then it decreases slowly until returning to a pre-void index close to the end of the voiding state.

CONCLUSIONS

With this novel technique, we were able to non-invasively capture in-vivo filling rates and characterize the filling of the human bladder without the use of catheterization (urodynamics) or perturbation on the abdomen (ultrasound). Current methodologies have lacked the ability to capture low flow voids and filling. This shows the ability of this novel methodology to characterize diverse bladder biomechanical aspects during any filling or voiding event. This subject's voided volume is close to be deemed unreliable for urodynamic studies as the voided volume was close to 150 cc. Nevertheless, our methodology allows us to analyze low flow events such as filling and low volume voids. Thus, demonstrating necessity for patient specific, non-invasive methodologies to analyze bladder biomechanics during filling and voiding.

MRI protocols have proven to be an invaluable and versatile imaging modality that can be used to characterize anatomical and functional information of the LUT dynamically in a safe, accurate, and reproducible way. Future work will be aimed at using this novel methodology to deepen the comprehension of bladder biomechanics during filling and voiding, and better understand how different diseases affect bladder biomechanics.

INTRODUCTION

Ultrasound molecular imaging (USMI) using targeted microbubbles (MBs) is a promising technique for assessing endothelial phenotypes. USMI has shown promising results to visualize targets that are usually associated with angiogenesis, thrombosis, and inflammation [1]. For example, angiogenesis is a crucial contributing factor that could potentially predict tumor growth and cancer progression. Targeted MBs include biomolecular ligands that bind specifically to endothelial receptors. These targeted MBs are injected into the body where they flow through the entire vasculature and their accumulation in the endothelial wall via cell-mediated adhesion is observed using ultrasound. However, more research is necessary to improve specificity and efficiency of MB targeting, here we used the RGD/ $\alpha_v\beta_3$ (ligand/receptor pair). It is known that acoustic radiation force (F_{rad}) increases the number of polydisperse RGD-MBs adhered to cells [2]. Moreover, it has been demonstrated that the combination of size-selected microbubbles with specific frequencies increases the microbubble displacements [3]. Therefore, we hypothesize that the F_{rad} can increase the number of monodisperse RGD-MBs attached to $\alpha_v\beta_3$. The main goal of this work aims to study and elucidate the role of ARF and MB parameters on the targeting of RGD-MBs using an in vitro $\alpha_v\beta_3$ -coated microvessel phantom. The use of F_{rad} in combination with MBs using buried-ligand architecture, represents a potential strategy to enhance the adhesion specificity and efficiency at the target site by matching the ultrasound pulse frequency to the MB resonance frequency. The goal of this work was to study the

effect of MB monodispersity on targeting specificity and efficiency for RGD-MBs to an in vitro $\alpha_v\beta_3$ -coated microvessel.

METHODS

Labeled polydisperse and 2 μm size- isolated MBs (DBPC/DSPE-PEG(5000)/DSPE-PEG(2000)-PDP/Vybrant DiI) attached with the peptides RGD and RAD, target and control ligand respectively, were synthesized with a buried-ligand architecture [4]. A mechanical centrifugation method was utilized to isolate the MBs into a monodisperse distribution [5]. To analyze the MBs targeting, monodisperse MBs were pumped at 1 mL/h in an $\alpha_v\beta_3$ -coated microvessel phantom, with a diameter of 200 μm , and pushed using the UlaOp ultrasound system in B-mode imaging. In addition, the MBs were manipulated using F_{rad} at 3 MHz, 20 cycles or 7 MHz, 47 cycles; 6.7 μs pulse length, 0.15 MHz PRF, and 133 kPa PNP. The number of peptide molecules bound to the MBs was measured by using a BCA assay. The effect of US frequency (3 vs. 7 MHz) and MB concentration (1×10^5 to 1×10^8 MB/mL) on F_{rad} targeting was evaluated. Finally, we compared the adhesion efficiency to polydisperse MB populations. Finally, z-stack pictures of 10 different sections of the phantom were taken using bright and fluorescent contrast. The attached MBs to the microvessel wall were counted and the amount of MBs attached per mm^2 was estimated. In all cases, specificity was estimated as the subtraction of nonspecific isoform control RAD-MBs from the targeting ligand RGD-MBs.

Equations

To calculate the adhesion efficiency of MBs attached to the phantom wall, the following equation was used:

$$\text{Adhesion Efficiency (\%)} = \frac{\# \text{ MBs attached}}{\# \text{ MBs interaction zone}} \times 100 \quad (1)$$

The # MBs interaction zone = $(Q \times t \times [\text{MBs}]) + (V \times [\text{MBs}])$, where V is the microvessel volume (mL), [MBs] is the concentration of MBs (MBs/mL), Q is the flow rate (mL/min) and t is the insonation time (min).

RESULTS

It was observed that the greatest MB adhesion occurred at 7 MHz and was dependent on MB concentration. Remarkably, the data shows that specificity was maximized at a concentration of 1×10^6 MB/mL, whereas at higher concentrations (1×10^7 to 1×10^8 MB/mL), there was a greater number of nonspecific interactions (Fig. 1A). Also, the adhesion efficiency for RGD-MBs decreased from 97% to 13%, for monodisperse and polydisperse populations at 10^6 MBs/mL, respectively (Fig. 1B).

Figure 1: A) Specific RGD-MBs targeting with varying concentrations and frequencies ($*p \leq 0.05$, $R^2 \geq 0.90$). B) Dependence of specific RGD-MBs adhesion efficiency on the MB size distribution ($*p < 0.05$ and $**p < 0.005$). Data represent the mean \pm standard deviation for 3 independent experiments.

DISCUSSION

The combination of US and MB parameters plays a key role in maximizing the adhesion efficiency and specificity of F_{rad} ultrasound targeting of buried-ligand MBs using the RGD/ $\alpha_v\beta_3$ ligand/receptor pair. The density of receptors on the microvessel internal surface represent an important feature to achieve successful MB targeting, specificity, and adhesion efficiency. However, as the MB concentration increased, the nonspecific interactions increased as well, resulting in low specific adhesion efficiency. The data suggest that this behavior could be attributed to the presence of secondary acoustic radiation forces, due to the high number individual MBs bumping into each other at high concentrations and making them dislodge from their binding site. In our study, MB concentration was optimized at $\sim 10^6$ MBs/mL. Furthermore, we also elucidated that the use of monodisperse MBs increases the adhesion efficiency by 8-fold when compared with polydisperse MBs at the same concentration. The results of this study provides a deeper understanding of the MBs behavior under ultrasound and flowing conditions inside a microvessel phantom. This is relevant to the field as we could be a step closer in using a widely-available, low-cost and minimally invasive method of detecting different pathologies in the endothelium with ultrasound technology and ultrasound contrast agents.

INTRODUCTION

The diagnostic efficacy of organ-level metrics such as the ejection fraction is challenged by the multifaceted nature of structural heart diseases [1]. The functional assessment of cardiac function through the mechanistic quantification of left ventricular (LV) motion is growing in prevalence. In particular, the imaging-based analysis and subsequent characterization of the global longitudinal strain (GLS) strains has been shown to be a strong early-stage marker for cardiac diseases in comparison with traditional volumetric metrics [2]. Despite their merits, such organ-level strain measurements fail to quantify the regional characteristics of LV function accurately. The LV exhibits complex four-dimensional (4D) deformation with remarkable transmural variations, thus confounding the accuracy of regional strain calculations and effectuating variability. The characterization of continuous 4D regional deformation offers excellent potential in establishing a complete LV structure-function relationship. Despite advances in medical imaging, the assessment of 4D continuous myocardial deformation remains vastly under-explored. In this work, we propose a classification-based super-resolution reconstruction (CSRR) framework to improve the characterization of myocardial strains. The CSRR framework combines sets of arbitrarily aligned anisotropic low-resolution cardiac magnetic resonance (CMR) scans to produce a high-resolution field of pixels to generate a 4D map of myocardial motion.

METHODS

The framework is divided into three modules, (i) the classification module, (ii) the interpolation module, and (iii) the registration module. Our objective was to categorize each tissue class, assign pixels from the image set of the low-resolution (LR) acquisitions, and generate query points over a global Euclidean space in the high-resolution (HR) grid. The endocardial and epicardial contours were drawn semi-automatically using Segment version 3.0. Our module assigned pixels to various regions of interest by converting the point clouds into convex hulls and

combining the 2D contours into 3D surfaces. The 2D contours were resampled longitudinally through Delaunay triangulation and smoothed through the application of radial basis functions to mitigate the effects of pixel spacing anisotropy on the segmentation quality in 3D reconstruction. The segmented LR images, along with the information describing the desired HR scan, were passed on to the interpolation module. The HR scan was defined either as an unstructured grid via a global interpolation scheme. Given the anisotropy in pixel distribution and to accommodate arbitrary orientations of LR images, scattered data interpolation was used. The region-specific pixel sets and a combined package comprising parameters such as the resampling ratios, the reference image index, and the segmented contours were passed on to the registration module. A diffeomorphic demons algorithm [3] was implemented to perform non-rigid image registration. The pixel displacements in the Cartesian frame of reference were used to calculate the Green-Lagrange strain tensor and were then transformed into clinically relevant anatomical coordinates. Scans at various orientations describing different views of the LV are desirable inputs for the CSRR framework. Imaging was performed in one diabetic mouse ($n = 1$, 6 months old) using a 7T Bruker Avance III HD scanner with a 72 mm quadrature proton volume coil (Bruker BioSpin MRI GmbH). A set of eight short-axis (SA) and five long-axis (LA) slices orthogonally sampled between the anterior and inferior walls of the LV were captured (Fig. 1A), and the combined stack was subjected to CSRR (Fig. 1B).

RESULTS

The reconstructed LV is shown across an arbitrary plane sampled perpendicular to the SA planes (Fig. 2A). Strains are reported for LV models reconstructed using standard imaging SA images only (standard imaging) and CSRR models. Since only eight LR SA slices were used in the sampling process, the standard LV model was hampered considerably by the slice thickness (Figs. 2A). Whereas in CSRR, the pixel distribution increased from $140 \times 140 \times 8$ to $280 \times 280 \times 220$.

Consequently, any number of planes could be sampled (Fig. 1B) without being restricted to the orientation of the original LA scanning planes. Reconstruction was vastly improved using CSRR with a clear distinction between the high-contrast blood pool and the relatively low-contrast myocardial tissue (Fig. 2A).

Figure 1: A) Enhanced imaging protocol with 8 SA, 5 orthogonally sampled images B) CSRR of the image stack at end-diastole and end-systole

At end-systole, regional epicardial strains using CSRR showed varying degrees of contraction between the base and the apex, with apical shortening exceeding the other regions. Although qualitative similarity in strain distribution was observed between the two methodologies, there was a significant difference in the peak strains. Specifically, for the standard model, there was a significant presence of positive longitudinal strains despite global LV shortening (Septal; SA stack only, $E_{ZZ} = 0.7342$ vs. CSRR, $E_{ZZ} = 0.4985$. Lateral; SA stack only, $E_{ZZ} = 0.5146$ vs. CSRR $E_{ZZ} = 0.3126$). Also, the regional circumferential shortening seen in CSRR was recapitulated in the conventionally reconstructed model with similar differences in peaks. However, there was an abundance of non-physical transmural strains, which were suppressed by CSRR (Fig. 2B).

DISCUSSION

Standard functional imaging is often limited to 7-9 SA planes with an optional LA or four-chamber view. The resulting pixel set is heavily anisotropic, which impediments accurate strain calculations. The LV exhibits twisting during systolic contraction, resulting in significant ‘through-plane’ deformation with corresponding ‘in-plane’ mechanical adjustments. These deformations translate as ‘out-of-plane’ pixel motions that are not captured by traditional CMR imaging of the LV [4]. We hypothesized that a CSRR-based methodology combining scan planes of varying orientations would considerably reduce pixel spacing, thereby improving strain calculations. The pixel spacing using CSRR was increased to about 25 times the original acquisition. Through this nearly isotropic pixel set, apical and endocardial shortening was captured more accurately, and a majority of myocardial features were preserved. The inadequacy of temporal resolution in standard CMR images results in sharp gradient changes between time points, thereby producing errors in frame registration. A strong correlation was noted between sharp image gradients and the generation of non-physical strains, which necessitate regularization. A by-product of regularizing the image registration process was the underestimation of strains, especially at the tissue-pool interface of the endocardium. In the absence of this regularization, notable variations were observed between the conventionally reconstructed strain representation, with pronounced differences in both the peak values and the patterns. In this study, we presented a novel and comprehensive analysis of 4D myocardial

deformation through the CSRR framework. The framework offers a translational tool that leverages combined CMR acquisitions and tissue classification strategies to improve LV reconstruction with minimal noise and artifacts. A detailed representation of 4D myocardial strains was made possible with such analysis, offering the potential to establish a continuous 4D LV structure-function relationship as a standard practice.

GROWTH AND REMODELING OF THE PULMONARY ARTERIAL TREE FOR EVOLUTION OF PULMONARY ARTERIAL HYPERTENSION

INTRODUCTION

In pulmonary arterial hypertension (PAH), vessels throughout the pulmonary arterial tree alter their geometry and composition in response to hemodynamic and biological stimuli. This remodeling increases pulmonary vascular resistance (PVR), which in turn increases afterload on the right ventricle, leading to heart failure and death [1]. Changes in mechanobiological stimuli alone are sufficient to induce PAH, where increased flow can drive altered endothelial cell behavior in response to increased wall shear stress (WSS) and induce an endothelial-to-mesenchymal transition that narrows distal vessels and contributes to progressive increases in PVR [2]. As such, tracking WSS development in PAH is critical to monitoring disease progress. Yet, WSS is difficult to measure and is typically simulated using modeling approaches from computational fluid dynamics (CFD). Studies tracking WSS changes with disease severity using CFD have shown distinct differences in behavior of large and small caliber vessels, where larger vessels have decreased WSS and smaller vessels have increased WSS [3]. Though these studies are useful in tracking mechanobiological stimuli at single time points, there is a need for simulating disease progression over time for each patient and incorporating both the structural and geometric changes that accompany remodeling to better identify potential interventions. To this end, we have developed a modeling framework using constrained mixture theory growth and remodeling principles combined with a morphometric tree model of the pulmonary arterial tree to simulate vascular evolution in PAH.

METHODS

To simulate growth and remodeling of the vasculature in pulmonary arterial hypertension, we used Strahler diameter-defined morphometric trees [4] to simulate a reduced order model of the mouse pulmonary arterial tree (**Figure 1**). Poiseuille flow conditions were assumed, and resistances were calculated for vessel geometries that were fit to match the total PVR to that of the murine pulmonary tree [5].

Biomechanical behavior of the large pulmonary arteries was taken from biaxial experiments on murine vessels [6]. To simulate loading for the tree, we then found mass fractions and material parameters in a four-fiber family constitutive model for each vessel order that allowed for

Figure 1: Schematic of the modeling approach for evolution of the pulmonary arterial tree. Strahler diameter-defined morphometric trees were simulated with inlet flow boundary Q_{in} and outlet pressure boundary condition P_{out} . Each order of vessels was represented by a constrained mixture model and remodeled in response to averaged hemodynamics from vessels across the order.

maintenance of the homeostatic vessel diameter when using average pressure loads \bar{P}_n from each order n . A constrained mixture theory growth and remodeling framework was adopted to simulate the adaptation of the vessels to changes in hemodynamic loads and with combinations of maladaptive remodeling stimuli [7]. Average flows \bar{Q}_n and average pressures in each order \bar{P}_n were updated at each time step with solution of the flow equations in the morphometric tree and average radii at each order \bar{a}_n was updated to satisfy the mechanical equilibrium equation with the updated loads. Loads and radius were then iteratively exchanged until convergence, and the model continued to march forward in time. Maladaptive remodeling stimuli were chosen to represent biological processes that have been associated with PAH, and stimuli were added sequentially to understand their net effect on changes in geometry and mechanobiological stimuli that contribute to PAH.

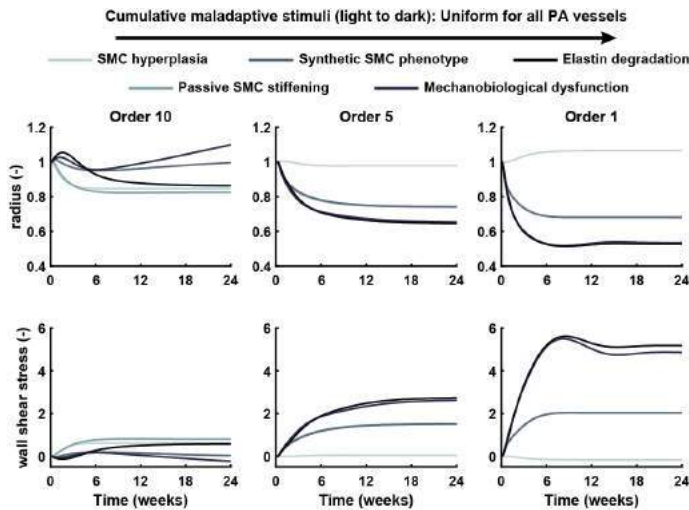

Figure 2: Changes in luminal radius and wall shear stress with maladaptive stimuli driving vascular remodeling. Combinations of stimuli related to multiple biological pathways induced greater dilatation of the proximal vessels and narrowing of the distal vessels as observed in clinical pulmonary arterial hypertension.

RESULTS

With our coupled modeling framework, we simulated the development of PAH in response to several types of cumulative maladaptive remodeling stimuli applied uniformly across the PA tree (**Figure 2**) consisting of: smooth muscle cell (SMC) hyperplasia represented by increased mass density production of SMCs, passive SMC stiffening given by an increase in the material parameter associated with SMC mechanical behavior, conversion to a synthetic SMC phenotype modeled as a decrease in the mass fraction of SMCs contributing to active contraction, mechanobiological dysfunction simulated as a decrease in the gains that mediate production of SMCs and matrix in response to WSS and intramural stress, and elastin degradation modeled as a decrease in elastin mass fraction over time.

With the addition of SMC hyperplasia alone, changes in radius were contrary to those in PAH, where the proximal vessels narrowed, and the distal vessels dilated. Further addition of SMC stiffening allowed for narrowing of both the proximal and distal vessels with more narrowing of the distal vessels and a corresponding greater increase in WSS. Altering the phenotype of SMCs in the modeling framework and decreasing the mechanobiological gains, in combination with the previous stimuli, then led to increases in the proximal vessel radius and greater narrowing of the distal vessels, as is seen moderate and severe

PAH [3]. However, addition of elastin degradation did not further contribute to a PAH-like phenotype, as it caused proximal vessel narrowing and had modest effects on distal vessel narrowing.

For each of these cases, we also simulated the evolving inlet pressure corresponding to the right heart afterload (**Figure 3A**). Each simulated combination of maladaptive stimuli led to increases in pressure, and those simulations with a greater degree of distal narrowing tended to exhibit larger fold increases in pressure. Variation of PVR at the end of the time course with applied changes in active tone from SMCs were performed to illustrate a loss of vasodilatory capacity, which could contribute to long-term disease progression with vasodilator therapy (**Figure 3B**). In the cases with the greatest increases in PVR and pressure, reduction of active tone to zero resulted in less than a 5% decrease in PVR.

Figure 3: (A) Changes in inlet pressure corresponding to right heart afterload with combinations of maladaptive remodeling stimuli. With additional stimuli, pressure tended to increase indicating more severe disease. (B) Changes in pulmonary vascular resistance (PVR) with simulated decreases in active tone at the end of remodeling. PVR increased with additional maladaptive stimuli and the ability to reduce PVR was lost with maladaptation.

DISCUSSION

PAH is a progressive disease with poor response to current treatments [8]. Computational modeling tools can be used to better understand the mechanisms underlying progression and identify new potential treatments. However, prior modeling approaches lacked the ability to simulate long-term changes in geometry and hemodynamics. In this work, we demonstrate a new framework that incorporates relations for biological mechanisms of maladaptive pulmonary arterial remodeling. Our approach allows for simulation of changes in clinical metrics and includes mechanobiological stimuli that are known to drive adverse changes in pulmonary cell phenotypes. With additional validation, this model could be used to predict the development of PAH in patients and identify novel interventions.

INTRODUCTION

Osteoarthritis (OA) is an incapacitating, chronic disease, characterized by the progressive degradation of articular cartilage. The structure and composition of articular cartilage are optimized for its mechanical performance. It is comprised of water (70-80% of wet weight) and negatively charged sulfated glycosaminoglycan (GAG, 5-15% wet weight) constrained by a fibrous network of type-II collagen (COL, 5-20% wet weight) that provides tribological material properties essential to support applied joint loads and to maintain a nearly frictionless shear interface between articulating joint surfaces. OA initiates with loss of GAG followed by COL network derangement, which increases hydraulic permeability and decreases cartilage stiffness. Promising therapies to treat OA include disease-modifying drugs that mitigate or reverse cartilage degeneration and chondro-regenerative tissue engineering platforms that recapitulate the composition and structure of healthy hyaline cartilage. The development of disease-modifying OA therapies is impeded by a lack of non-destructive clinical assessments of cartilage composition and mechanical properties. Histopathology scoring (OARSI, Mankin grades) serves as an *ex vivo* 'gold standard' for the evaluation of cartilage degeneration and recently has been shown to predict changes to functional tissue properties in early OA [1]. However, these assessments are invasive, destructive, and incompatible with repetitive clinical monitoring. Evidence-based evaluations of the utility of OA therapies should be predicated on measuring biomarkers that reflect OA pathophysiology and portray the structure and composition of regenerated or neo-cartilage repair tissue relevant to its function. Image-based assessments (radiographs and magnetic resonance imaging (MRI; dGEMRIC, T1rho, T2*)) are biased toward late-stage OA pathology and are only moderately correlated with quantitative assessments of the tissue's material properties [2]. MRI measurements of cartilage composition and structure may also be affected by lack of consistency, signal-to-noise ratio (SNR), and insufficient image resolution. Therefore, robust methods capable of

measuring changes in the functional properties of damaged cartilage are required for advancing OA treatment.

Raman spectroscopy is an inelastic optical light scattering technique that can provide a quantitative, point-wise optical fingerprint of a tissue's molecular building blocks (amides, sulfates, carboxylic acids, and hydroxyls), thus allowing recognition of the predominant molecular constituents of articular cartilage: GAG, COL, and H₂O. In our prior work, we developed a Raman arthroscopic needle probe and real-time spectral analysis platform capable of measuring specific compositional biomarkers of hyaline cartilage that reflect the health and function of articular cartilage [3]. In this work, we aim to further advance this platform by investigating the capability of our Raman probe to assess the composition and material properties of cartilage using a unique *ex vivo* early-stage OA model system, consisting of bovine femoral condyles that present with focal chondral lesions, akin to those observed in patients in response to joint trauma. The capability of Raman-derived biomarkers to predict the functional mechanical properties of articular cartilage is compared to histopathological OARSI scoring and compositional T2* MRI mapping.

METHODS

Tissue specimens: Bovine specimens were harvested from medial femoral condyles of twelve skeletally mature bovine knees: six healthy condyles (HC) exhibited no macroscopic degeneration (Outerbridge grade (OB0), and six condyles exhibited a ~Ø15mm focal chondral lesion site (LS; OB2) within the load bearing region, but no macroscopic degeneration (OB0) in the surrounding lesion peripheral sites (LPS). Rectangular osteochondral blocks (~5x5x5mm) were sectioned from the HC (N=37), LS (N=32), and LPS (N=35) regions for analysis. **Raman analysis:** The Raman platform consisted of an NIR diode laser (ex=785nm, 500mW, B&W Tek), fiber-coupled spectrograph (QEPro, Ocean Optics), and needle probe with a 2mm sapphire ball lens [2]. Raman spectra were acquired with the probe lens in gentle contact with

the chondral surface over 30s acquisition time. The spectral fingerprint range (800-1800cm⁻¹) was preprocessed and subjected to a multivariate least-squares linear regression model to calculate the relative contribution of the predominant cartilage constituents (GAG, COL, and H₂O) to the composite cartilage Raman spectra (Equation 1).

$$\text{Cartilage spectra} = \text{GAG}_{\text{score}} * (\text{GAG}_{\text{REF}}) + \text{COL}_{\text{score}} * (\text{COL}_{\text{REF}}) + \text{H}_2\text{O}_{\text{score}} * (\text{H}_2\text{O}_{\text{REF}}) \quad (1)$$

where GAG_{REF}, COL_{REF}, and H₂O_{REF} are the component spectra of purified reference chemicals for each ECM constituent. In the high wavenumber region (2700-3800cm⁻¹), the area under the OH peak (OH area) represents tissue hydration [4]. **Property measurements:** The elastic modulus of the chondral layer for each tissue block was derived by indentation using a Ø3mm spherical indenter and the slope of the loading curve (Hertzian). The central Ø3mm chondral core of each block was sub-punched and GAG content was determined by DMMB assay. **OARSI histological scores:** The OARSI scores (grade×stage) were assessed by a board-certified pathologist on Saf O sections for a random subset of tissues from all analyzed regions (N=30). **MRI measurements:** MRI examination was performed using a 9.4T Bruker BioSpec MRI scanner to obtain T2* relaxation times for an additional 2 healthy and 2 lesion-afflicted condyles. Condyles were subsequently sectioned into blocks and subjected to Raman and mechanical analysis (N=42 blocks total). The imaging protocol included 3D fat-suppressed with gradient echo (GRE) sequences followed by TR/TE=29.74/2.94 ms, flip angle=15, FOV=50x50mm, matrix=250×250, spatial resolution=0.2x0.2mm, and slice thickness=1mm utilizing six echoes for the mono-exponential fit. T2* relaxation times were mapped for the full cartilage thickness and coregistered with the position of each sectioned block. T2* was also measured for the topmost 200µm of cartilage to maintain consistency with the ROI achieved via depth of tissue sampling from the Raman probe [3].

RESULTS

The multivariate regression model accounted for 91±1.5% of the variation in composite Raman spectra. Compared to healthy bovine specimens (HC), tissue from the specimen with lesions was degraded as evidenced by significantly reduced GAG content and elastic modulus within both LS (OB2) and LPS (OB0) (p<0.001; Fig 1A-C).

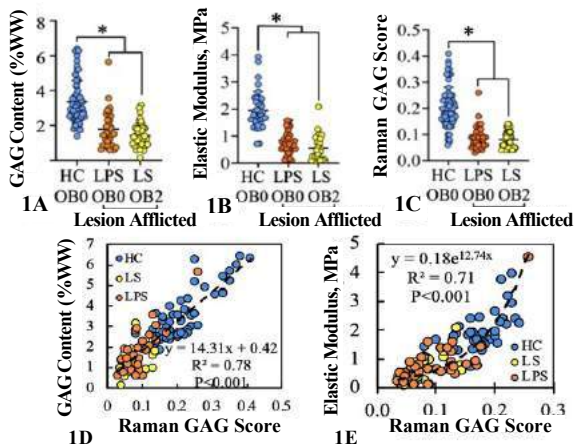

Fig 1: (A) GAG content, (B) elastic modulus, and (C) Raman GAG score for healthy cartilage (HC), lesion sites (LS), and lesion peripheral sites (LPS) of cartilage blocks. Raman GAG score vs (D) assay-measured GAG content and (E) elastic modulus, *p<0.001.

Raman GAG scores predicted 78% of the variation in GAG content and 71% of the variation in elastic modulus (p<0.001; Fig.1D&E). Raman GAG scores accounted for a significantly greater percentage of variation in modulus than OARSI (78% vs 54%; p<0.05; Fig 2A&B). Similarly, Raman biomarkers accounted for a significantly greater percentage of variation in modulus than T2* relaxation times. (62% vs

33%; p<0.001; Fig 3A&C). The utilization of a linear set of multiple Raman biomarkers (GAG score and OH area) improved predictions of modulus (62% to 67%, Fig 3D).

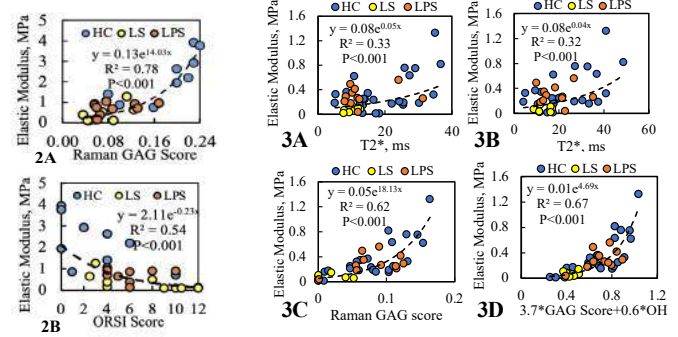

Fig 2: (A) Raman GAG score vs elastic modulus for cartilage blocks. (B) OARSI score vs elastic modulus for cartilage blocks.

Fig 3: Elastic modulus vs measured T2* relaxation time for (A) full cartilage thickness and (B) topmost 200 µm of cartilage. Elastic modulus vs (C) Raman GAG score and (D) linear combination of GAG score and OH area.

DISCUSSION

GAG “scores” derived from multivariate regression spectral analysis represent the relative contribution of GAG to the composite Raman spectra of cartilage using the Raman probe platform. The GAG score accounted for 78% of the variation in the measured GAG composition and predicted 71% of the variation in the elastic modulus of tissue over a range of cartilage morphologies, including intact (OB0) and focal chondral lesions (OB2). OARSI histopathology scoring, the gold standard for *ex vivo* assessment of cartilage pathology, only predicted 54% of cartilage mechanical properties after injury. Compositional T2* MRI assessments, the state-of-the-art for clinical diagnostics of cartilage, only predicted 33% of properties.

Notably, Raman GAG scores revealed depleted GAG content that predicted cartilage softening where there were no visual macroscopic lesions. As such, Raman spectra can arthroscopically “optically biopsy” cartilage and quantify the relative contribution of key biochemical constituents that serve as biomarkers for determining cartilage composition, structure, and material properties in normal and pathological tissue, and in response to chondroprotective and/or chondroregenerative treatments.

This work supports the use of Raman spectroscopy as a research platform to objectively assess the efficacy of emerging OA therapies across the hierarchy of *in vitro*, *in vivo*, and clinical model systems. Raman arthroscopy can also serve as a transformative clinical platform for discrimination of healthy versus degraded tissue, diagnosing early OA, and guiding clinical treatment courses. This study shows that Raman arthroscopy, a low-cost, minimally invasive, fast, and portable diagnostic platform, has the potential to complement other state-of-the-art and emerging OA diagnostic platforms, such as compositional MRI, in portraying changes in cartilage composition, structure, and material properties.

INTRODUCTION

Sickle cell disease (SCD) is a genetic blood disorder caused by an amino acid substitution in the beta globin chain of the hemoglobin. The abnormal molecule hemoglobin S formed by this mutation polymerizes when deoxygenated. The polymerization of HbS is key to the formation of sickled shape red blood cells. Sickle cell disease can lead to hemolysis, chronic inflammations, pain, infections, cardiovascular complications, chronic anemia, vaso-occlusion and increased mortality. Pulmonary hypertension (PH) is among the complications caused by sickle cell disease. [1] Pulmonary hypertension is defined as mean pulmonary artery pressure ≥ 20 mmHg. Pulmonary hypertension is divided into 5 different categories and the pulmonary hypertension due to chronic hemolytic anemia including sickle cell disease is categorized in group 5 (miscellaneous effects) in the updated classification by World Symposium on Pulmonary Hypertension (WSPH). [2, 3]

Pulmonary hypertension has a prevalence of 10% in patients with sickle cell disease and sickle cell disease patients with pulmonary hypertension are at higher risk of morbidity compared to patients who do not have pulmonary hypertension. [4]

Although non-invasive methods such as echocardiography and clinical imaging via magnetic resonance (MR) and computed tomography (CT) are used as techniques to diagnose pulmonary hypertension, physics-based models could be used as powerful tools to quantify the hemodynamics and vasculature mechanics of pulmonary artery and better understand the mechanism of disease progression.

Due to increased hemolysis, whole blood viscosity in sickle cell disease patients is lower compared to normal. [5] Fluid flow analysis of pulmonary hypertension is addressed by several studies (Tang et al. and Kheyfets et al.). Kong et al., Zambrano et al. and Pearce et al. have performed fluid structure interaction simulation of pulmonary hypertension. Rabidou et al. have studied pulmonary hypertension in sickle cell disease but the impact of altered blood viscosity on hemodynamics in sickle cell disease has not been explored. In this study

we have used computational fluid dynamics to study the effect of altered blood viscosity in sickle cell disease patients. The CFD results are then compared with the results from fluid structure interaction simulations to assess improvement of the results. Wall mechanical parameters are also predicted from FSI simulations.

METHODS

Of the four subjects' data included in this study, one (Subject 1) did not have pulmonary hypertension, a control subject, and the other three subjects (2, 3, 4) had pulmonary hypertension. Subjects 1 and 2 had sickle cell disease, the others did not. MR images were gathered on a Siemens Espree (subject 1) 1.5 T or Siemens Aera 1.5 T model MR scanner (subjects 2, 3, and 4). The patient specific pulmonary artery geometries were reconstructed using the segmentation techniques in Mimics 20.0 (Materialise, Inc.; Plymouth, MI) and further postprocessed in SolidWorks 2017 (Dassault Systems; Waltham, MA). The solid models were then imported into ANSYS Workbench (ANSYS Inc.; Canonsburg, PA) where the arterial wall thickness was added in Spaceclaim and the computational mesh was generated. Ansys Fluent and transient structural modules were used to perform computational fluid dynamics and coupled fluid-structure interaction simulations. Geometry and mesh sizes for all four subjects are listed in Table (1). MRI data from patient and control subjects indicate larger diameter of main pulmonary artery in subjects who have pulmonary hypertension.

Table 1: Geometry and mesh properties of subjects 1-4

Subject	Diameter (cm)	Area (cm ²)	Fluid mesh no. of elements	Fluid mesh size (mm)	Structural mesh No. of elements	Structural mesh size (mm)
1	2.69	5.70	1270974	0.35	155190	0.65
2	4.03	12.76	1023147	0.7	211049	1
3	3.62	10.29	1234915	0.5	164041	0.9
4	3.58	10.06	1238648	0.5	164651	0.9

Figure (1) shows the velocity waveforms used as the inlet boundary conditions for subjects 1-4. Also as shown in Figure (1) measured volumetric flow rate is lower in PH subjects.

Figure 1: Inlet velocity waveforms for subjects 1-4

CFD SIMULATION RESULTS

Results discussed in this section are from CFD simulations using the rigid wall assumption. Blood density was taken to be 1060 kg/m3. Contours of wall shear stress are presented in Figure (2) for subjects 1 and 2.

Figure 2: Wall shear stress contours in main, left and right pulmonary arteries at peak systole of 3rd cycle, CFD simulations

Values of maximum wall shear stress (WSS) for subjects 1-4 are shown in Table (2). In these simulations constant viscosity of 1.87 cP is assumed for SCD subjects (1, 2) and 3.5 cP for non-SCD subjects (3, 4). Simulations with Carreau viscosity model were also carried out for all four subjects to compare with constant viscosity results.

Table 2: Maximum WSS of subjects 1-4 for two viscosity models at peak systole of 3rd cycle, CFD simulations

Subjects	Constant viscosity	Maximum WSS (Pa) at Constant viscosity	Max WSS (Pa) at Carreau viscosity model
1 (SCD)	1.87 cP	114.714	162.438
2 (SCD/PH)	1.87 cP	14.578	19.294
3 (PH)	3.5 cP	23.913	23.356
4 (PH)	3.5 cP	13.214	13.228

Wall shear stress values obtained using Carreau viscosity model in sickle cell disease subjects are higher than constant viscosity model but closely match the values in subjects without sickle cell disease.

Maximum wall shear stress is substantially higher is subject 1 who does not have pulmonary hypertension compared to other subjects.

FSI SIMULATION RESULTS

In the FSI simulations blood viscosity was taken to be 1.87 cP for sickle cell disease subjects (1, 2) and Carreau viscosity model was used for subjects without sickle cell disease (3,4). The arterial wall was assumed to behave as a linear elastic solid with density of 1200 kg/m3, elastic modulus of 2 MPa and Poisson ratio of 0.48. [6]

Results are presented here for FSI simulations of subjects 1-4. Data in Table (3) is a summary of fluid flow and structural analysis results as obtained from FSI simulations for subjects 1-4.

Table 3: Results from FSI simulations of subjects 1-4 at peak systole of 3rd cycle

Subjects	Viscosity	Maximum WSS (Pa)	Maximum Total Deformation (mm)	Maximum Stress (MPa)
1 (SCD)	1.87 cP	116.105	1.8252	0.11494
2 (SCD/PH)	1.87 cP	12.7068	0.97273	0.035268
3 (PH)	Carreau	24.2988	0.23	0.014797
4 (PH)	Carreau	13.364	0.1235	0.0077651

Subject 1 who does not have PH has smallest main pulmonary artery diameter and highest inlet flow rate. Simulations results show largest value of wall shear stress and maximum total deformation and stress for subject 1. Subject 2 suffers from both SCD and PH and has the largest diameter. Maximum inlet flow rate of this subject is approximately half of that of subject 1. Therefore subject 2 is experiencing lowest value of wall shear stress among four subjects. Total deformation for this subject is about half of subject 1 and maximum stress is also less than half of subject 1. Subjects 3 and 4 arteries are almost of the same size and inlet flow rate of subject 3 is about 1.5 times of subject 4. So higher values of wall shear stress, total deformation and mechanical stress are observed in subject 3 compared to subject 4.

DISCUSSION

MRI data reveals larger main pulmonary artery diameter and lower volumetric flow rate in PH subjects. Our results confirm lower values of WSS reported in PH subjects [7]. According to CFD simulations, constant viscosity results are closer to Carreau viscosity model results in non-SCD subjects compared to SCD subjects. Maximum WSS values from FSI and CFD simulations are in good agreement using the same viscosity model for each subject. So CFD simulations with much lower computational time yield good approximation of the coupled fluid-structure interaction simulation. The FSI simulations could be further improved by using a more accurate value for the arterial wall modulus of elasticity of subject 1 who does not have pulmonary hypertension.

INTRODUCTION

The intervertebral disc is responsible for maintaining and distributing large multiaxial spinal loads. The structure and composition of the healthy IVD are optimized for this mechanical performance. The IVD is comprised of a collagen (COL)-rich, fibrous outer annulus fibrosus (AF) ring that surrounds a glycosaminoglycan (GAG)-rich, gel-like nucleus pulposus (NP). The osmotic response to the anionic sulfated GAG of the NP, in conjunction with the restraining tensile properties of the AF, allow the multiaxial spinal loads to be distributed through pressurization of the interstitial fluid in the NP extracellular matrix (ECM). In response to aging and injury, the IVD undergoes detrimental changes to its composition and structure. Notably characterized by a significant loss of GAG and consequently pressurization of the NP which leads to structural breakdown in the AF as the loading is altered from predominantly tension to compression within the AF.

As there is known association between disc degeneration and low back pain, the leading cause of years lived with disability in the US and around the world [1], there are emerging pharmacological and biomaterial therapies aimed at rescuing the composition and material properties of the IVD to restore its mechanical function. However, the ability to uniformly assess the efficacy of treatments that preserve and/or regenerate the IVD is burdened by a lack of standardized biomarkers that can be applied across the spectrum of *in vitro*, *in vivo* and clinical testing platforms. Conventional biochemical and histological assays for composition are destructive, obviating repeated measures and clinical assessment.

Raman spectroscopy is an inelastic light scattering technique that provides a non-destructive, quantitative, optical fingerprint of the molecular building blocks of key molecular constituents in the ECM of articular cartilage: GAG, COL, and H₂O. We recently demonstrated the capability of a Raman spectroscopic to perform high precision assessments of the composition of articular cartilage both *in vitro* and *in vivo* with extremely high correlation to the articular cartilage mechanical properties [2,3].

In the current study, we examine the capability of our Raman spectroscopy to assess the composition, as well as its correlation to mechanical properties, for IVD specimens in health and disease. Assessments are performed using an *in vitro* model system of isolated bovine IVDs subjected to enzymatic degenerative treatment to model compositional changes that are manifest in IVD degeneration.

METHODS

Twenty seven IVDs were isolated from six skeletally mature bovine oxtails and frozen until testing. The cartilage end plate was excised exposing the NP and AF. For an initial batch of 15 disks, Raman measures initially were performed on the center of the NP and at three positions within the AF to differentiate between the spectral properties of these tissue regions. These IVDs were subsequently subjected to an enzymatic degeneration treatment, consisting of incubation in PBS supplemented with 2mg/mL trypsin at 21°C. To prevent IVD swelling during digestion treatment [4], IVDs were confined between two meshed acrylic plates. A polymer filter was inserted used between the IVD and meshed plate to inhibit tissue herniation into mesh holes (Fig 1).

Fig 1. (A) Side view of IVD which is confined between two acrylic plates to restrict swelling during enzyme treatment regimens. (B) Top view of IVD with a polymer filter between IVD and mesh plate to inhibit tissue herniation into mesh holes.

IVDs were subjected to trypsin exposure for 0, 10, or 21 hours (N=5 IVDs per time point). Subsequently, each disk was subjected to

Raman probe analysis in the NP, which was subsequently axially cored via a Ø7mm biopsy punch and subjected to confined compression testing for the aggregate modulus. Mechanical testing consisted of three successive ramps of 5% applied strain (0.5µm/s), followed by 2 hour stress relaxation periods. An additional batch of twelve IVDs were subjected to trypsin exposure for 0 (N=8), 10 (N=2), or 21 (N=2) hours, after which, the NP was cored and subjected to biochemical analysis for water content (gravimetrically) and GAG content (DMMB assay).

Raman analysis: The Raman probe consisted of a NIR diode laser (ex=785nm, 500mW, B&W Tek), fiber-coupled spectrograph (QEPro, Ocean Optics), and needle probe with a 2mm sapphire ball lens [2]. Raman spectra were acquired with the probe lens in gentle contact with the disk surface over a 30s acquisition time. The spectral fingerprint range (800-1800cm⁻¹) was preprocessed and subjected to a multivariate least-squares linear regression model to decompose the Raman spectra to calculate the relative contribution of the predominant cartilage constituents (GAG, COL, and H₂O) to the composite cartilage Raman spectra (Equation 1).

$$\text{Cartilage}_{\text{spectra}} = \text{GAG}_{\text{SCORE}} * (\text{GAG}_{\text{REF}}) + \text{COL}_{\text{SCORE}} * (\text{COL}_{\text{REF}}) + \text{H}_2\text{O}_{\text{SCORE}} * (\text{H}_2\text{O}_{\text{REF}}). \quad (1)$$

where GAG_{REF}, COL_{REF}, and H₂O_{REF} are the component spectra of purified reference chemicals for each ECM constituent [2].

RESULTS

The cumulative spectral contribution of the extracellular matrix constituents by multivariate regression accounted for 94% of the variation in the IVD composite spectra (Fig.2B). Raman-derived biomarkers reflected the biochemical composition of the IVD, as marked by higher Raman GAG and H₂O scores in the NP, relative to the AF (Fig 2D&E). In response to trypsin exposure, NP regions IVDs exhibited a trend of decreased Raman GAG score with digestion time (Fig 3A). For these specimens, Raman GAG score predicted 60% of the variation in aggregate modulus (Fig 3B, p<0.001). For the second experiment of digested IVDs, the NP further exhibited a trend of increased Raman H₂O score with digestion time (Fig 3D). For these specimens, Raman GAG score predicted 80% of the variation in the assay-measured NP GAG content (Fig 3E) and 89% of the variation in the NP H₂O content (Fig 3F).

Fig 2: (A) Raman probe in contact with IVD. Representative 2D stacked area plot of contribution of GAG, COL, and H₂O to IVD Raman spectra in (B) NP and (C) AF. (D) Raman GAG score and (E) H₂O score in NP and AF.

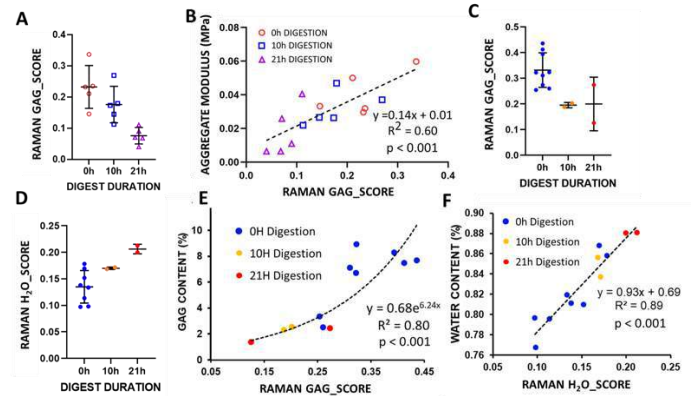

Fig 3: (A) Raman GAG score with trypsin digestion. (B) Correlation of Raman GAG score vs aggregate modulus. (C) Raman GAG score, and (D) Raman water score with trypsin digestion. Correlation of (E) Raman GAG score vs GAG content, and (F) Raman H₂O score vs H₂O content.

DISCUSSION

Results establish the capability of our Raman probe to achieve non-destructive measures of the composition and mechanical properties of IVD tissue specimens. Raman assessments are predicated on a spectral analysis that yields ECM-specific biomarker scores, which reflect the contribution of ECM constituents to underlying acquired Raman spectra. The Raman GAG score accounted for 80% of the variation in the assay measured GAG content and 60% of the variation in the aggregate modulus of the NP. The Raman H₂O score accounted for 89% of the variation in the measured water content. The ability of Raman analysis to faithfully characterize IVD tissue composition was further supported by differential analysis of NP and AF tissue regions, whereby Raman biomarkers depict the GAG and water rich composition of the NP in contrast to the collagen-rich makeup of the AF. These measures support the use of benchtop Raman probes to serve as a novel research tool for rapid, non-destructive, repeated-measure assessments of IVD composition and material properties. Here, Raman can serve as a standardized objective measure of IVD degeneration and treatment response across a heirarchy of preclinical model systems, spanning from *in vitro* explant tissue studies to *in vivo* animal investigations, thus helping to guide new therapies into the clinic.

INTRODUCTION

Tagged magnetic resonance imaging (MRI), a noninvasive approach for quantifying motion *in vivo*, has been previously applied to evaluate brain deformation in live human subjects during head rotation at low accelerations [1,2]. This approach uses a custom device designed to support and constrain the head motion of a human subject with an MRI scanner, facilitating the acquisition of repeated motions to build up the image data (Fig. 1a). Releasing a latch initiates a passive head rotation about the inferior-superior axis towards the left shoulder [2] (Fig. 2a). A rapid deceleration is caused by a padded stop after rotating about 32 degrees.

Two different approaches have previously been proposed to trigger the MRI tagging pulse and initiation of the scan acquisition. Standard triggering applies the tags and acquires the scan when the head rotation is initiated [1]. This approach suffers from inconsistent data due to its high sensitivity to variations in head kinematics. Because tagged MRI can require over 124 repetitions of the head rotation to obtain 3-dimensional (3D) data [2], such variations are highly likely to occur. To remedy this problem, a double trigger (DT) approach has been proposed [2], that applies tag lines when the motion is initiated, but only begins to acquire images near the end of the rotation. This approach has the advantage of realigning the data just before impact, increasing robustness to variations in the head kinematics. In this work, we propose a late trigger (LT) approach, which triggers both the tagging and acquisition near the end of the head rotation. An advantage of this approach over DT is that tag fading [3] is potentially reduced since the tag application is delayed. In addition, a limitation in the tagging scanner software limits the acquisition window (the duration of the scan following acquisition) to be equal to the time between the tagging trigger and the scan trigger when they are not equal. The LT does not suffer from this limitation, allowing for the acquisition of longer time histories (~2x time range) to characterize the brain deformation.

METHOD

MRI scanning was performed on a 3T Siemens mMR Biograph. To evaluate and optimize the tagged MRI acquisition, a gel phantom was used in lieu of the human subject. A homogenous phantom of Sylgard 527 silicone dielectric gel was fabricated with a 1:1.25 base:catalyst ratio (645 grams and 805 grams, correspondingly) [4]. The cylindrical gel-container was firmly fixed to the device. The angular position for each rotation was measured in real-time by an angular position sensor [2]. The LT applied a single trigger to initiate the SPAMM tagging acquisition at 25 degrees (impact is at 32 degrees). We first applied 8 rotations for each tag line direction, repeated twice. Secondly, we applied 4 rotations per tag line direction at reduced temporal resolution. For all phantom scans, images with two orthogonal tag line directions for measuring x and y displacements were acquired in an axial slice at the middle of the gel (Fig. 1b and 1c). Motion was tracked between image frames using harmonic phase (HARP) analysis with the shortest-path refinement algorithm [5]. Lagrangian strain tensors were computed from the displacement vectors.

Four healthy male adults (age: 38.8 ± 10.3 years) with no traumatic brain injury history were recruited (2 adults using DT with 4 rotations per tag line direction, and 2 adults using LT with 2 rotations per tag line direction). Note that the reduced number of rotations using LT was performed to increase subject comfort by reducing the number of phase encodes (PE) from 24 to 16. A third tag line direction on the sagittal plane was added in human scans to investigate the 3D motion, tracked using the HARP-FE method [6] (Fig. 2b-d).

Figure 1: (a) The head rotation device; (b&c) Axial plane with anterior-posterior and right-left tag lines of the gel phantom.

Figure 2: (a) Schematic of head at rest (dotted blue line) and stop (solid red line) positions; (b&c) Axial plane with anterior-posterior and right-left tagging lines of a subject; (d) Sagittal plane with anterior-posterior tagging lines of a subject.

RESULTS

The peak angular acceleration was $282.3 \pm 5.8 \text{ rad/s}^2$ ($N=80$ rotations) for the gel phantom and $236.3 \pm 75.2 \text{ rad/s}^2$ for the human subjects ($N=372$ rotations). In-plane maximum principal strain (E_1), maximum shear strain (G_{\max}), and the area fraction (AF) of E_1 greater than 0.02 were computed for the gel phantom (Fig. 3-5) and the human brain (Fig. 6-7). The E_1 maps of 5 time points around peak E_1 values of gel phantom with 8 rotations for each tag line direction were illustrated in Fig. 3. The repeatability test showed that the differences of the peak 95th percentile E_1 and G_{\max} between every two repeated scans for DT and LT were less than 5% in the first 150 minutes of data acquisition, while the differences of peak AF were less than 3%, indicating high reproducibility of the experiment (Fig. 4). When using 4 rotations, the differences of the measurements between DT and LT also showed a good match (Fig. 5). However, due to the lower stiffness of the phantom compared to human brain, this resulted in a somewhat under sampled measurement.

Figure 3: E_1 maps of 5 time points during the time of impact for gel phantom with 8 rotations for each tag line direction: (a) DT with 24 PE; (b) LT with 24 PE.

Figure 4: Gel phantom with 8 rotations for each tag line direction: (a) E_1 (95th %ile); (b) G_{\max} (95th %ile); (c) AF of $E_1 > 0.02$. TR = 6 ms.

Figure 5: Gel phantom with 4 rotations for each tag line direction: (a) E_1 (95th %ile); (b) G_{\max} (95th %ile); (c) AF of $E_1 > 0.02$. TR = 15.96 ms.

For a subject scanned using DT, a total of 124 rotations was needed, while for a subject scanned using LT and fewer PE required 62 rotations. The temporal resolution was 18.06 ms for DT scans and was 19.52 ms for LT scans. Distributions of in-plane E_1 over time of one

axial image are shown in Fig. 6. Time histories of E_1 , G_{\max} , and volume fraction (VF) had similar patterns within 50 ms during the time of impact, indicating the feasibility and reproducibility of the LT with 16 PE approach vs. DT with 24 PE (Fig. 7).

Figure 6: E_1 maps over time of 2 different human subjects: (a) DT with 24 PE (124 rotations per subject); (c) LT with 16 PE (62 rotations per subject). The second frame corresponds to the impact time.

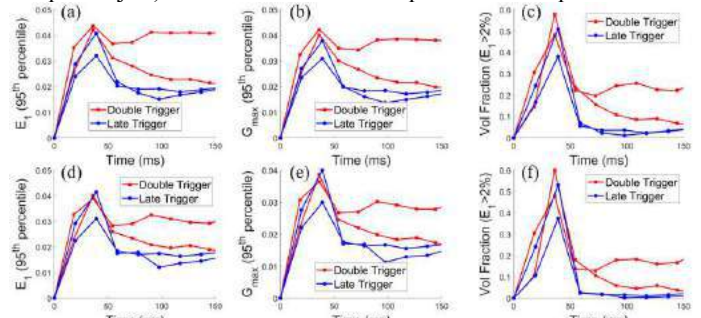

Figure 7: Human brain response in 4 different subjects: (a) E_1 (95th %ile); (b) G_{\max} (95th %ile); (c) VF of $E_1 > 0.02$. Top row: cortical gray matter. Bottom row: white matter. Each line represents one subject.

DISCUSSION

We evaluated a new acquisition approach using LT, which provided comparable results vs. DT in phantom experiments. The LT approach was successfully applied in human subjects in combination with a reduced number of rotations. The reduced rotations could save data acquisition time and reduce the fatigue of repeated neck rotation during MR scans. Lower residual strains following impact were visible, potentially a result of reduced tag fading and lower number of rotations. One limitation is that when using reduced number of rotations, temporal resolution was also slightly reduced. Investigation of strain patterns of these approaches on the same subjects and additional optimization of MR sequence parameters merit further study.

INTRODUCTION

Flow stagnation and the resulting high blood residence time are related to the severity of diseased arterial flow and the risk of thrombosis. As a non-invasive treatment for cerebral aneurysms, flow-diverting stents have been used to increase blood residence time and thus induce thrombus formation in the aneurysm sac [1]. Accurate quantification of the residence time in the aneurysm is crucial in assessing the effectiveness of the treatment. In this experimental work, we used time-resolved 3D particle tracking velocimetry (PTV) with a particle trajectory extension algorithm to quantify the blood residence time in a patient-specific cerebral aneurysm model. The effects of different inflow pulsilities on the residence time were studied after validating the method against more traditional pseudo particle tracking, which based on 3D velocity data. Results have shown that the highly pulsatile inflow causes a large variation and a significant increase in the mean blood residence time.

METHODS

The patient-specific PDMS (Sylgard 184, Dow Corning) flow phantom used in this study is shown in Fig. 1. The geometry was based on patient-specific CT image data, and the phantom was made by the lost core casting method. The aneurysm dome width is about 15mm, and the vessel diameter is 5mm.

Figure 1: The patient-specific cerebral aneurysm flow phantom.

The inflow to the model was generated by a computerized piston pump (Shelley Medical CompuFlow 1000) and monitored using a flow probe (Transonic Systems Inc.) at the inlet. Three waveforms with different pulsatility used in the study are shown in Fig. 2 and tabulated in Table 1. The patient-specific waveform was based on healthy adult measurement data [2]. The Pulsatility Index (PI) at 70 beats per minute is defined as:

$$PI = (\text{Max flow rate} - \text{Min flow rate}) / (\text{Mean flow rate}) \quad (1)$$

Figure 2: Three waveforms with different pulsatility indices.

Table 1: Mean, Max flow rates and PI for three waveforms.

	Constant	Patient-Specific	Sinusoidal
Mean flow rate (L/min)	0.47	0.46	0.33
Max flow rate (L/min)	0.47	0.56	0.73
PI	0	0.48	2.54

The four-camera 3D PTV setup is shown in Fig.3. Particles were illuminated by a thick (~10mm) laser volume that covered the entire aneurysm sac and part of the inlet and outlet vessels. To ensure zero image distortions, a Urea-Glycerin-Water mixture was used as the blood analog, which matched the viscosity of the blood ($\nu=3.5\text{cSt}$) and the refractive index of the PDMS rubber ($n=1.48$). During the experiment,

the flow phantom was placed in an optical box filled with the same solution. The particle traces viewed by the four cameras are shown in Fig. 4. The images were recorded at 1,200 fps and for about three cardiac cycles. Data was processed in DaVis 10, and particle trajectories at different time steps were obtained using Shake-the-Box (STB) algorithm [3].

Figure 3: Four-camera 3D PTV setup.

Figure 4: Particle traces viewed by four cameras from different angles.

RESULTS

Sample particle tracks color-coded by the velocity magnitude are shown in Fig. 5a. Unfortunately, the particle tracks generated from STB cannot be used directly to calculate the residence time due to the limited lengths of the tracks. As shown in Fig. 5b, most of the track lengths are less than 100 timesteps, not enough to follow a particle from the entrance to the exit. Moreover, many particles disappear or reappear in the aneurysm sac. To enable direct quantification of residence time, we employed a particle trajectory extension algorithm discussed in [4], which used adjacent particles' movements to extrapolate the missing particle's location to the next time step. The trajectory extension algorithm was applied forward and backward in time to ensure the particles could be traced continuously in the measurement domain. Figure 5c shows the length distributions after trajectory extension. The average length has increased drastically to over 100 timesteps.

Figure 5: (a) A sample particle track. Particle track length distributions (b) before and (c) after trajectory extension.

The mean residence times in the aneurysm sac for all three waveforms are shown in Fig. 6. The curves were obtained by setting the residence time for all particles to zero at $t=0$ and calculating the average age of the particles in the sac for all subsequent time steps. As a result, the mean residence time at $t=0$ is zero and increases gradually until a stable value is reached. For the constant inflow, the mean residence time in the sac plateaus around 0.27s, about 32% of a cardiac cycle length. The mean residence time for the patient-specific waveform varies slightly during a cardiac cycle, and the mean value for the three cycles is 0.31s, slightly higher than the constant inflow case. The mean residence time oscillates significantly for the sinusoidal waveform,

reaching near 0.7s. The mean residence time for the sinusoidal case is 0.40s, considerably higher than the other two cases.

Figure 6: Mean residence time in the aneurysm sac for three waveforms

To validate the accuracy of this new method, a more traditional 3D pseudo particle tracking study was carried out for comparison. First, 3D time-resolved velocity fields were reconstructed based on the original particle tracks [5]. Then, massless particles were continuously seeded at the inflow and tracked through time based on the velocity data, a method called pseudo-tracking. The tracking would stop once a particle exited the domain or reached the boundary of the model. The mean residence time can be calculated later using the same method for the PTV data. The comparisons between these two methods for two different flow waveforms are shown in Fig. 7. Results have shown good agreements between the two methods, and the pseudo-tracking method generates slightly higher residence times.

Figure 7: Residence time comparisons between two methods for (a) constant and (b) patient-specific waveforms.

DISCUSSION

The effects of different inflow pulsatility indices on the residence time in a patient-specific aneurysm was studied experimentally using 3D time-resolved particle tracking velocimetry. A method based on a particle trajectory extension algorithm has been developed to directly quantify the blood residence time based on the 3D particle tracks. Results have shown that increased pulsatility increases the residence time in the aneurysm sac, and the mean residence time varies with the pulsatile inflow. The accuracy of the method has been validated by comparing it with pseudo-particle tracking.

TELOCOLLAGEN INJECTABLE SIGNIFICANTLY IMPROVES SUPRASPINATUS TENDON MECHANICAL STRENGTH AFTER FULL-TENDON TEAR IN RATS

INTRODUCTION

Rotator cuff tears are extremely common, difficult to heal, and can significantly impair a patient's quality of life. The rotator cuff is a group of muscles and tendons attached to the humeral head, assisting with shoulder motion and stability. The tendons primarily comprise type I collagen, organized into a hierarchy of fibrils, fibers, and bundles. The intermolecular cross-linking and organization of the collagen is responsible for the tendon's tensile strength and ability to bear and transmit forces. These forces, in turn, can further strengthen the tendon by recruiting more collagen monomers and protecting against enzymatic degradation [1,2].

During the tendon healing process, cells are recruited to synthesize collagen and other extracellular matrix (ECM) molecules which form fibers that are then remodeled and organized. Unfortunately, tendon repair is a complex and slow process. Many patients are unable to fully heal, even after surgical intervention, and tendon retear is common [3]. To improve tendon healing and strength, many bioengineering therapies are currently being explored, such as extracellular patches, stem cells, and growth factors. Collagen-based therapies primarily comprise xenogeneic atelocollagen, where the potentially immunogenic collagen telopeptides have been cleaved, but no significant conclusions have been drawn from clinical trials [3]. We hypothesize this is due to the lack of telopeptides. During collagen fibril formation, telopeptides form covalent cross-links with adjacent collagen molecules, increasing the speed of collagen fibril self-assembly and providing strength. Atelocollagen molecules only associate via hydrogen bonding, resulting in a weaker structure [4]. We hypothesize that telopeptides (present in telocollagen) are essential for tendon repair, strength, and function.

The aim of this study was to address the deficiencies in current atelocollagen therapies by comparing the healing capabilities of telocollagen, atelocollagen, and saline injection treatments after a full-thickness rotator cuff tear in a rat model. We hypothesize that active

telocollagen will home to the damaged tissue, undergo fibrillogenesis in the path of load, and cross-link with the tendon, resulting in increased mechanical strength when compared to atelocollagen and saline.

METHODS

Telocollagen, Atelocollagen, and Saline Injection Preparation. To create atelocollagen, 3mg/mL rat telocollagen (Advanced Biomatrix) was incubated with 0.03 mg/mL pepsin for 3 days, and then salted out to remove pepsin. Atelocollagen was confirmed by assessing its polymerization kinetics [5]. Telocollagen and atelocollagen solutions were concentrated to 10 mg/mL and a saline solution was created. All treatments were sterile, kept at pH 3, and had a final concentration of 1X Penicillin-Streptomycin and 0.9% sodium chloride. Single-dose syringes were prepared and kept at 4°C until injection.

Trackable Collagen Preparation. Azidohomoalanine (Aha), a noncanonical amino acid that can replace methionine and subsequently be fluorescently labeled with click chemistry, was used to create trackable collagen [6]. RAT2 fibroblast cells were cultured at 37 °C with 5% CO₂ with complete media comprising DMEM with 4 mM L-glutamine, 4.5 g/L glucose, 1 mM sodium pyruvate, 10% fetal bovine serum, 0.5 mM L-ascorbic acid, antibiotic, and antimycotic. On day 16, 500 µM Aha was added to cell media and incubated for 48 hours. Then, cells were fixed and stained with Click-iT DIBO Alexa Fluor 488 and confocal microscopy was performed. We attempted to extract this trackable Aha-collagen [4]; however, we were unable to achieve this within the timeframe of this study.

Tendon Detachment and Repair. 36 male adult Sprague-Dawley rats underwent bilateral detachment and transosseous repair of the supraspinatus tendon [7]. Each shoulder received a series of three injections (either 3 saline, 3 atelocollagen, or 3 telocollagen) in the subacromial space. Injections occurred immediately after surgery, postop day 7, and postop day 14. Animals were euthanized at either 30-

or 60- days post-surgery, and for each shoulder, the humerus and supraspinatus tendon were collected. For each treatment group and healing time (saline-treated, atelo-treated, telo-treated, day 30 and day 60), 8 tendons were used for mechanical testing and 4 were used for histologic scoring. Control rats that were weight-matched for day 30 and day 60 rats did not undergo surgery and tendons were used for mechanical testing.

Mechanical Testing. Following established protocols for rat supraspinatus mechanical testing [7], the tendon's cross-sectional area was measured using a 670 nm laser and the humerus was potted with polymethyl methacrylate. Tendons were loaded into the ElectroForce 5500 mechanical tester and submerged in 37°C 1X phosphate buffered saline. They underwent preconditioning, stress relaxation test, frequency sweep, and quasistatic ramp to failure. Load at failure, failure stress, percent relaxation, and stiffness were calculated. The stress-time curve was fitted to Equation 1 to determine τ_1 and τ_2 .

$$E = E_0 + E_1 e^{-x/\tau_1} + E_2 e^{-x/\tau_2} \quad (1)$$

RESULTS

Mechanical testing results are shown in **Figure 1**. 30 days post-surgery, telo-treated tendons had the largest cross-sectional area which remained constant from day 30 to day 60. Conversely, the area of saline-treated and control tendons significantly increased ($p=0.03$) from day 30 to day 60. After 60 days, atelo-treated tendons had the lowest area which was significantly less than control tendons ($p=0.02$) and slightly less than saline-treated tendons ($p=0.33$).

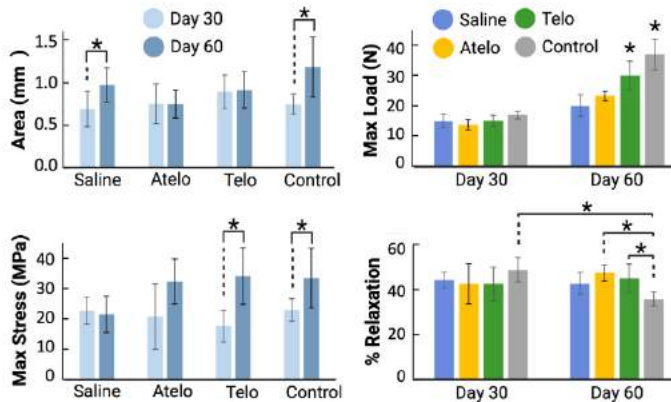

Figure 1: Results of mechanical testing. Data shown as average \pm standard deviation, asterisks represent statistical significance ($p < 0.05$)

On day 30, there was no significant difference in maximum load between experimental tendons, and by day 60, all tendons could withstand significantly more load than day 30 ($p < 0.02$). 60 days post-surgery, telo-treated tendons could withstand significantly more load than atelo-treated ($p=0.025$) and saline-treated tendons ($p < 0.01$) but less than control tendons ($p=0.02$). When normalized for cross-sectional area, the tensile strength significantly increased for only telo-treated and control tendons ($p < 0.03$) over time, and by day 60, and these tendons could withstand the same maximum stress ($p > 0.9$).

The percent relaxation for control tendons significantly decreased ($p=0.005$) from day 30 to 60 and was lower than atelo-treated ($p=0.015$), telo-treated ($p=0.001$), and saline-treated tendons ($p=0.06$) on day 60. Control tendons were significantly stiffer ($p < 0.0001$) than all experimental groups on day 60. No significant differences were found for τ_1 , and control tendons had a significantly higher τ_2 ($p=0.03$) than telo-treated tendons on day 60.

While we did not successfully extract Aha-collagen to inject in our animals, we successfully induced its production in cell culture. **Figure 2** shows that Aha-collagen incorporated into cell-synthesized ECM throughout the depth of the culture and was successfully labeled with DIBO Alexa Fluor 488. This bio-orthogonal collagen reporter will be critical to assess telocollagen treatment in the future.

Figure 2: Confocal microscopy of RAT2 cells. Aha-collagen (green) incorporates into collagen fibrils in the extracellular matrix.

DISCUSSION

These results demonstrate that our low-dose telocollagen injectable treatment significantly improves tendon strength and healing within 60 days when compared to saline and atelocollagen treatments in a rat model of a full-thickness supraspinatus tendon tear and surgical repair. Telo-treated tendons formed a larger amount of weak tendon within 30 days post-surgery which strengthened and further organized over time, by day 60, telo-treated tendons could withstand significantly more load than atelo-treated and saline-treated tendons. This suggests that lysyl oxidase-mediated cross-linking begins between day 30 and 60. Additionally, saline-treated tendons had the same tensile strength on day 30 and day 60, suggesting that the tissue formed between day 30 and day 60 was not load-bearing and likely not cross-linked.

The Ruberti Lab has previously demonstrated that strain alone can drive the organized assembly of Type I collagen monomers [8], monomers home to and incorporate with existing collagen fibrils under load [2], and monomers incorporate with existing collagen in cell culture [5]. To determine if our collagen injectable incorporated with the healing tendon, we created trackable Aha-collagen, but were unable to extract it and use it in this study. We plan to conduct future research with Aha-collagen to track the fate of our injectables. Ultimately, these results provide a possible materials-based mechanism for tendon healing and suggest that telocollagen is “active” during the repair process; without telopeptides, collagen treatments are likely not capable of creating a stable, long-lasting, or mechanically robust repair.

IN VIVO MULTISCALE MEASUREMENTS OF SOLID STRESSES IN PRIMARY AND METASTATIC TUMORS

INTRODUCTION

Solid stress, defined as the mechanical force generated and transmitted by the solid components of a tumor, is a newly identified physical hallmark of cancer with crucial consequences for tumor progression and treatment response¹. Cells sense solid stresses directly and indirectly via mechanosensitive interactions such as cell-extracellular matrix (ECM) and cell-cell adhesions, activation of tensile-responsive ECM proteins, and nuclear deformation. Solid stress causes the compression of blood and lymphatic vessels which contributes to hypoxia and impedes drug delivery, affects T-cell trafficking and infiltration, promotes invasiveness of cancer cells, stimulates tumorigenic pathways, and induces neuronal damage. Targeting solid stress, when combined with standard-of-care anti-cancer treatments, prolongs survival in preclinical studies and is currently being evaluated in clinical trials²⁴ with promising outcomes. While some of the pathophysiological consequences of solid stresses in tumors are now better known, the direct cellular responses to solid stresses and the molecular pathways that are directly activated by them are not fully understood. This is due mainly to a lack of appropriate tools to measure the solid stresses that individual single cancer cells experience *in vivo*, where the complexities of tumor microenvironment are present.

Despite the recent progress in measuring solid stresses *ex vivo* and *in vitro*, *in vivo* measurement of solid stress in tumors is an unmet need. An *in vivo* measurement of solid stress with high spatiotemporal resolution would allow deeper insight into the origins and consequences of solid stresses. In addition, the existing methods to measure solid stresses in murine and human tumors are at the tissue scale and lack the spatial resolution to measure the stresses that individual tumor cells experience. These existing methods are also invasive, typically performed at terminal points, and lack the capabilities for longitudinal monitoring of solid stresses. Furthermore, the existing methods are limited to reporting 1-D and 2-D profiles of solid stresses and do not

provide the 3-D distribution of solid stress as a tensor, which is necessary to describe the anisotropy and heterogeneities of stresses. Therefore, it is critical to develop a method to non-invasively monitor *in vivo* solid stresses at high spatiotemporal resolution across the length scales from the cellular to the tissue scale.

METHODS

Fluorescent PAMs were fabricated (tissue-scale: $397 \pm 69 \mu\text{m}$, cellular-scale: $28.7 \pm 18.2 \mu\text{m}$) and conjugated with fibronectin. For primary breast cancer, mammary intravital windows were implanted on female FVB/NJ mice and PAMs were co-injected with MCA-M3C-H2B-dendra2 cancer cells into the mammary fat pad. Two-photon microscopy (2P) and optical coherence tomography (OCT) was used to image *in vivo* cellular- and tissue-scale PAMs, respectively (Fig. 1). For lung metastasis experiments, PAMs and cancer cells were co-injected via tail-vein. After ~4 weeks, the lung was extracted and imaged using 2P and confocal microscope. Procedures were approved by BU IACUC. Finite-element modeling was used to translate stress-induced deformation to solid stress.

Figure 1. a, Multi-scale intravital microscopy to estimate solid stress in primary and metastatic tumors from the same cancer cells.

RESULTS

Figure 2. Validation of solid stress measurement at the cellular and tissue scales *in vivo*. a, Relaxation of solid stresses at the tissue scale was demonstrated by enzymatic treatment (collagenase/hyaluronidase) of the tumor *in situ* post-euthanasia and imaging of the beads.

Using intravital microscopy of deformable PA beads, we quantified solid stresses in *in vivo* murine tumors at the cellular and tissue scales in 3-D (Fig. 2). Tumors with cellular-scale beads were formed separately from tumors with tissue-scale beads. We measured the bead aspect ratios after pushing them through 25G and 23G needles (for cellular and tissue scale, respectively) used for tumor injections and our analysis shows that the beads exhibited an aspect ratio of approximately 1 before injecting them into mice. When PA beads are injected into the mammary fat pad without cancer cells and immediately imaged, the aspect ratios of the beads are 1.26 ± 0.10 , suggesting that the baseline mechanical stress applied to the spheres by surrounding normal tissue is much smaller than the deformation measured in the presence of tumors. 5-7 days after injecting the PA beads and MCA-M3C-H2B-dendra2 cancer cells into the mammary fat pad of mice, we observed unexpectedly dramatic deformations in the PA beads with an aspect ratio of 3.41 ± 0.59 (mean \pm STD, N=4) *in vivo* at the tissue scale measured via OCT (Fig. 3a), and aspect ratio of 1.87 ± 0.42 (mean \pm STD, N=3) *in vivo* at the cellular scale measured via two-photon microscopy. Thus, we next sought to determine if the deformation was plastic (irreversible) or elastic (reversible), and if the beads were still intact or broken. To investigate this, we used enzymatic dissociation of the tumor as an effective method to relax the intratumoral solid stresses to observe the relaxation of the highly deformed PA beads to their original stress-free geometry. For the *in vivo* setting, we used a solution

of collagenase and hyaluronidase immediately post-euthanasia *in situ*, and longitudinally imaged the relaxation of the solid stress reflected by a change in the geometry of the PA beads using two-photon microscopy and OCT.

We report the first *in vivo* measurement of intratumoral solid stresses in primary and metastatic settings in mice, and report the unexpected finding that solid stresses experienced at the cell level is significantly lower than that at the tissue level. Our method equips cancer researchers with a multi-scale tool to better understand the spatiotemporal evolution of cancer biophysics and will further inform the discovery of new therapeutic strategies that sensitize cancer cells to solid stresses to e cell death.

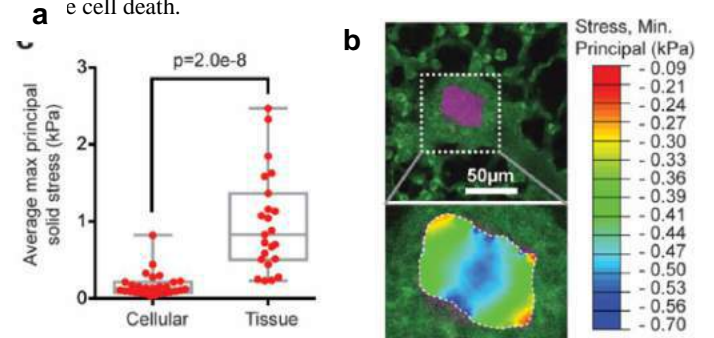

Figure 3. (a) Scale-dependence of solid stress *in vivo* (mean \pm STD, unpaired t-test). (b) Deformed PAM (magenta) in lung microvasculature (green).

The principal solid stress at the tissue scale (0.978 ± 0.64 kPa) was significantly higher (6x) than that of the cellular scale (0.172 ± 0.15 kPa) (Fig. 3a). This was unexpected, as stress (force normalized by area) does not depend on the scale of measurement in homogeneous and linear materials. This finding implicates the presence of potential biophysical mechanisms that dissipates solids stress at the cellular scale and protect tumor cells against lethally high solid stresses. Imaging of lung micrometastasis revealed that cellular-scale PAMs are arrested at the arteriole-capillary junction. Through imaging the deformation of PAMs in the microvessels, we quantified the stresses that single cancer cells experience inside lung microvasculature during metastasis (Fig. 3b).

DISCUSSION

We report the first *in vivo* measurement of solid stresses in mouse models of primary breast cancer and breast cancer lung metastasis. There are four (i-iv) key advantages of our method over existing methods. (i) Longitudinal monitoring of the solid stress, as opposed to the terminal point measurements in existing methods, is critical to characterize the role of solid stress in tumor progression and treatment response. We demonstrate this capability by longitudinally monitoring the stress relaxation *in vivo*. (ii) Our *in vivo* method allows multi-scale measurement of the solid stresses. (iii) Our method affords a measurement of the full magnitude and direction of solid stresses. (iv) Finally, our method accounts for solid stress exerted by surrounding normal tissues since tumors are retained *in situ* and are not excised.

INTRODUCTION

The integrity of the cell nucleus is a function of structural stability involving proteins found in the nuclear envelope and maintenance of genomic architecture. A loss of nuclear integrity presents structurally as an abnormal nucleus morphology, and impacts downstream mechanotransduction events as well as chromatin organization and containment. Alterations in the physical environment such as an increase in stiffness or perturbations in applied mechanical force, impact nuclear structural integrity and cellular differentiation [1,2]. This can result in architectural disruption of the nucleus both along the nuclear envelope (i.e. nuclear wrinkling or increased nuclear area) and disorganized spatial localization of heterochromatin domains as seen in disease states such as cancer and cardiac fibrosis [1].

Force transmission from the environment to the nucleus is modulated through the cytoskeletal network, nuclear envelope, and nuclear lamina. Maintenance of nuclear architecture at the nuclear periphery involves interactions between the chromatin and nuclear lamina. Along with the fibrous network of Lamin A/C and Lamin B proteins, epigenetic modifiers help to organize and support the physical tethering of the chromatin to the nuclear periphery [1].

Previous work from our laboratory has demonstrated that H3K9me3 plays a crucial role in maintaining the cardiomyocyte (CM) phenotype and changes to substrate stiffness, and tissue stiffening disrupts the spatial organization of H3K9me3 and influences the cellular differentiation of CMs [3]. Additionally, we have shown substrate stiffness alters nuclear strains in the actively contracting CMs with cells on stiffer substrates having altered intranuclear strain [4]. Our objective of this study was to determine the extent to which the presence of H3K9me3 protects the structural integrity of the nucleus in the CM. We hypothesized that the restoration of H3K9me3 and chromatin spatial organization using epigenetic treatments could aid in decreased cellular differentiation, and provide structural support necessary for force transmission. To assess this, we exposed CM cultures to substrates of

varying stiffness and inhibitors of epigenetic modifiers to examine the effects on nuclear architecture and organization.

METHODS

Substrate Preparation: 3.5cm² ibidi dishes were coated with Sylgard 527 PDMS at two ratios (A:B), 1:1 (Soft, healthy model) and 1:4 (Stiff, diseased model). A 100µm PDMS layer was deposited uniformly across the culture area. PDMS coated dishes were degassed and cured overnight at 80°C. 24 hours prior to the tissue harvest, dishes were sterilized, plasma treated, and coated with Geltrex overnight at 37°C. **Cell Culture:** Primary cardiac cultures were derived from embryonic (E18.5) H2b-eGFP mice (Jax# 00609). Embryonic hearts were isolated and digested in an enzymatic cocktail at 37°C with gentle agitation. Cardiac co-cultures were plated at a concentration of 1x10⁶/mL in 3.5cm² dish on different substrate stiffnesses (Soft or Stiff) for 4 days. Medium changes occurred on day 1 and 2 along with epigenetic treatments. To study restoration of the healthy phenotype, only cells plated on Stiff substrates received epigenetic treatments. On day 4, cultures were fixed with 4% PFA. **Epigenetic Treatments:** Cardiac cultures were treated with inhibitors of epigenetic modifiers: ML324 (5µM), GSK343 (2µM), or DMSO (0.1%, vehicle control). ML324 is the KDM4 inhibitor which should lead to an increase of the methylation of H3K9. GSK343 is an Ezh2 inhibitor which disrupts the methylation of H3K27. **Microscopy/Immunofluorescence:** All samples were stained with Phalloidin Texas-Red (561nm) and conjugated H3K9me3-640R (633nm). Endogenous GFP signal allowed for visualization of the nucleus without secondary labeling. Using a Nikon A1R confocal, z-stacks of each nucleus were collected with an oil immersion objective at a resolution of 0.08µm/pixel. **Image Analysis:** Max intensity z-projected stacks were created in ImageJ and analyzed using a custom MATLAB code. Peripheral enrichment (PE) was calculated as the ratio of the normalized fluorescent intensity of the performed on max intensity z-projected images.

RESULTS

Primary cardiac cultures were plated on Soft (13kPa) and Stiff (140kPa) PDMS substrates of similar stiffness to that of healthy and diseased cardiac tissue, respectively (Figure 1). With confocal imaging, we observed an increase in PE of H2b-eGFP and H3K9me3 fluorescent intensity in CMs on Soft PDMS with DMSO compared to the Stiff PDMS with DMSO. This confirmed that DMSO did not influence nuclear architecture and reproduced previous studies from our lab [3]. To test if we could restore the PE of H3K9me3 in cardiomyocytes, we treated cardiac cultures with ML324 and GSK343. We observed an increased in H3K9me3 towards the nuclear periphery in ML324 treated cultures (Figure 1).

Figure 1: Epigenetic treatment of cardiac cultures impacts nuclear organization in cardiomyocytes. Representative image slices of nuclei from cardiomyocytes (CMs) on Soft (13kPa) and Stiff (140kPa) substrates with epigenetic treatments, ML324 or GSK343. Localization of H3K9me3 of CMs on Stiff PDMS substrates treated with 5 μ M ML324 appeared to have similar localization of H3K9me3 at the nuclear periphery as CMs cultured on Soft PDMS substrates. Soft and Stiff cultures include DMSO (vehicle control). Scale bar = 10 μ m.

After quantifying our observations with a custom MATLAB code, we confirmed that CMs on Stiff substrates had decreased PE levels compared to CMs on Soft substrates as previously shown [3]. Surprisingly, we observed an increase in H2b PE for CMs cultures on Stiff substrates that were also treated with ML324 or GSK343 (Figure 2A). Examining the PE of H3K9me3, we found the PE of CMs on the Soft substrate increased compared to the CMs cultured on the Stiff substrate (Figure 2B). CMs treated with ML324 showed an increase in PE of H3K9me3 compared to CMs on the Stiff substrates, suggesting that the ML324 treatment rescues the PE levels of CMs cultured on Stiff substrates. Other studies have observed an increase in H3K9me3 with a decrease in H3K27me3 levels with the treatment of GSK343 [5]. However, no increase in H3K9me3 PE was observed with GSK343 (Figure 2B). To examine if the changes in H3K9me3 PE were due to increased H3K9me3 throughout the nucleus, we counted H3K9me3 foci. While we still observed an increased number of H3K9me3 foci on Stiff PDMS, ML324 or GSK343 treated CMs displayed a decreased shift in the distribution of foci (Figure 2C).

DISCUSSION

Previous work has shown that culturing CMs on Stiff substrates not only drives the loss of the cardiomyocyte phenotype, but also a

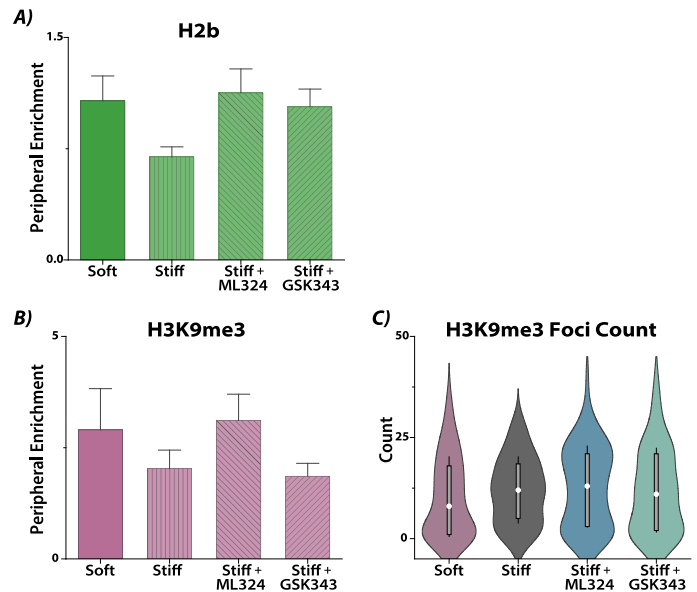

Figure 2: CMs treated with ML324 or GSK343 have increased peripheral enrichment (PE) and altered H3K9me3 organization. A) PE levels of H2b for CMs on Soft PDMS and Stiff PDMS treated with 5 μ M ML324 and 2 μ M GSK343 were elevated compared to CMs on Stiff PDMS. B) PE of H3K9me3 displayed a trending increase in CMs on Stiff PDMS treated with ML324 similar to CMs on Soft PDMS. Error bars = s.e.m. C) The distribution of H3K9me3 foci was affected by substrate and epigenetic treatments, ML324 and GSK343. Box = 25th to 75th percentile, \pm s.d., circle = median. N = 3 animals, n>20 nuclei per treatment.

change in the nuclear architecture [3]. We have also previously linked this change in nuclear architecture to cardiac disease states in which there is an altered mechanical environment (e.g. cardiac hypertrophy). This most recent work shows preliminary evidence that epigenetic treatments can restore the nuclear architecture of CMs cultured on Stiff substrates (diseased model) to that of the nuclear architecture of CMs plated on Soft substrates (healthy model). While we expected an increase in H3K9me3 in the nucleus due to the decrease in the demethylase inhibitor, KDM4, it was unclear how the treatment would alter nuclear architecture in terms of H3K9me3 spatial organization. Finding that the epigenetic treatment restores PE of H3K9me3 and H2b could indicate a cellular state similar to that of the CMs on the Soft substrates. Gene expression analysis for key markers of cardiac maturation can be used to validate the (de)differentiation with the epigenetic treatments. Future work involving GSK343 and H3K27me3 will examine potential causes of the increased PE of H2b. Finally, how restored levels of H3K9me3 and H2b around the nuclear periphery aids in improving structural integrity will be examined through live cell imaging of actively contracting CMs. Using deformation microscopy [4], results will be evaluated to examine the extend that increased H3K9me3 provides structural support leading to decreased intranuclear strains during cellular contraction.

INTRODUCTION

Many organs or tissues exist lumens, and reach to certain sizes during development and maturation. Understanding the development and growth of lumen holds the key for disease modeling and future functional regeneration of distal organs with lumen. While the chemical regulations, such as water and ions transportation are well understood [1], the mechanical regulation of lumen growth and the equilibrium luminal size remain relative unknown.

METHODS

Alveolosphere Model. To study the mechanical regulations of lumen growth, we use a human lung alveolosphere system cultured in 3D in Matrigel (FIG. 1a) [2-3]; this system contains a monolayer of human induced pluripotent stem cells (iPSC)-derived alveolar epithelial type II cells (iAEC2s) and exhibits a spherical lumen. These iAEC2s cells express a global transcriptome and ultrastructure that resemble primary adult Alveolar epithelial type 2 (AT2) cells, thus serving as an *in vitro* model of AT2-related human lung development and diseases. The lumen grows bigger during the growth of alveolospheres and eventually appear an equilibrium luminal size.

Mechanical Force balance. Since the alveolosphere is highly spherical, tension should be dominant in preserving the shape. Therefore, Laplace's law must be satisfied [3],

$$\Delta P = P_o - P_i = \frac{2\sigma}{R} \quad (1)$$

where ΔP is the hydrostatic pressure difference between inside and outside of lumen, σ is surface tension, and R is alveolosphere radius. Hydrostatic pressure difference caused by surface tension.

Water Transportation. The hydrostatic pressure difference caused by higher luminal ion concentration drives passive water transport from inside lumen to outside, while the osmotic pressure difference drives passive water transport from outside into lumen. Together, the net water transport is from outside into lumen: $J_w =$

$\Lambda_w(\Delta\pi - \Delta p)$, where Λ_w is the cell layer permeability. Therefore, our simplified volume conservation equation becomes

$$dR/dt = \Lambda_w(\Delta\pi - \Delta P) \quad (2)$$

Which tells that the change rate of radius is related to the osmotic pressure difference and hydrostatic pressure difference.

Figure 1: Force balance and water & ions transport in human iPSCs derived lung iAEC2s.

RESULTS

To measure the evolution of $\Delta\pi - \Delta p$ during lumen growth, we perform osmotic compression by adding PEG300 (1.0-2.0v/v%) outside the lumen. Interestingly, we observe that when the hyperosmotic shock π_s is not too large, the size of alveolosphere will decrease first and then increase, which suggests a minimum radius during this process. When the π_s is too large, the alveolosphere lumen will collapse, and therefore the tension becomes compression within the cell layer (Fig. 2). In Eqn. (2) when the minimum size radius is reached, we have $\Delta\pi = \Delta p$ (Fig. 3a). As we analyze the change of $\Delta\pi$ during this process (Fig. 3b), we find that for osmotic pressure difference $\Delta\pi$, it suddenly decreases by a value of π_s after hyperosmotic shock is added. Afterwards, the sphere shrinks and ion concentration increases, resulting in the increase of osmotic pressure. The osmotic pressure difference will increase until the minimum radius is achieved when $\Delta\pi = \Delta p$, and at this moment the radius reaches to a minimum.

Figure 2: Alveolosphere morphology and force change after osmotic compression.

To relate the lumen radius change with initial osmotic and hydrostatic pressure difference $\Delta p_0 - \Delta \pi_0$, we integrate the volume conservation equation over time

$$R_0 - R_{min} = \Lambda_w \left(\frac{1}{2} t_{min} (\Delta p_0 - \Delta \pi_0 + \pi_s) \right) \quad (3)$$

Rearrange the above the equation, we have

$$\Delta \pi_0 - \Delta p_0 = -\frac{2}{\Lambda_w t_{min}} (R_0 - R_{min}) + \pi_s \quad (4)$$

where the original osmotic pressure difference minus hydrostatic pressure difference $\Delta \pi_0 - \Delta p_0$ can be calculated by measuring t_{min} , $R_0 - R_{min}$, hyperosmotic shock π_s . The measurement of a series $\Delta \pi_0 - \Delta p_0$ with different alveolosphere radii is shown in Fig. 3c-d. Indeed, we find that $\Delta \pi_0 - \Delta p_0$ decreases as the radius of alveolosphere increases. When $\Delta \pi_0 - \Delta p_0$ reaches 0, the alveolosphere stops growing. This indicates a maximum lumen size for alveolospheres system $R_{max} \sim 150 \mu m$, which is consistent with the size of largest alveolosphere range that we observe.

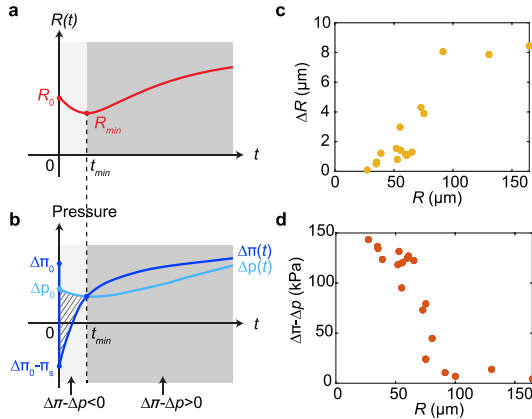

Figure 3: The difference between osmotic pressure and hydrostatic pressure evolution with growth measured by osmotic compression.

To measure the cell layer tension and thus calculating hydrostatic pressure difference, we use micropipette aspiration method (Fig. 5) [5]. At steady state, the cell layer tension can be calculated by Laplace's law,

$$\sigma = \frac{\Delta p}{2} \frac{R_p R}{R - R_p} \quad (5)$$

where the suction pressure is when the tongue length is equal to the micropipette radius R_p and R is the radius of alveolospheres at that time point. The elastic modulus of cell layer can be measured based on [6],

$$\Delta P = \frac{2\pi}{3} E \frac{L_p}{R_p} \phi \quad (6)$$

From the experimental data, we find that the surface tension is $\sim 20 \text{ mN/m}$, corresponding to $\Delta P \sim 10 \text{ kPa}$. The elastic modulus of cell

layer is $\sim 876 \text{ Pa}$. Using this method, we can measure the evolution of cell layer tension, hydrostatic pressure difference, as well as cell layer elastic modulus during the lumen growth.

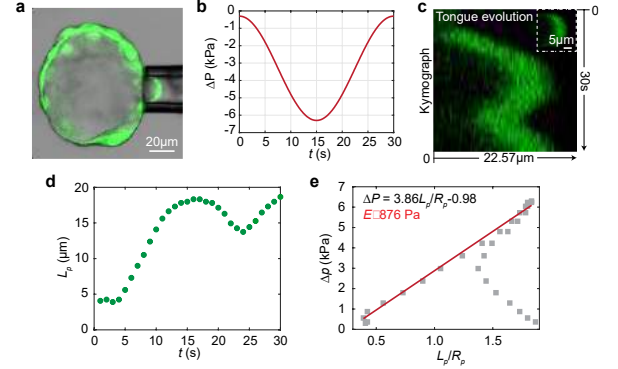

Figure 4: Tension evolution with the growth of alveolospheres.

Furthermore, with this mechanical understanding, a phase diagram explaining how mechanical factors together regulate the equilibrium size is shown in Fig. 5. Pumping ions regulates the osmotic pressure difference, while the cell layer tension regulates the hydrostatic pressure difference. When osmotic pressure equals hydrostatic pressure, an equilibrium lumen size will be reached. As tension in cell layers increases, the equilibrium luminal size decreases; as the pumping ion speed or pump density increases, the equilibrium luminal size will increase.

Figure 5: Phase diagram of the mechanical and chemical regulations of lumen growth.

DISCUSSION

To summarize, we study the mechanical regulations of lumen growth and understand the equilibrium luminal size using a human iPSCs-derived alveolosphere system. We find that hydrostatic pressure, osmotic pressure, and cell layer tension together regulate the lumen growth: as lumen grow bigger, $\Delta \pi - \Delta P$ decreases; when $\Delta \pi - \Delta P$ becomes zero, the lumen reaches to maximum size. These findings are essential for understanding other luminal developmental processes as well, such as the budding process of intestinal organoids.

INTRODUCTION

Low back pain (LBP) is a debilitating condition that is currently listed as the leading cause of disability globally.¹ As a result, the ailment has a high cost both from a health and a socioeconomic perspective. The inability to adequately localize the pain source in LBP and the complexity of the lumbar region necessitates kinematic understanding of lumbar vertebrae to better understand mechanically induced LBP. The functional unit exhibits coupled motion patterns dependent on anatomic variability such as bone morphology, ligament rigidity/laxity, and muscular strength.² Bony morphology contributes predominantly to off axes motion and can be highlighted by measuring the proximity of the facet joints that make up the functional unit of the spine. The degree motion coupling can be understood through an instantaneous helical axes (IHA) approach to generate rich temporal, three-dimensional measures of spinal motion.³⁻⁶ Identifying the instance when coupling is initiated during motion is critical to understanding the behavior of the spine under load and abnormalities due to pathology. The lax zone of motion has been shown to highlight the region of minimal kinematic impedance by the bone morphology, ligament rigidity/laxity, and muscular strength and its end points can act as an aggregate measure of where the resistance of motion begins.⁷⁻⁸ This work aims to investigate coupled motion patterns observed within the L4-L5 functional unit of the spine by quantifying helical axis orientation and facet joint proximity of the segment throughout motion.

METHODS

Seven lumbar spines (age 61 ± 17 yrs; 5 male) were obtained by the University of Minnesota Anatomy Bequest program and screened for spinal abnormalities. The L4 and L5 segments were osteoligamentously isolated and four 1mm tantalum beads were embedded into the transverse processes and vertebral bodies for each vertebra. The spinal units were each imaged with a CT scanner utilizing a B60 kernel scan sequence to enable high contrast between the surrounding tissue and the

bone (Siemens Biograph PET/CT, Germany). To prepare the bone for kinematic testing, the superior and inferior portion of the segments were potted in polymethyl methacrylate and care was taken to insure proper alignment of the L5 vertebrae. Each specimen was then loaded into calibrated Spine Kinetic Simulator (8821 Biopuls, Instron, USA). Retroreflective makers were rigidly drilled into the vertebral bodies of the specimen to be recorded via optical motion capture at 100Hz (MX 40, Vicon Motion Systems, Centennial, CO). Each of the embedded beads were digitized to ensure proper bone model transformation. Pure moments of up to 7Nm were applied to the segment for axial rotation, flexion/extension, and lateral bending at 0.015Hz for 3 cycles of preconditioning and 1 cycle for data analysis.

Mimics Software (Materialise NV, Leuven, Belgium) was used to segment the CT images into bone models. The tantalum beads positions were recorded and their relationships to the anatomic landmarks located on adjacent surfaces of each endplate established within the CT coordinate system. The spine tester and optical motion capture data underwent a spatial frequency analysis to establish lowpass Butterworth cutoff frequencies and were filtered at 15Hz and 6 Hz, respectively and were time-synchronized. Kinematic data was transformed to the anatomic landmarks using a custom MATLAB code that utilized the digitized beads to link the CT and optical motion capture coordinate systems.

The fourth cycle was isolated and lax and stiff zones were determined by the zero-load extrapolation process as outlined in Crawford et al.⁸ The linear regions of the hysteresis curve were calculated via linear regression, and the fit was extrapolated to zero load where the corresponding moments were recorded. (Figure 1) These points act as the boundary between the lax and stiff zone. Helical axes were calculated over a 0.42Nm increment for all directions of bending.³⁻⁴ The axes were categorized based on the zone and its alignment to the L5 coordinate system computed. The kinematics were applied to the bone models of one specimen (37F) via a custom MATLAB

program and the proximity maps of the facet surfaces generated by calculating the minimum Euclidean distance between the facet surfaces of L4 and L5. The percent change was dynamically calculated.

Figure 1: Lax Zone-Stiff Zone calculation: Lax zone of the hysteresis curve shown in green, and the stiff zone shown in red. The lax zone's percentage of the applied moment reported across all specimens.

RESULTS

Figure 2 displays the helical axes for one specimen during a flexion extension movement. The average orientation was calculated across all specimens for each motion. The helical axes were better aligned with the primary anatomical axes within the lax zone when compared to the stiff zone for all motions. Figures 3 and 4 display the proximal data of each facet surface on L5 for axial rotation.

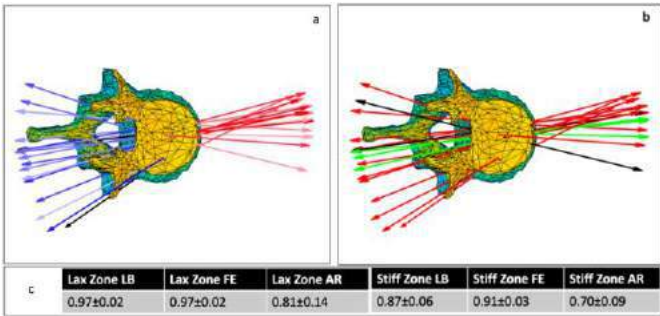

Figure 2: Helical Axes: (a) Dynamic helical axes during an induced lateral bending movement. Flexion is shown in red and extension in blue. (b) Helical axes binned by zone location. Green is within lax zone and red is within stiff zone. (c) Average orientation of helical axes across specimens. A value of 1 indicates a pure hinge joint

Figure 3: Dynamic percent change in proximity within the facet joints for axial rotation: (a) Left facet surface on L5. (b) Right facet surface on L5. Dashed lines indicate lax zone boundaries and the blue and red lines indicate max applied moment

Figure 4: Proximity maps of the facet surfaces of L5 during axial rotation from the posterior perspective: (a) Proximity under zero applied load. (b) Proximity under 7Nm rotating left. (c) Proximity under -7Nm rotation right. Averages shown.

There is a decrease in facet joint spacing on the contralateral joint while the ipsilateral joint space increases. The percent change in proximity is larger for the expanding joint when compared to its compressed counterpart. The lax zone was the smallest percentage of the applied moment for axial rotation and flexion had the largest (Figure 1)

DISCUSSION

The helical axes indicate that the stiff zones of all the applied moments exhibit a higher degree of coupling when compared to their lax zone counterparts. Axial rotation exhibited the most coupling due to the facet joints limiting motion.² The unequal percent change of proximity between left and right facets during axial rotation showcases that the contralateral joint will plateau in its compression while the ipsilateral joint will be forced to expand in a different plane. Flexion lacks this bony influence from the facet joints and would be restricted only by soft tissue.² This resulted in the largest lax zone of all the applied moments. The lax zone shows potential at predicting the bony influence in axial rotation, as the proximity changed the most rapidly during that zone. Some limitations of this study are the lack of active musculature driving the motion, and the quasi-static application of the moment prevents momentum from affecting the trajectory of the motion. Going forward, we plan on applying the proximity map analysis to all the specimens and generate dynamic pressure maps within the joint. We also want to implement a stiffness matrix analysis for each specimen to further quantify the coupling of the L4-L5 functional unit.

REDUCED SENSOR SET FOR ASSESSMENT OF HAND POSTURE

Ranjith Madhana-Gopal (1), Sara E. Wilson (1,2)

(1) Mechanical Engineering, University of Kansas, Lawrence, Kansas, USA

(2) Bioengineering Graduate Program, University of Kansas, Lawrence, Kansas, USA

INTRODUCTION

Instrumented gloves that can capture hand posture are useful in simulation and training for a variety of clinical applications. For example, in obstetrics training, a glove that can capture hand posture, coupled with pressure sensors, can be used to assess forces applied by the physician. Forces during delivery that are too high have the potential to lead to brachial plexus injuries. In previous work, such a set of instrumented gloves were created using inertial measurement units to capture finger segments and palm orientation and pressure sensors on the fingertips [1]. A low profile is an important feature of such instrumented gloves, so using sensors on only some finger segments is preferable. As such, this work will examine whether it is possible to have sensors on only the palm and distal phalanx of each finger and whether, from that data, the proximal phalanx orientation can be predicted.

Figure 1. Sensors were affixed the palm and proximal and distal phalanx of each finger. The goal of the research was to determine if the distal phalanx orientation could predict the proximal phalanx orientation for an array of motions and orientations.

METHODS

With the approval of the human subjects committee of the University of Kansas and consent of the participants, hand posture data was collected on five subjects performing flex-extension and abduction-adduction in four hand orientations (palm down, palm up, thumb up (shake), and finger tips up (high five)) for both hands. Electromagnetic sensors (Trakstar, Northern Digital) were affixed to the palm and proximal and distal phalanxes of the fingers and proximal and distal phalanx of the thumb. These sensors can return position and orientation of the sensor. The joint centroid of each segment was digitized using an additional sensor and an array of four points around the joint. Due to a limited number of sensors available, data from the index finger and thumb were collected in a separate data collection from the other three fingers. Both the left and right hands were assessed.

Rotation of each segment was assessed relative to palm rotation. The palm was designated as orientation 2, the proximal phalanx as orientation 3, and the distal phalanx as orientation 4. Rotation of the proximal phalanx relative to the palm was designated as $2R_3$ and rotation of the distal phalanx relative to the palm was designated as $2R_4$. $2R_4$ data was plotted against $2R_3$ and a linear regression was performed between the two measures to examine if there was a consistent relationship between the segment postures (Figure 2). These linear regressions were performed for each subjects, for each hand orientation and each motion, for the three rotational axes (x, y, and z)

Figure 2 Linear regression of flexion-extension in the palm down orientation for one subject for the index finger for rotation along the primary direction of rotation for flexion-extension. Linear regression was assessed both with a fixed intercept of zero and with a non-zero intercept.

RESULTS

Examining flexion-extension motion it was found that the rotation of the distal segment was 2.81 times that of the proximal segment in the primary direction of rotation with an average r^2 of 0.91 (Figure 3).

Figure 3 The slope of the linear regression between $2R_4$ and $2R_3$ for the four orientations in flexion-extension across 5 subjects was relatively consistent with an average of 2.81 and an average r^2 of 0.91.

Unlike flexion-extension, where we saw almost 3 times the rotation of the distal phalanx to the proximal phalanx, in abduction-adduction of the index finger, the distal phalanx rotated 1.08 times that of the proximal phalanx with an average r^2 of 0.88 (Figure 3).

Figure 3 The slope of the linear regression between $2R_4$ and $2R_3$ for the four orientations in abduction-adduction across 5 subjects was relatively consistent with an average of 1.09 and an average r^2 of 0.88.

Unlike the index finger, the relationship between the two segments for the thumb has found to be less consistent. For the flexion-extension, the distal segment rotated 1.54 times the proximal segment with an average r^2 of 0.75 and for abduction-adduction the distal segment rotated 1.05 times the proximal segment with an average r^2 of 0.74. This may reflect the more complex motion of the thumb relative to the other fingers.

DISCUSSION

The findings in this study demonstrate that it is possible to predict proximal segment orientation in the fingers from a sensor located on the most distal segment. As might be expected there is close to a one-to-one correlation between the abduction-adduction of the proximal and distal segments of the index finger and thumb but much greater rotation of the distal segments in flexion-extension, particularly in the index finger. Future work will continue to examine the remaining fingers and to examine more complex motions.

INTRODUCTION

Nearly 35 million musculoskeletal injuries are reported each year only in the United States (1). Innate immune cells are critical regulators in musculoskeletal (MSK) tissue regeneration. Among the innate immune cells, macrophages are key elements that can polarize toward pro-inflammatory or -healing phenotypes which can further hinder or promote tissue regeneration (2). Physiotherapy or “mechanotherapy” is a therapeutic approach that introduces forces to activate certain molecular signaling pathways that promote tissue repair. Mechanotherapy through regulating macrophages can be promising for musculoskeletal tissue repair, however, specificity and timeliness are the challenges. Utilizing the amplitude and frequency of the mechanical stimulation can make the therapy more macrophage-specific (3). So far, the role of mechanical strain modalities on macrophage polarization on 2D surfaces was investigated. This research used the comprehensive methodology to decipher the macrophage lineage commitment of naïve (M0) and proinflammatory (M1) macrophages encapsulated in 3D tissue analog exposed to different amplitudes of mechanical strain. The result of this study will shed light into the macrophage mechanome which can be adapted to mechanotherapy research.

METHODS

Synthesizing Macrophage-laden 3D Tissue Analogs and Mechanical Loading Application

First, the human pro-monocytic cell line U937 RPMI 1640 medium, Then, the U937 monocyte cells were treated with 100 ng/mL of phorbol 12-myristate 13-acetate (PMA) for 24 hours to be differentiated to naïve macrophages (M0). The cells were further cultured within the media supplemented with 20 ng/ml interferon gamma (IFN γ) and 100 ng/ml lipopolysaccharide for 24 hours to polarize to M1. To mimic the extravasated macrophages within the musculoskeletal tissue, the M1 and M0 macrophages were encapsulated within a separate neutralized 3mg/ml collagen type-1 solution using our established protocols (4). Then, macrophage-laden 3D tissue analogs were deposited into the mechanical loading apparatus as shown in Figure 1. Following 24-hour incubation, the various mechanical strains with 3%, 6%, or 12% amplitudes, and 0.1 Hz frequency were applied to the 3D tissue analog for 2 hours a day for a period of 7 days.

Figure 1. Schematic representations of synthesizing macrophage-laden 3D tissue analog, and mechanical loading of the tissue analog.

Structural Changes in 3D Macrophage-laden Tissue upon Mechanical Loading: M0-laden tissue and M1-laden tissue analogs exposed to various mechanical strain amplitudes were analyzed by scanning electron microscopy (SEM) images and Masson’s trichrome staining analysis to understand how fiber diameter and porosity changes with the mechanical loading and different macrophage phenotype.

Macrophage Polarization within 3D Tissue Analog upon Mechanical Loading: The quantitative real-time polymerase chain reaction (RT-qPCR) was used to perform gene expression fold change analysis of several genes to quantify different responses of the macrophages encapsulated in collagen to different mechanical stimulation modalities. The relative gene expression for fold difference was quantified using the $\Delta\Delta C_t$ method.

RESULTS

The structural changes in M0- and M1-laden 3D Tissue:

M1-laden tissue analog demonstrates higher porosity and smaller fiber diameter when exposed to 3% mechanical strain.

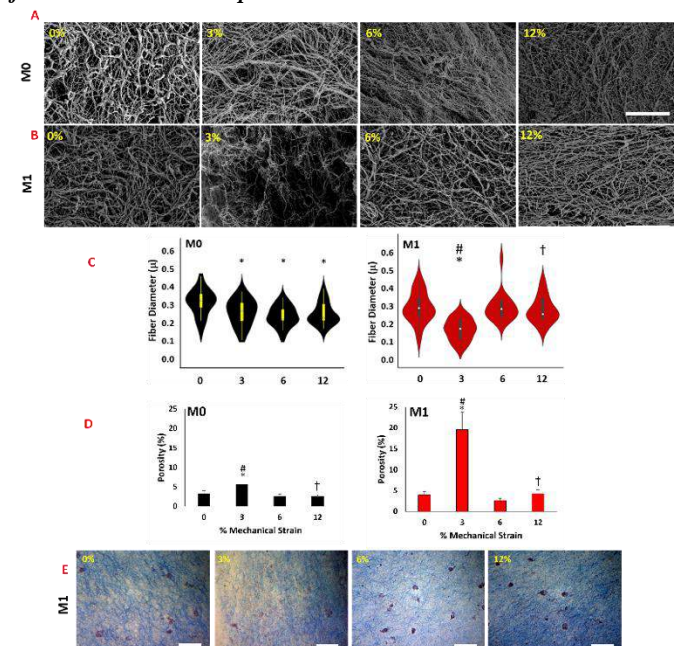

Figure 2. The SEM images of (A) M0- and (B) M1-laden 3D matrix (C) The changes in fiber diameter and (D) The changes in porosity upon mechanical loading, (E) Shows the Masson’s trichrome staining of M1-laden collagen. The scale bar= 10 μ m.

Figure 2 (A) and (B) show that increasing the mechanical strain on M0-laden collagen matrix and M1-laden collagen matrix results in higher fiber alignment. Figure 2C represents the random porosity percentage in M0-laden collagen while higher porosity in M1-laden collagen matrix exposed to 3% mechanical strain. Figure 2D shows that M0-laden

collagen matrix exposed to various amplitude of mechanical strain did not show any different fiber diameter. However, M1-laden collagen matrix exposed to 3% mechanical strain has smaller fiber diameter compared to other strain groups. Figure 2E represents the Masson's trichrome staining of M1-laden collagen constructs which shows the lower fiber density in the scaffolds that are exposed to 3% mechanical strain which further confirms the higher porosity observed in Figure 2D and smaller fiber diameter in Figure 2C.

Early Mechanoresponse of M0 and M1 Macrophages and Phenotypic Changes upon Mechanical Loading:

c-Fos is an early mechanoresponsive gene activated by the external mechanical stimuli. Figure 3 shows c-Fos (early mechanoresponsive gene) expression increased with the increased mechanical strain amplitude for both M0 and M1 macrophages. The highest expression was observed for hyper-mechanical strained group (12%).

Figure 3. The effect of various amplitude of mechanical strains on relative fold change of c-Fos gene.

Following confirming the external mechanical loading was translated into cellular responses, the polarization state of M0 and M1 macrophages were assessed. Figure 4 and 5 demonstrate the relative fold-change of pro- and anti-inflammatory genes for M0 and M1 macrophages upon various mechanical strain exposure.

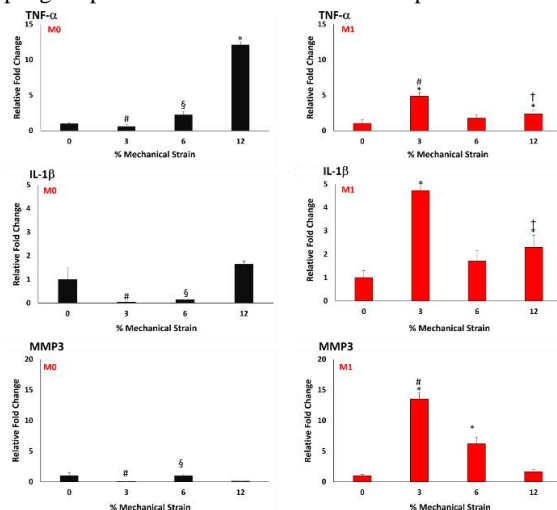

Figure 4. The relative fold change of pro-inflammatory genes in both M0 and M1 macrophages exposed to various mechanical strains.

Figure 4, in M0 macrophages, the expression of the pro-inflammatory gene (TNF-α, IL-β) were highest at 12% mechanical strain. Also, in M1 macrophages the expression of TNF-α, IL-β and MMP3 at 3% mechanical strain is significantly higher than other strain groups. While, the increased expression of TNF-α, IL-β, and MMP3 is the hallmark of the inflammation, the polarization of macrophages toward prohealing phenotype can be recognized through upregulation of anti-inflammatory markers.

Figure 5 shows that anti-inflammatory markers (IL-10, CD163 and CCL18) upregulated at hyper-mechanical strain in M0 macrophages while it increased at 6% in M1 macrophages.

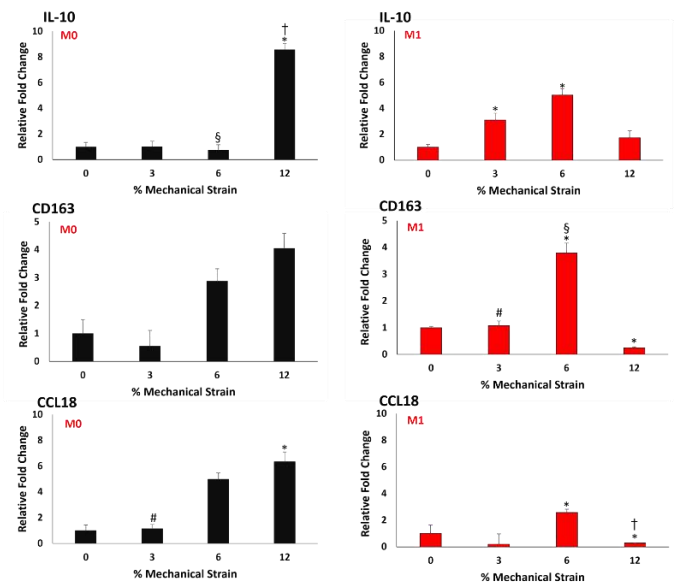

Figure 5. The relative fold change of anti-inflammatory genes in M0 and M1 macrophages exposed to various mechanical strains.

Overall, the data suggested that there is differences in mechanosensitivity of M0 and M1 cells after extravasating within 3D tissue and exposed to even same mechanical strain loading amplitude. For M0, anti-inflammatory genes upregulated with the increased mechanical strain. For M1 macrophages, while 3% mechanical strain pushed M1 cells differentiation into pro-inflammatory lineage, 6% mechanical strain upregulated the anti-inflammatory gene expressions.

DISCUSSION

This research highlighted the different responses of M0 and M1 macrophages to the same amplitude of mechanical strain. M0 macrophage encapsulated in 3D tissue analog demonstrated upregulation of both inflammatory and anti-inflammatory markers at 12% mechanical strain. M1 macrophages encapsulated in 3D tissue analog demonstrated highest upregulation of inflammatory genes at 3% mechanical strain. Furthermore, the higher porosity and smaller fiber diameter observed in M1 macrophages exposed to 3% mechanical strain can be attributed to the upregulation of inflammatory marker MMP3. Moreover, 6% mechanical strain led to upregulation of anti-inflammatory markers in M1 macrophages which suggests that 6% mechanical strain may offset the inflammatory properties of M1 macrophages. This study showed that the modulation of macrophages toward specific phenotype depends on amplitude of mechanical strain. The knowledge from this research can be used to suggest therapeutic window in mechanotherapy exercises.

INTRODUCTION

Magnetic resonance elastography (MRE) provides a non-invasive way to measure dynamic deformation of soft tissue in the brain caused by external motion of the skull [1,2]. MRE images capture displacement data that is typically processed to estimate tissue mechanical properties, but this data can also be used to estimate wave motion, strain, and energy propagation in the human brain [2–5].

We have recently shown that the ratio of strain energy (SE) to kinetic energy (KE) computed from MRE displacements depends strongly on both excitation direction and frequency[6]. Lateral excitation induces primarily left-right head motion and rotation about the long axis of the neck (“no” neck rotation); whereas occipital excitation induces anterior-posterior head motion and rotation in the sagittal plane (“yes” nodding). We found that the SE/KE ratio was consistently higher for lateral excitation. While brain deformation during MRE is very small, our finding suggests that lateral impacts may cause larger amplitude strains than occipital impacts for a given impact energy, consistent with recent measurements on human cadaver brains [7] and with computational models. In this work, we extend our approach to evaluate regional relationships between deformation and head motion and show how these relationships are influenced by frequency and excitation direction.

METHODS

Thirty-two human participants (16 M, 16 F; age 21-68 Y) were scanned using a Siemens Prisma 3T MRI scanner at Washington University in St. Louis. After standard anatomical images were acquired, skull vibrations were induced at 20, 30, 50, 70, and 90 Hz by acoustic pressure waves generated by an active driver (Resoundant®, Rochester, MN) and transmitted by a deformable actuator at the back of the skull (occipital) or the right temple (lateral); one excitation direction per participant. Phase-contrast images were obtained using an EPI sequence [5] (imaging volume: 240 x 240 x 132 mm, 3 mm isotropic

voxels) with harmonic motion encoding gradients (MEG) and 4 phase offsets.

T1-weighted and T2-weighted anatomical images of each participant were processed using a multi-atlas segmentation that was then registered with MRE image volumes [5]. The segmentation was used to classify voxels into five brain regions of interest: cortical gray matter (CGM), cerebral white matter (CWM), deep gray matter (DGM), cerebellum and brainstem. Mean shear storage moduli (G') for each region were estimated from high-resolution MRE shear moduli maps and corresponding segmentation of six participants scanned at the University of Delaware with occipital excitation at 30, 50, and 70 Hz with regional segmentation data [5]. Regional values of G' were linearly extrapolated to 20 and 90 Hz.

MRE phase images were processed to obtain 3D complex-valued harmonic displacements throughout the brain. Total displacement fields \mathbf{u} were separated into rigid body (bulk) displacement, $\bar{\mathbf{u}}$; and wave displacement fields $\hat{\mathbf{u}}$. Components of the three-dimensional deviatoric strain tensor, $\boldsymbol{\epsilon}_{dev}$, were calculated from the spatial derivatives of $\hat{\mathbf{u}}$. Time-averaged kinetic energy density, W_k [J/m³], was computed from tissue density ($\rho = 1000$ kg/m³), velocity \mathbf{v} and its complex conjugate \mathbf{v}^* at each image voxel and kinetic energy, KE in each brain region was summed:

$$W_k = \frac{1}{2} \left(\frac{1}{2} \rho \mathbf{v} : \mathbf{v}^* \right) \text{ where } \mathbf{v} = i\omega \mathbf{u} = i(2\pi f) \mathbf{u} \quad (1a)$$

$$KE = \sum_{i=1}^n V W_k \quad (1b)$$

where f is the excitation frequency in Hz, $V = 2.7 \times 10^{-8}$ m³ is the volume of each image voxel, and n is the number of voxels in each region.

Deviatoric strain energy density, W_s [J/m³], was computed at each voxel using the corresponding regional G' , $\boldsymbol{\epsilon}_{dev}$, and its complex conjugate, $\boldsymbol{\epsilon}_{dev}^*$ and strain energy in each brain region was summed:

$$W_s = \frac{1}{2} \left(G' \boldsymbol{\epsilon}_{dev} : \boldsymbol{\epsilon}_{dev}^* \right) \quad (2a); \quad SE = \sum_{i=1}^n V W_s \quad (2b)$$

We also computed the mean values of W_k and W_s within each region, denoted by \bar{W}_k and \bar{W}_s respectively, for each participant to account for

variation in the size of the brain and brain regions between participants. To explore the relationship between motion and deformation, we also computed the dimensionless ratio SE/KE within each region for each participant at each frequency.

RESULTS

Estimated values of G' for each region as a linear function of frequency are shown in Figure 1. Consistent with previous studies [8,9], the brainstem and DGM were stiffer than CWM, while CGM and the cerebellum were softer. Stiffness of all regions increased with frequency, approximately doubling from 20 – 90 Hz.

Figure 1: Shear storage modulus G' estimated from high-resolution MRE of six participants at the University of Delaware [5]. Dashed lines indicate linear fit as a function of frequency and extrapolated, black symbols show mean values used for linear fit.

The fractions of the total brain volume in each region were similar for the six high-resolution MRE studies and the participants scanned at Washington University, shown in Table 1.

Table 1: Brain regions and imaged brain volume (mean \pm 1 SD) for 32 participants

Region	Fraction of brain volume	Volume (cm ³)
CGM	44 \pm 3 %	550 \pm 71
CWM	38 \pm 3 %	473 \pm 51
DGM	5.0 \pm 0.2 %	56 \pm 5
Cerebellum	11 \pm 0.2 %	140 \pm 5
Brainstem	1.5 \pm 0.2 %	19 \pm 2
Total		1240 \pm 118

The regional values of \bar{W}_k , \bar{W}_s and SE/KE are shown in Figure 2. \bar{W}_k is larger for occipital excitation than lateral excitation in all regions (Fig. 2a, d); this is expected due to the greater amount of bulk motion observed in occipital excitation than lateral excitation [5]. The regional SE/KE ratios are larger for lateral excitation than occipital excitation at all frequencies and decrease with frequency, particularly in the regions of the cerebrum For occipital excitation, the SE/KE ratio is largest for the brainstem at all frequencies; for lateral excitation, the SE/KE ratio is largest for the brainstem at 20 and 30 Hz, but largest for the cerebellum at 50 – 90 Hz.

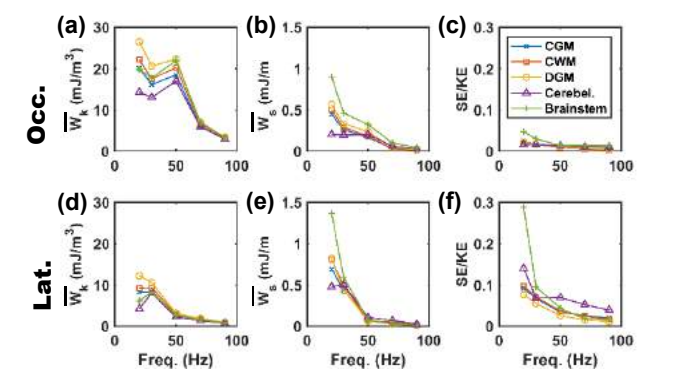

Figure 2: Regional estimates of energy quantities for occipital excitation (top row, N=16, 8M/8F) and lateral excitation (bottom row, N=16, 8M/8F). Mean values of \bar{W}_k (a,d), \bar{W}_s (b,e), and SE/KE (c,f) are plotted at each excitation frequency.

DISCUSSION

Similar to our findings for SE/KE of the entire brain, regional values of SE/KE are larger for lateral excitation than occipital excitation. The decrease in SE/KE ratio with frequency is less pronounced for the cerebellum than for other regions. This suggests that the cerebellum may be more vulnerable to impacts that contain high frequencies than other region.

In this study, regional values of G' were estimated from young adult subjects, but our study population included some older participants who are expected to have softer brain tissue properties [10]. Future work includes using additional high resolution MRE data to obtain age and sex matched tissue properties.

IMPACT OF BLOOD PRESSURE ON CORONARY AND SINUS FLOW DYNAMICS AFTER AORTIC VALVE REPLACEMENT

INTRODUCTION

Aortic stenosis (AS) affects 5%–10% of the elderly population and is expected to double by the year 2050¹. Currently, aortic valve replacement (AVR) is the only effective therapy for AS. Transcatheter AVR (TAVR) emerged as a less invasive alternative to surgery with less morbidity and quicker recovery, though surgical AVR (SAVR) is still performed in many patients.

Despite the procedural success of AVR, up to 40% of patients experience death, rehospitalization (principally for heart failure), or poor quality of life 1 year after AVR. In two large patient cohorts, Lindman et al.^{2,3} found that lower systolic and diastolic blood pressures—in the range that is currently recommended as the optimal target in blood pressure (BP) guidelines³—are independently associated with an increased cardiovascular mortality. The reasons for this association are still unclear. We have previously shown that BP is an important factor in maintaining an adequate epicardial coronary flow to prevent myocardial ischemia⁴. Lindman et al.^{2,3} have speculated that having a prosthesis in the aortic root may alter flow in the sinuses, thereby potentially requiring a higher BP to have adequate epicardial coronary flow. Studies have shown that the implantation of a bioprosthetic valve alters the sinus flow dynamics and may compromise or obstruct coronary access, leading to potential impairment of coronary perfusion. However, there are no studies investigating the effect of BP on sinus and coronary flow dynamics after AVR.

The aim of this study is to investigate the effects of BP on sinus and coronary flow dynamics after AVR. We hypothesize that higher BPs will have a stronger, more positive, effect on the flow dynamics in these regions as opposed to lower BPs. We propose using a PIV approach to test this hypothesis.

METHODS

The sinus and coronary flow dynamics of a 25mm Magna Ease (Edwards Lifesciences, Irvine, California), 29mm Evolut R (Medtronic,

Minneapolis, Minnesota) and 26mm SAPIEN 3 (Edwards Lifesciences, Irvine, California) were assessed in a pulse duplicating left heart flow loop simulator at various BP conditions. The flow loop consists of a fluid reservoir to store a blood analog (water-glycerin, 60-40% in volume), a mechanical mitral valve separating the fluid reservoir and pump, a bladder pump controlled by an in-house LabView program, an idealized aortic model, a compliance chamber to simulate arterial distensibility, a gate valve to control the aortic flow, a pinch valve to control the total coronary flow, and ultrasound clamp-on flow rate sensors (Transonic Systems Inc., Ithaca, NY) to measure the flows before the valve and in the total coronary branch. A schematic of the flow loop is shown in **Figure 1**.

The cardiac conditions used were BPs of 100/60mmHg and 160/60mmHg, a heart rate of 60bpm, and a cardiac output of 5L/min.

The total CF was set to 4–5% of the cardiac output which results in a range of 200–250mL/min. In addition, the total CF was set at a BP of 120/80mmHg and was left to vary based on the different BP conditions.

Particle image velocimetry (PIV) was performed to assess the flow dynamics of the sinus and coronary for each

of the valves. The blood analog was seeded with rhodamine B particles. Time-resolved PIV images of the sinus and coronary were taken for

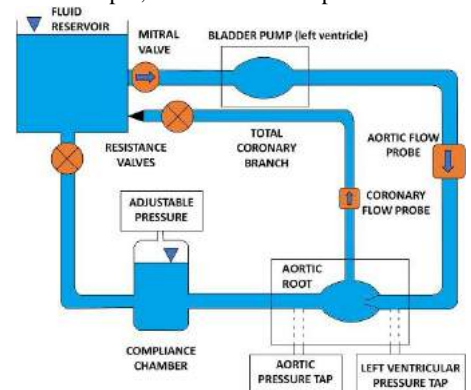

Figure 1. Left heart flow loop with a total coronary flow connection

each valve using a temporal resolution of 4000Hz. Velocity vectors were calculated using DaVis PIV software (DaVis 10; Lavisvision, Göttingen, Germany). The velocity information was extracted and used to calculate the vorticity(ω). Different vector scales were used for the sinus and coronary regions, 1.8 and 0.6, respectively.

RESULTS

Velocity vectors and vorticity contours for each valve at acceleration, peak systole, deceleration, early diastole, and late diastole, are shown in **Figures 2-4**. Note that the purpose of this study is to investigate sinus and coronary flow dynamics at different blood pressure conditions, not to compare performance between each valve.

There were no observable differences in vortex formation at acceleration, deceleration, and late diastole for the Magna Ease. Though, vorticity magnitude is elevated in the coronary with a BP of 160/60mmHg. At peak systole, a small anticlockwise vortex formed towards the back of the sinus which is present only for the 160/60mmHg condition. At early deceleration, two large opposing vortices formed in the center of the sinus, promoting flow into the coronary from both sides of the sinus in the 160/60mmHg. However, these vortices are not present in the 100/60mmHg condition, where flow into the coronary comes from only the back half of the sinus.

Figure 2. Velocity vectors and vorticity contours at different phases in the cardiac cycle for the Magna Ease.

There were no observable differences in vortex formation at acceleration, and late diastole for the SAPIEN 3. Strong vortices are present throughout the sinus at peak systole and deceleration only at a BP of 160/60mmHg. However, at early diastole a large clockwise vortex surrounded by several smaller anticlockwise vortices is present only at a BP of 100/60mmHg. Furthermore, it appears that this large vortex causes less flow to enter the coronary which is reflected by the decrease in velocity vector size in this region compared to the vectors at a BP of 160/60mmHg.

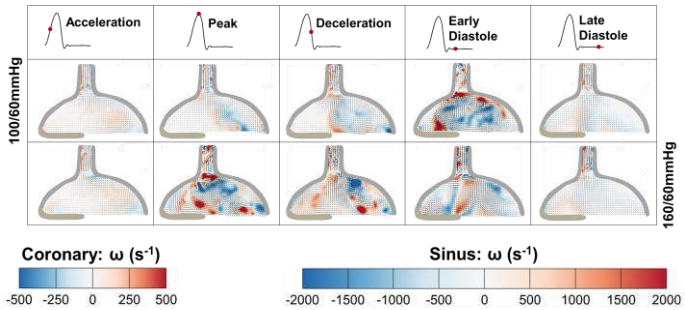

Figure 3. Velocity vectors and vorticity contours at different phases in the cardiac cycle for the SAPIEN 3.

A shadow was present in the back side of the sinus during imaging for the Evolut R, causing incorrect velocity vector calculations in this region which have been removed in **Figure 4**. There were no observable differences in vortex formation at acceleration, peak systole, deceleration, and late diastole for the Evolut R. Though, velocity vector length is moderately longer at some phases for a BP of 160/60mmHg. During early diastole, there is a large clockwise vortex along the right side of the sinus for both BP conditions, but the strength of the vortex is elevated at a BP of 160/60mmHg.

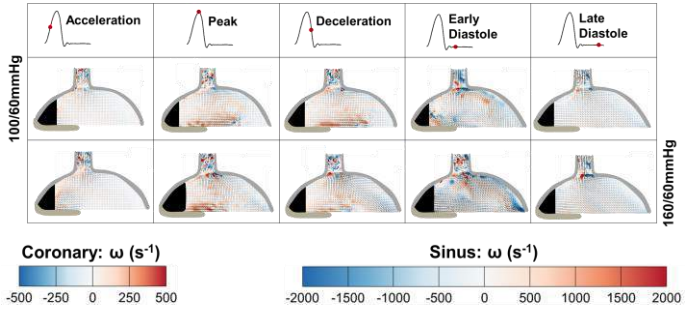

Figure 4. Velocity vectors and vorticity contours at different phases in the cardiac cycle for the Evolut R. The black region represents the location of a shadow present in the sinus.

The timeseries data was divided into systolic and diastolic phases; average velocity was then calculated in the coronary for both BP conditions (**Table 1**). An increase in velocity was observed when increasing the BP from 100/60mmHg to 160/60mmHg regardless of the phase. From systole to diastole, a minor increase in velocity was observed for some of the valves at the different BP conditions.

DISCUSSION

In a previous study, we have reported the effect of BP on maintaining adequate epicardial coronary flow after AVR⁴. We found that higher BPs, not lower, had elevated levels of epicardial coronary flow. Herein, a similar result was observed where an increase in coronary velocities were observed regardless of the cardiac phase.

It has been reported that vortices generated in the sinus play a role in supplying blood to the coronaries⁵. We observed differences in sinus vortices during certain phases of the cardiac cycle for each valve. In addition, it appears that vortices were often more present and encouraging of flow into the coronary at the higher BP.

In this study, we have investigated the effect of BP on sinus and coronary flow dynamics for different bioprosthetic aortic valves using PIV. We observed minor differences in vortex formation, vorticity, and coronary velocities. Currently, we are investigating more combinations of systolic and diastolic BPs, as well as different heart rates.

CALCIFIED PLAQUE HAS A LOCAL EFFECT ON THE DISSECTION BEHAVIOR OF HUMAN AORTAS

Carly L. Donahue (1), Ruturaj Badal (2), Victor H. Barocas (1)

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA
(2) Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN, USA

INTRODUCTION

Acute aortic dissection (AAD) is a life-threatening condition in which a tear is initiated in the wall of the aorta, allowing blood to enter and further separate the layers, propagating the tear and creating a false lumen. Nearly 18% of patients who experience AAD die before reaching the hospital [1]. Mortality rates for hospitalized AAD patients are 21% in the first 24 hours and 45% at 30 days [1].

Improving patient outcomes from these lethal events is largely dependent on screening high-risk patients. The most prevalent comorbidities of AAD include hypertension, aneurysm formation, and aortic calcification [2,3]. A recent study [3] used CT angiograms to identify the location of calcifications in AAD patients. They found that the nearest calcification was on or slightly distal to the initiating intimal tear in 60-88% of cases, depending on tear location within the aorta. These results suggest that calcifications have a local effect on the aorta's propensity for dissection.

The mechanics of aortic dissection have been extensively studied using both experimental and computational techniques. Notably, Kozuń et al. correlated peel experiment findings and histological classifications to demonstrate that the progression of atherosclerosis decreased the average delamination strength of the aortas [4]. However, the local mechanical implications of calcifications on aortic dissection remain unknown. The current work correlates calcification location from micro-CT analysis to the local mechanical behavior observed during peel tests to assess the hypothesis that calcifications have a local effect on the delamination strength and behavior of aortas.

METHODS

Sample Preparation: Three human cadaveric aortas (73F, 75M, 86F) were obtained (Anatomy Bequest Program, U of Minnesota) and stored in a 1XPBS solution at 4°C. Excess connective tissue was removed and rectangular strip samples with widths of approximately 5 mm were cut from the vessel wall (Fig. 1A). Samples were cut either in

the circumferential or longitudinal direction. A total of 115 samples were collected, 22 of which were identified as thoracic aorta samples with a calcification detected by the micro-CT and 23 of which were identified as non-calcified samples. Discrepancies between calcification identification performed visually and with the micro-CT were not included. Each sample was marked with horizontal stripes across the width and thickness using a tissue marker. Distances between each mark were measured to aid in mapping the micro-CT results to the local mechanical behavior.

Micro-CT Analysis: Samples were laid flat on a foam stage, sprayed with 1XPBS to keep them hydrated, and scanned with an average resolution of 95.5 μm (NSI, Rogers, MN). Scans times were ~6 minutes. Image analysis was performed using MATLAB's image processing toolbox. Vessel wall and calcification were segmented using Otsu's thresholding method [5], identifying the location and volume of the calcifications within samples (Fig. 1B).

Mechanical Testing: Incisions were made in the center of the media at one end of each rectangular strip to initiate peel propagation. Both "arms" of the incised sample were clamped, loaded onto a uniaxial testing machine (MTS, Eden Prairie, MN) equipped with 10N load cells, and pulled at 10 mm/s (Fig. 1C). Grip force vs. position was recorded. Peel tension was calculated as the force divided by the sample width. The experiment was video recorded to allow for mapping between the mechanical and micro-CT results.

Figure 1: A) Human aorta sample with calcification (arrow). B) 3D rendering of micro-CT image. The vessel wall has been made partially transparent for visibility of the calcification (arrow). C) Aorta sample mounted for peel test.

Data Analysis: All 22 calcified thoracic samples were computationally segmented into three regions: 1) >2mm before the calcification (control), 2) <2mm before the calcification, and 3) calcification region which started at the calcification front and extended 2mm distal to the lesion. Regional minima, maxima, means, and slopes were calculated for samples and compared with paired t-tests. A Bonferroni correction set the p-value cutoff for 95% confidence at $p = 0.05/3 = 0.016$.

RESULTS

The tension required to peel through the sample varied across regions demonstrating a local effect of the calcification (Fig. 2). Fig. 3 shows the average minima, maxima, means, and slopes for each region. The difference between the minimum values for region 2 and regions 1 and 3 were significant ($p = 0.0049$ and $p = 0.0104$, respectively), demonstrating a rise in the minimum peel tension approaching a calcification and a drop in that minimum tension adjacent to a calcification. There were no significant differences in the maximum or means between the three regions.

Slopes were calculated by fitting a linear model to peel tension vs. actuator displacement for each sample. Slopes varied greatly, but tended to be positive in the regions before calcifications and negative in the calcified region. The slope in the calcification region was significantly different from the control region furthest from the calcification ($p = 0.0089$).

In addition to comparing local properties, we also compared 23 samples that did not have any signs of plaque or calcification buildup with the 22 calcified samples. The calcified samples had a mean peel tension of 33.4 N/m, significantly higher than the non-calcified samples, 25.1 N/m ($p < 10^{-6}$). Additionally, the standard deviation of the peel tension within the samples (a measure of mechanical heterogeneity) varied greatly between the two groups. The calcified samples had an average standard deviation of 8.919 N/m, again significantly higher than that observed in the non-calcified samples, 4.86 N/m ($p = 2 \times 10^{-6}$).

Figure 2: A) 3D rendering of sample micro-CT image. The vessel wall (dark grey) has been made slightly transparent for visibility of the calcification (white). B) Local peel tension mapped to its location within the sample shown above. The curvature is divided into regions: >2mm before the calcification (grey), <2mm before the calcification (gold), and on the calcification (maroon). Peeling started at the green arrow.

DISCUSSION

The results demonstrate that calcifications in the vessel wall have a local effect on the tension required to delaminate the aorta. In general, the peel tension of samples with calcifications exhibited a “rise and fall” behavior, suggesting that calcifications might have an initially

protective effect against peel propagation, but might result in a more brittle failure event when the yield strength is exceeded. This trend is demonstrated in the peel tension graph in Fig. 2 and is captured by the rise and fall of the local minima and the slope turning from positive to negative when the peel front hits the calcified region (Fig. 3).

Figure 3: Average regional minima, maxima, and means for peel tension (N/m), and slopes (kN/m²). Error bars are 95% confidence intervals.

The “rise and fall” behavior caused the average peel tension for each calcified sample to be significantly higher than the non-calcified samples. Interestingly, this contradicts the findings of Kozuń et al. who found that atherosclerotic progression reduced average peel tension [4]. In their study, however, Kozuń et al. peeled through the intimal-medial or medial-adventitial interfaces of the aortic samples, while we peeled through the media. This discrepancy could explain the differences in observed trends. Average peel tensions of non-calcified samples agreed with previous studies [6].

The micro-CT is only able to distinguish dense calcifications from the surrounding vessel wall tissue. As a result, “soft plaques”, which likely have an effect on the peel strength, went undetected. This limitation at least in part explains the highly heterogeneous mechanical behavior observed even outside of the calcification regions and the significant increase in peel tension heterogeneity (measured by the standard deviation of each sample) of calcified samples compared to non-calcified samples.

In conclusion, this study demonstrates that calcifications have a local effect on the peel tension and is, to our knowledge, the first to correlate media peel tension mechanics to CT imaging, a modality routinely used in clinical monitoring and diagnostics and thus potentially valuable in assessing aortic wall failure risk.

INTRODUCTION

A major obstacle impeding engineered tissues and organs is the lack of vasculature. At clinically relevant cell densities, functional tissues create significant metabolic demand requiring robust nutrient/oxygen delivery and waste removal. Because engineered tissues often do not have a pre-existing vascular model to incorporate, techniques in synthetic vascular generation have emerged as ways to improve perfusion strategies of fabricated tissue constructs [1].

These computer-generated vascular networks typically rely on combinations of morphometric data and simplified fluid dynamics and demonstrate qualitatively biomimetic topologies to native vasculature. Constrained constructive optimization (CCO) is one popular method for generating synthetic vasculature relies on adequate constraint assignments governing assumptions about vascular scaling, bifurcation angles, and cost function parameters [2]. However, the performance of CCO synthetic vasculature at perfusing living matter remains unclear. Current CCO cost function optimization is dedicated to minimizing blood volume during vascular construction; thus, there is no guarantee that synthetic vasculatures thoroughly perfuse volumes of interest.

To address this, we leverage derivative-free a optimization framework previously developed in our lab for more accurate generation of synthetic vasculature towards target functional perfusion metrics [3]. To inform our optimization we leverage multi-fidelity computational fluid dynamics (CFD) and perfusion modeling to estimate oxygen saturation within tissue volumes.

METHODS

We consider a cube bioreactor volume requiring synthetic vasculature. Models are created using CCO methods through custom scripting and model building tools available in the open-source package, SimVascular. The topology of generated synthetic vasculature is dependent on global parameters including Murray's law and bifurcation angle constraints as well as search, length, and radius exponents [4]. In general, our optimization problem can be expressed as a black-box system of the following form:

$$\begin{aligned} & \underset{\xi}{\text{minimize}} J(\mathbf{u}; \xi) \\ & \text{subject to} \quad \begin{aligned} & N(\mathbf{u}; \xi) = 0; \\ & \mathbf{M}(\mathbf{u}; \xi) \leq 0; \quad 0 < \xi < 1 \end{aligned} \end{aligned} \quad (1)$$

These design parameters (ξ) as well as the pressures and velocities (\mathbf{u}) together are used to satisfy our objective-function, $J(\mathbf{u}; \xi)$, which is an integral metric of tissue volume at ischemic risk. $N(\mathbf{u}; \xi) = 0$ represents the multi-scale equations governing blood flow and diffusion through a porous medium. The pressures, velocities, and design parameters are also explicitly constrained $\mathbf{M}(\mathbf{u}; \xi) \leq 0$. Diffusion modeling is governed by the single-compartment Darcy model:

$$\begin{aligned} & \mathbf{w} + K \nabla p = 0 \\ & \nabla \cdot \mathbf{w} = \beta_{source}(p_{source} - p) - \beta_{sink}(p - p_{sink}) \end{aligned} \quad (2)$$

Here K and w are the permeability tensor and Darcy velocity, respectively. The pressures (p) are obtained from solutions the hydraulic circuit equations governing the fluid domain of the vascular network. β represents the conductance of flow entering and exiting the tissue domain through sources and sinks along the vessels of a vascular network. The Darcy model shown in (2) is solved using a finite-element implementation. To optimize this expensive black-box problem (1), we use the surrogate management framework (SMF) method which relies on surrogate searching and objective-function polling steps to converge upon a given grid resolution threshold [3].

RESULTS

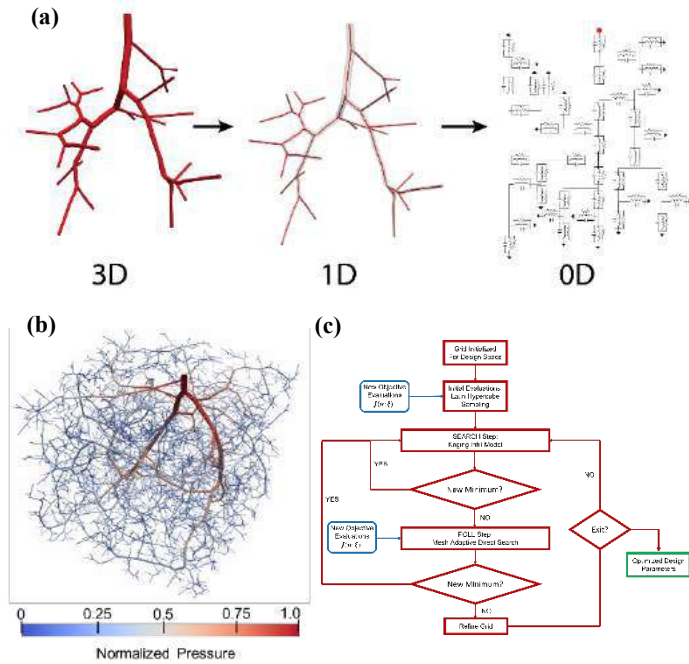

Figure 1: (a) schematic overview for obtaining the hydraulic circuit equations to solve for flows and pressures starting with 3D mesh geometries, 1D centerline extraction, and finally discrete 0D circuit components (b) synthetic vascular network generated within the cube perfusion volume showing normalized pressure distribution obtained from 0D circuit model solution (c) schematic overview of SMF optimization framework. During initialization and POLL steps the objective-function is evaluated

An automated framework for synthetic vascular generation, flow and perfusion simulation has been developed for use within an SMF optimizer. This involves successful generation of reduced order models from initial vascular meshes into circuit representations (Fig. 1a). This forms a set of “0D” differential algebraic equations which are solved with our open-source svZeroDSolver. Obtained pressures are linearly interpolated along vessel segments (Fig. 1b) and used to set the source and sink pressures in the tissue mesh for subsequent perfusion simulation. These steps are repeated for each objective-function evaluation throughout the SMF optimization routine (Fig. 1c).

DISCUSSION

This work presents a framework for generating synthetic vasculature towards more rigorous functional perfusion targets by further optimizing for global constraints including Murray’s law and bifurcation angle constraints as well as search, length, and radius exponents. Overall, this work aims to provide more reliable vascular networks perfusing future engineered tissues by identifying design parameters minimizing ischemic regions. Preliminary work has been undertaken to create a framework for automated SMF optimization which will be used in future work to determine optimal design parameters for convex bioreactor volumes.

METHOD OF APPLYING TWIST TO COMPLEX FEMOROPOPLITEAL ARTERY DEFORMATIONS IN A FINITE ELEMENT STUDY

Ali Ahmadi (1), Anastasia Desyatova (1)

(1) Department of Biomechanics, University of Nebraska-Omaha, Omaha, Nebraska, USA

INTRODUCTION

The femoropopliteal artery (FPA) is the main artery of the leg that maintains blood supply to the lower limb's tissues. One of the main disease modalities of FPA is a peripheral arterial disease (PAD) which manifests as an atherosclerotic lesion that reduces blood flow to the downstream tissues. PAD is among the most expensive vascular diseases to treat, mainly because of the high rate of reconstruction failures that require reintervention [1–3]. One of the reasons for the high prevalence of PAD and poor treatment outcomes can be the complex mechanical deformations that FPA undergoes during everyday activities, which have been characterized in detail using a perfused human cadaver model previously [4]. Severe deformations of FPA can contribute to its high intramural stresses and strains that may cause arterial injury with the initiation of the disease or restenosis after the treatment. FPA intramural stresses due to leg bending were quantified on separate deformation modalities by [5,6], but there is still a lack of understanding of the combined effect of twist and bending on the FPA stresses. In this study, a method of applying twist in addition to complex bending deformations was proposed and evaluated using one FPA.

METHODS

Model. Finite element analysis using Abaqus 2017 (Simulia, Dassault Systemes) was performed to evaluate the effects of combined twist and bending. Centerline FPA in straight and acutely bent leg positions for a 71-80 year-old-group from [7] was adopted for this study. Here, FPA was modeled as an annular section with 6.0 mm internal diameter and 1.5 mm thickness extruded along the centerline in the straight limb position (180°), scaled with the inverse of longitudinal pre-stretch of 1.10. Soft, highly compressible surrounding tissues were modeled around the FPA as an annular cross-section extruded along the same centerline. Tissue properties were selected using a parametric study to ensure FPA in the bent position matches with the bent centerline. FPA was modeled using the New-Hookean model with $C_{10}=167$ kPa. The

FPA and surrounding tissue parts were meshed with linear hexahedral elements, and time increment was set to keep the kinetic energy below 5% of the internal energy to maintain quasi-static simulation.

Boundary conditions. Boundary conditions were applied in three steps: 1) prestretch, 2) twist, and 3) bending and compression. Prestretch was calculated as a displacement from the scaled-down straight centerline to the CT centerline in the straight position and applied to one end of the artery while the other end remained pinned. Centerlines in the straight (180°) and gardening (60°) postures from [7] were used as bending and compression boundary conditions. Twist deformation along the centerline for the same cadaveric FPA is shown in Figure 1 (black markers).

After prestretch step, the twist deformation was applied to 9 locations along the centerline with the highest values of the twist (Figure 1, red markers) by imposing a rigid body constraint on the FPA's outer surface sections. Constraining only the outer surface allowed to maintain some through-wall compressibility of the artery during bending and compression. Twist was applied to each of the twist sections' reference points in the local coordinate system aligned with the rotation of the twist section. Next, bending deformation was applied to the stiff catheter part around the surrounding tissues that was led from the straight to the bent configuration according to the displacement difference in bent and straight centerlines.

RESULTS

The proposed computational model was able to realistically portray complex deformations of the FPA during the acute bent leg. Figure 2 demonstrates maximum principal strains in the FPA in the unstretched (A) and prestretched (B) configurations, with applied twist deformations (C), and with bending and compression deformations applied (D) as the last step. Regions of strain concentration after applying bending deformations were found to be highly non-uniform. High strains and stresses were localized to the segments with acute

kinks, i.e., near the Adductor Hiatus (AH) and in the popliteal artery (PA) below the knee (Figure 2D). However, it was found that some sections did not fully transform twist deformation after bending deformation (Figure 1, blue markers).

Figure 1: Twist along the FPA length (black, experimental; red, applied BC in the model, blue: measured twist at the end of bending step).

Figure 2: FPA model, demonstrating shape and maximum principal strains of (A) unloaded FPA without residual prestretch, (B) prestretched, (C) with twist applied, and (D) with combined deformations at 60° limb flexion.

DISCUSSION

A model with combined limb-flexion induced deformations was developed using rigid rings to apply twist in addition to a guiding catheter and surrounding tissues to apply bending and compression. Like a previous study that only included bending and compression deformations [8], this study has confirmed highly heterogeneous stress

and strain distribution with high concentrations at the AH and PA below the knee area. These locations are also highly prone to atherosclerotic disease [8] which shows there might be a relation between high strains/intramural stresses and atherosclerotic disease of FPA.

While the study presents a way to include twist in the simulation of combined bending-compression deformation of the FPA, it should be viewed in the context of its limitations. First, twist was applied through the inclusion of rigid rings. These rings introduce artificial localized stress concentrations and limit deformations of the FPA in the vicinity of the rings. Care must be taken to place the rings away from the regions of high kinking, so it is not artificially limited. Second, only one FPA geometry with the simplified material model was used here. A more realistic material model and additional cases of FPA deformations would improve the fidelity of the obtained results.

IMAGE DRIVEN SIMULATION OF HEMODYNAMICS AROUND A DYNAMIC CLOT IN VIVO

Chayut Teeraratkul (1), Timothy J. Stalker (2), Maurizio Tomaiuolo (3), Debanjan Mukherjee (1)

INTRODUCTION

Clot formation is an essential physiological response to injury, while pathological clotting (thrombosis) is the leading cause of stroke and other major cardiovascular diseases. Complications occur when clots grow to occlude a key vessel or embolize, causing occlusion in distal vessels. Quantitative characterization of flow-induced clot mechanical behavior under realistic hemodynamic forces is key to discerning disease etiology. Advances in *in silico* methods enables highly resolved simulation of local flow environment around clots. Realistic clots have highly arbitrary shapes and are observed to deform dynamically under hemodynamic forces. However, existing *in silico* methods are often limited to idealized or static clot geometries [1, 2]. Intravital microscopy is a molecular-based fluorescence imaging technique which enables quantification of hemostatic response in animal models through high-resolution time-ordered image sequences [3, 4]. Leveraging intravital microscopy, we present an image segmentation methodology that obtains dynamic clot configuration during the clotting process *in vivo*. These clot configurations are used to inform *in silico* simulations of flow and flow-induced forces, to quantitatively characterize clot mechanics and dynamic flow environment in the clot neighborhood *in vivo*.

METHODS

Automatic clot domain segmentation: Intravital microscopy images of clot formation in mouse cremaster arterioles are obtained from a laser injury experiment (Fig. 1a). High-frequency noise artifacts in the images are filtered through a combination of a median filter and a Gaussian filter using the open-source image processing library OpenCV [5] (Fig. 1b). The filtered images are segmented based on pixel intensity using a k-means clustering method implemented in the Python library scikit-learn [6], and the pixels comprising the clot boundary are obtained (Fig. 1c). The extracted clot boundary is represented as a smooth BSpline curve using the open-source library NURBS-Python [7] and imposed onto a computational grid. This segmentation workflow is repeated for each frame of the image stack (Fig. 1d).

In-silico modeling of flow around dynamic thrombi: Local hemodynamics around the dynamic clot is simulated using a fictitious domain

stabilized finite element formulation [1]. The clot interior is assumed to be a heterogeneous porous domain, and resisted flow inside the clot is modeled using a Brinkman equation for flow inside porous media [8]. Blood plasma is assumed to be Newtonian with a bulk density of 1 g/cc, and viscosity of 4 cP. The inlet flow is assumed to be parabolic, with the centerline flow velocity experimentally measured to be 1.3 mm/s.

Figure 1: Schematic of the *in vivo* to *in silico* workflow: (a) image frame obtained microscopy experiment; (b) filtered image removes noise content; (c) identified thrombus boundary using ; (d) imposed thrombus boundary as a fictitious domain on the computational grid.

RESULTS

In this work, we demonstrate that our coupled *in vivo* to *in silico* method enables quantification of thrombus stability *in vivo*. Specifically, we used

our framework to analyze microscopy data of the hemostatic plug formed in a wild-type (WT) mouse compared to that formed in a DiYF variant mouse. DiYF variant mice are genetically modified mice that are observed to have hindered clot retraction behavior [9, 10]. The spatiotemporally varying clot configuration is automatically extracted from the intravital microscopy images and is directly coupled with the *in silico* flow simulation. The resulting flow velocity field, clot kinematics, and hemodynamic loading on the clot, for the WT and DiYF variants are presented in Fig. 2 and Fig. 3 respectively. Here, hemodynamic loading is quantified as surface-averaged traction force from blood flow acting on the clot boundary. The results show a greater clot volume, higher level of occlusion, and subsequently higher hemodynamic loading in the WT variant compared to the DiYF variant. Both variants exhibit a critical hemodynamic load at which the clot starts to “yield” (see time **T2** in Fig. 2 and Fig. 3). At this critical hemodynamic load, WT variant clot is observed to stretch laterally along the flow direction without a significant drop in thrombus area, indicating clot deformation and stretching that relieves the hemodynamic load but does not fragment and embolize. This point is identified by the sharp drop in the clot aspect ratio (Fig. 2c). Conversely, after the critical hemodynamic load, DiYF variant clot area sharply decreases (Fig. 3a). This corresponds to a sharp loss of mass, which in turn signifies clot embolization, as also observed in the experimental images.

Figure 2: Wild-type variant clot dynamics and corresponding hemodynamic loading: (a) velocity field at initial size, maximum size, late time configuration; (b) thrombus area over time; (c) thrombus aspect ratio over time; (d) surface averaged traction force over time.

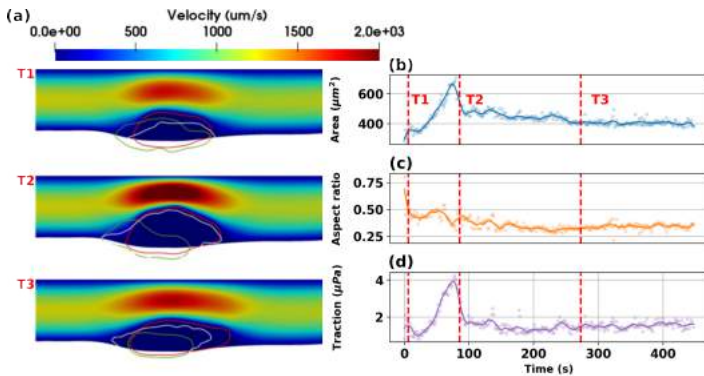

Figure 3: DiYF variant clot dynamics and corresponding hemodynamic loading: (a) velocity field at initial size, maximum size, late time configuration; (b) thrombus area over time; (c) thrombus aspect ratio over time; (d) surface averaged traction force over time.

DISCUSSION

Our custom *in vivo* to *in silico* workflow enables quantitative characterization of clot mechanics and dynamic flow environment in the *in vivo*

clot neighborhood - information that is not otherwise available from intravital imaging alone. Here, we establish this using two illustrative simulation cases - a wild-type (WT) and diYF variant of genetically modified mice. Specifically, the DiYF variants are known to have defective clot retraction, which can result in loosely packed, potentially weaker clot. Fig. 2d and Fig. 3d show a significant decrease in critical hemodynamic load between the WT and DiYF case which is consistent with our understanding of DiYF variant clot. Furthermore, clot mechanical behavior and deformation in response to hemodynamic forces, can be quantified based on this coupled *in vivo-in silico* approach. Specifically, at the time of critical hemodynamic load, a sharp decrease in clot aspect ratio signifies that the clot sustains more stable deformations along the flow. In contrast, sharp decrease in clot volume corresponds with flow mediated fragmentation. This space-time varying force-response mechanical behavior is condensed into a time-envelope plot as shown in Fig. 4. The figure indicates that WT variant with normal retraction properties grew a larger clot sustaining a greater hemodynamic loading (that is, a bigger bounding box in the envelope curve) compared to the impaired retraction behavior in DiYF variants.

Figure 4: Clot volume vs surface averaged traction for both wild-type and diYF variants, indicated as a time-envelope of the dynamic force-deformation behavior combined with growth/embolization.

A NEW APPROACH TO CHARACTERIZE TRABECULAE CARNEAE STRUCTURES USING HIGH-RESOLUTION HUMAN HEART IMAGES

Yasamin Seddighi (1), Keith Bartels (2), Hai-Chao Han (1)

(1) Department of Mechanical Engineering, The University of Texas at San Antonio, San Antonio, TX, USA

(2) Southwest Research Institute, San Antonio, TX, USA

INTRODUCTION

Trabeculae carneae are irregular muscular structures in the heart that cover the endocardial surfaces of both ventricles. Although these trabeculae account for a significant portion of human ventricular mass, their role in the ventricular function is not well understood [1,2]. Reports have shown that the trabeculae structure changes in pathological (e.g., ventricular noncompaction) and physiological (e.g., pregnancy and anemia) conditions [3]. However, the trabeculae carneae are difficult to resolve in clinical cardiac imaging modalities (e.g., echocardiogram and MRI imaging) in vivo due to their small sizes and there is no report of an effective approach to characterize the complex trabecular structure. Therefore, the objective of this study was to acquire high-resolution ex-vivo CT images of human hearts that capture the detailed trabeculae structure and to use 3D image processing and analysis to characterize that structure.

METHODS

Human heart explants were obtained from the South Texas Blood and Tissue Center (San Antonio, TX) after being de-identified and consents for research from the donors' families were obtained in accordance with Institutional Review Board (IRB) requirements. To prepare for CT imaging, heart chambers were filled with a Loctite® Tite foam which provided structural support to prevent the collapse of the chambers and has low density to provide good contrast to the tissue. Each heart was imaged inside a container surrounded by cotton balls to prevent direct contact with the container and reduce movement during scanning. CT-scans were performed using a GE v|tome|x m240 cone-beam micro-focus X-ray CT imaging system. Scanning parameters (tube voltage, beam-hardening filters, scan times, etc.) were determined so that high-resolution (voxel size near 70 microns) were obtained. Scan times of approximately 30 minutes provided images with relatively high signal-to-noise ratio (SNR).

The 3D CT images were imported into MATLAB for 3D visualization and image processing. A combination of custom tools and MATLAB built-in functions were used to automate the measurement of the length and cross-sectional area of the trabeculae.

In the first processing step, the trabeculae structure was isolated from the endocardium by removing the myocardial wall from the left ventricle (LV) (Figure 1a & b). Two layers of voxels were added to the top edge of the initial binary image (bw_1) to close the ventricular chamber and form a void representing the volume of the apex of the LV (Figure 1c). Then, this closed ventricular volume was filled (Figure 1d) and the volume obtained from subtracting bw_1 from the filled chamber gave the lower ventricular volume (Figure 1e). Finally, voxels of the outer edge of the LV chamber were identified and all voxels (0 and 1) within the chamber volume were flipped to obtain the trabeculae structure T (Figure 1f).

After smoothing the outer edges of T, MATLAB was used to find the 3D skeleton (S) of the binary image T. The branch points of the S were removed to separate the branches of the skeleton segments CC_s [4]. However, some larger trabeculae are connected to multiple small trabeculae and thus are broke into multiple short segments. To resolve this issue, thinner trabeculae segments were removed by an iterative process using morphological operation "opening" with a spherical structuring element (SE) of increasing radius R ($R=1, 2, \dots$). In each iteration, "opening" with a given R was applied to T and the resulting image was subtracted from T to obtain T_R . T_R is the reduced structure containing partial or full segments of the trabeculae with maximum inscribed sphere smaller than SE of radius R. This process is repeated for SEs with increasing radii. For a given branch segment, since the cross sections varies along its length, as the radius of the SE increases, the portion of the segment in T_R grows until it contains more than one CC_s (CC_s of its own and neighboring segments) in the N^{th} iteration. Then, the desired configuration representing this trabecula segment is the one obtained at iteration N-1 which is the largest cut (volume) of the

segment that contains only one CC_S. The segment was labeled and stored as an individual segment for further measurement and the skeleton of the segment was removed from the skeleton structure S. After all branching segments are removed, the isolated large trabecular segments having only one CC_S within their volume were labeled and stored as a single trabeculae segment.

After all trabeculae and corresponding skeletons were separated and labeled, the length and central cross-sectional area of all the trabeculae were measured. For each trabecular segment, a second order polynomial curve (p) was fit to its skeleton voxels. The length of each trabecula was determined as the curve length of p between its intersection points with the trabecular surface. The normal plane at the midpoint of the curve p was determined and the trabecular voxels intersected by the normal plane were used to determine the cross-sectional area.

Figure 1: Schematic illustration of the process of removing endocardium from (a) 3D image of human LV to get the (b) isolated trabeculae structure. (c) LV chamber enclosed at the top, (d) LV with void filled, (e) LV chamber after subtracting initial image from (d), (f) isolated trabeculae structure.

RESULTS

Three human hearts have been scanned and all scans successfully captured the fine structure of trabeculae carneae. The rendered volume representation of the LV showed 3D images containing trabeculae structure (Figure 1a).

The segmented trabeculae structure of one heart was analyzed to measure the length and thickness of the free running trabeculae. Our results showed that central trabeculae area varies between 0.004 mm² and 2.43 mm² and trabeculae length ranges from 0.22 mm to 7.00 mm

at the apex of the current LV model (Figure 2). The majority of the trabecula lengths and areas are in the range of 0.22-2 mm and 0.004-0.6 mm², respectively.

Figure 2: Length and cross-sectional area distribution of the trabeculae carneae at the apex part of the LV

DISCUSSION

A new method to acquire high resolution CT images of the human heart was presented. The method captures the small and complex trabecular structure. Automated 3D algorithms were used to segment and characterize the complex structure of the trabeculae carneae.

There are limitations in this study that could be addressed in future studies. First, the trabeculae carneae structure of only one heart was analyzed with this method. Second, this method cannot automatically distinguish between trabeculae carneae, papillary muscle and chordae tendineae and thus requires manual separation/identification.

Despite limitations, this study provides the groundwork of a new method to automatically capture trabeculae structure that can be used to develop the detailed heart models in future studies. Additionally, characterizing the trabeculae structure in different pathological conditions may shed light on the trabeculae carneae function.

INTRODUCTION

Mild Traumatic Brain Injury (mTBI) is a public health concern and often seen in contact sports. As per the CDC in 2019, 15% of US high school students self-reported a concussion in the past 12 months[1]. With the help of instrumented mouthguard sensors, it is now possible to measure and record head kinematics of a player during an impact. The head impact data can be used to determine brain injury metrics to determine to assess the severity of the impact. Several research groups are now using sensor data to run finite element simulations to estimate these metrics. In this study, 500 impacts obtained from Prevent biometrics, some of which were identified as severe head impacts, were analyzed using the brain simulation research platform to test if the 95th percentile Maximum Principal Strain (MPS-95) can accurately identify the severe impacts.

METHODS

Impact Dataset: In this study, 500 head impacts collected by Prevent biometrics were analyzed using the brain simulation research platform. A keyword titled “CHECK_ENGINE” was assigned to all the impacts that were visually determined to be severe impacts. A total of 31 impacts were listed as “CHECK_ENGINE” and the others were treated as though they were non-injurious.

Brain Simulation Research Platform: All simulations were carried out on the brain simulation research platform which is a brain modeling service that can simultaneously run several finite element simulations of a brain mesh. The platform uses a finite element modeling code called FEMTech which has been developed to carry out the simulations using a non-linear explicit

dynamics scheme. FEMTech has been tested against brain experiments in literature and the validation results are available on the platform at <https://brainsimresearch.io/validation>.

Finite Element Model: All 500 impacts were run on the platform using a hexahedral mesh of the brain that includes sulci and gyri (Figure 1). The geometry of the brain corresponds to a male individual head model that scaled to match the dimensions of the 50th percentile male model. The brain was modeled using hyper-viscoelastic material properties obtained from [2]; the parameters used have been listed in Table 1.

Figure 1: Brain mesh used to simulate the 500 impacts.

Table 1: Material properties used in the simulations.

Part	Model	Properties
Skull	Rigid/Elastic[2]	$E=15\text{GPa}$, $\nu=0.22$, $\rho=2000\text{ kg/m}^3$
CSF	Hyper-elastic[3]	$K=22\text{MPa}$, $G=50\text{kPa}$, $\rho=1040\text{ kg/m}^3$
Brain	Hyper-viscoelastic[2]	$G_1=320\text{kPa}$, $\beta_1=10^6/\text{s}$, $G_2=78\text{kPa}$, $\beta_2=10^5/\text{s}$, $G_3=6.2\text{kPa}$, $\beta_3=10^4/\text{s}$, $G_4=8\text{kPa}$, $\beta_4=10^3/\text{s}$, $G_5=0.1\text{kPa}$, $\beta_5=10^2/\text{s}$, $G_6=3\text{kPa}$, $\beta_6=10^1/\text{s}$, $\nu=0.49999$, $\rho=1040\text{ kg/m}^3$

RESULTS

By plotting the MPS-95 on the x-axis and categorizing the “CHECK_ENGINE” cases on the y-axis, the relationship between severity of the impact and strain can be evaluated. According to the findings in Figure 2, there seems to be no obvious relation between 95th percentile MPS and visible symptoms of a head injury.

Figure 2: Check Engine vs 95th Percentile MPS; no obvious correlation can be seen in this dataset.

The severe cases were further studied by plotting all the MPS-95 vs time curves. MPS-95 curves for the brain often exhibit two peaks[4]; hence these plots have been color-coded based on whether it is apparent if the highest peak has been reached. The green plot shows two peaks and a decline in the trend indicating that it has likely reached the peak. The yellow plot is cut off at what may be the peak but it is uncertain. The red plot is truncated before the second peak is even hit, leaving the possibility of it being larger. Amongst all 31 severe cases, 8 appear to have reached the peak (green), 4 may have reached the peak (yellow) and 19 were cut off too early (red).

Figure 3: 95th Percentile Maximum Principal Strain vs Time for three "CHECK_ENGINE" cases.

DISCUSSION

In this study, 500 head impact kinematics collected by Prevent Biometrics were analyzed using the brain simulation research platform. Some of these impacts were considered severe and listed as such based on the symptoms that the players exhibited after the impacts, as reported by the sensor company. MPS-95 was computed for each impact to test if it can identify the severe impacts. Based on these results, there is no clear difference in the MPS-95 values between both kinds of impacts, which was unexpected as strain has been thought to relate to head injury in literature[5].

Upon further examination of the severe impacts, it was identified that more than half the cases did not conclusively hit a peak. A possible theory is that larger brain strains may have been missed and that MPS-95 is a better indicator of impact severity than what the results currently show. This is also supported by

some other research that discuss the importance of the recording time window of the kinematics for an impact[4], [6].

Another limitation of the study is that the severe cases were identified as the ones that had visible symptoms of a head injury, which may introduce error and result in cases that were severe but went undetected due to the lack of symptoms. A more reliable approach to distinguish between severe and non-severe cases would be to use a sideline cognitive testing such as the ImPACT test[7]. That data can then be compared with similar brain injury metrics to test for a correlation. Such a study is planned and will take place in the near future.

A THREE-NODE ROTATION-FREE KIRCHHOFF-LOVE SHELL FORMULATION FOR CARDIOVASCULAR APPLICATIONS

L. Shi (1), Y. Chen (1) V. Vedula (1)

(1) Department of Mechanical Engineering, Columbia University, New York, NY, USA

INTRODUCTION

Kirchhoff-Love shell formulations are often used to model the biomechanical response of thin structures such as heart valves, skin, and cartilage that undergo finite nonlinear deformation. Shell formulations are also computationally efficient as they substantially reduce the size of the problem compared to 3D solid elements, making them a popular choice for many biomechanics applications. The Kirchhoff-Love shell formulation considers both membrane and bending strains but typically requires both translational and rotational degrees of freedom to resolve the bending strains. On the contrary, rotation-free shell formulations retain only the three translation degrees of freedom at each node, thus further reducing the problem size compared to formulations involving rotations. However, these formulations require additional element treatment or isogeometric analysis, limiting their utility to patient-specific modeling and simulation [1, 2].

We present a novel 3-node rotation-free thin shell formulation for incompressible and compressible hyperelastic materials, implemented in an open-source finite element solver, *svFSI*. Our work is based on the rotation-free formulation developed by Stolarski et al. [1] for St. Venant-Kirchhoff material. We extend the methodology for general hyperelastic materials while also satisfying the plane stress condition. We derive multiple 3D constitutive models in compressible and incompressible forms, including the isotropic (neo-Hookean and Mooney-Rivlin) and anisotropic (Gasser-Ogden-Holzapfel (GOH) and Lee-Sacks) hyperelastic models, routinely employed in cardiovascular biomechanics applications.

We validated the formulation by comparing the model results against analytical solutions for a beam under uniaxial tension and a plate subjected to a transverse pressure load for both compressible and incompressible materials. We also simulated the mechanics of a patient-specific aortic valve subjected to a physiological transvalvular pressure gradient.

METHODS

In this Kirchhoff-Love shell formulation for finite deformations, we split the Green-Lagrange strain tensor into the membrane and bending components. The standard 3-node triangular element shape functions are used for discretization that eliminates membrane locking, typically observed in higher-order shell formulations [1]. Computing the variation of the membrane strain tensors on each element of the triangular mesh is straightforward. However, to accurately account for the bending strain of an element, a complete quadratic polynomial is used to represent a patch of elements in the neighborhood of the main element (Fig. 1) and is used to evaluate the element curvature tensor [1].

Figure 1: A patch of elements in the neighborhood of the main triangular element is used to resolve bending strains. [2]

The governing weak form of the shell formulation in the reference configuration is given by, [2]

$$\int_{A_0} [\rho \dot{\mathbf{u}} \cdot \delta \mathbf{u} + n^{\alpha\beta} \delta E_{\alpha\beta}^m + m^{\alpha\beta} \delta E_{\alpha\beta}^b - \mathbf{f}_{ext} \cdot \delta \mathbf{u}] dA = 0 \quad (1)$$

where \mathbf{u} is the displacement, $\dot{\mathbf{u}}$ is the acceleration, h is the shell thickness, A_0 is the area of the shell surface in the reference configuration, $n^{\alpha\beta}$ and $m^{\alpha\beta}$ are the stress resultants obtained by integrating the 2nd Piola-Kirchhoff stress tensor ($S^{\alpha\beta}$) through the thickness as,

$$n^{\alpha\beta} = \int_{-h/2}^{h/2} S^{\alpha\beta} d\tau, \text{ and } m^{\alpha\beta} = \int_{-h/2}^{h/2} \tau S^{\alpha\beta} d\tau, \quad (2)$$

with $\alpha, \beta = 1, 2$ denoting the in-plane curvilinear components of the shell mid-surface, and E^m and E^b are the membrane and bending components of the Green-Lagrange strain tensor, respectively.

The stress tensor for incompressible materials is derived by satisfying the plane stress condition and can be expressed by

$$S^{\alpha\beta} = 2 \frac{\partial W}{\partial C_{\alpha\beta}} \quad (3)$$

where W is the free-energy density, and $g_{\alpha\beta}$ is the covariant metric tensor of a shell layer in the current configuration. The compressible stress tensor is obtained by iteratively solving for the off-plane component of the right Cauchy-Green deformation tensor (C_{33}) to satisfy the plane stress condition using the Newton method [2]. The stress tensor can be derived by the standard 3D stress equation, $S^{ij} = 2 \frac{\partial W}{\partial C_{ij}}$, but the right Cauchy-Green deformation tensor $\mathbf{C} = C_{ij} \mathbf{G}^i \otimes \mathbf{G}^j$ here is expressed in the metric coefficients form, where \mathbf{G}^i is the contravariant base vector in the reference configuration.

Here, we apply the above formulation for four hyperelastic constitutive models, including the neo-Hookean, the Mooney-Rivlin, GOH, and the Lee-Sacks valve models [3, 4]. The expressions for the 2nd Piola-Kirchhoff stress tensor for each of these material models are shown below (Eq. 4) in incompressible form as,

$$\begin{aligned} S_{NH}^{\alpha\beta} &= \mu(G^{\alpha\beta} - J^{-2}g^{\alpha\beta}) = \mu S_{I_1}^{\alpha\beta} \\ S_{MR}^{\alpha\beta} &= c_1 S_{I_1}^{\alpha\beta} + c_2 J^{-2}(G^{\alpha\beta} - G_{\gamma\delta} g^{\gamma\delta} g^{\alpha\beta}) + c_2 J^{-2} G^{\alpha\beta} \\ S_{GOH}^{\alpha\beta} &= \mu S_{I_1}^{\alpha\beta} + 2a_f(g_{\gamma\delta} A_f^{\gamma\delta} - 1) \exp[b_f(g_{\gamma\delta} A_f^{\gamma\delta} - 1)^2] [\kappa S_{NH}^{\alpha\beta} + (1 - 3\kappa) A_f^{\alpha\beta}] \\ &\quad + 2a_s(g_{\gamma\delta} A_s^{\gamma\delta} - 1) \exp[b_s(g_{\gamma\delta} A_s^{\gamma\delta} - 1)^2] [\kappa S_{NH}^{\alpha\beta} + (1 - 3\kappa) A_s^{\alpha\beta}] \\ S_{LS}^{\alpha\beta} &= a S_{I_1}^{\alpha\beta} + 2a_0 \mu b_1 (g_{\gamma\delta} G^{\gamma\delta} - 3) \exp[b_1(g_{\gamma\delta} G^{\gamma\delta} - 3)^2] S_{NH}^{\alpha\beta} + 2a_0 (1 - \mu) b_2 \chi (g_{\gamma\delta} A_f^{\gamma\delta}) (g_{\gamma\delta} A_f^{\gamma\delta} - 1) \exp[b_f(g_{\gamma\delta} A_s^{\gamma\delta} - 1)^2] A_f^{\alpha\beta} \end{aligned} \quad (4)$$

where $A_i^{\alpha\beta} = A_i^\alpha A_i^\beta$ is the directional tensor, $g^{\alpha\beta} = g_{\alpha\beta}^{-1}$, $G_{\alpha\beta}$ is the covariant metric tensor of a shell layer in the reference configuration, $G^{\alpha\beta} = G_{\alpha\beta}^{-1}$, $J^2 = \det[g_{\alpha\beta}] / \det[G_{\alpha\beta}]$.

RESULTS

A uniaxial tension simulation is performed to test the ability of the presented shell models to solve the membrane-dominated problem. In this case, a rectangular incompressible strip with length \times width \times thickness = $9 \times 3 \times 0.3 \text{ mm}^3$ is pulled by a force as shown in Fig. 2. For the neo-Hookean model: the elasticity modulus = 0.3 MPa. MR model: $c_1=4 \text{ MPa}$ and $c_2=8 \text{ MPa}$. GOH model: $a_4=10 \text{ MPa}$, $b_4=5$, $a_6=30 \text{ MPa}$, $b_6=5$, and μ changes from 0 to 1/3. Lee-Sacks model: $a=0.1 \text{ MPa}$, $a_0=3 \text{ MPa}$, $b_1=0.3$, $b_2=1$, and κ changes from 0.5 to 1. The fiber directions for the GOH model are shown in Fig. 2, and the fiber is along $+30^\circ$ for the Lee-Sacks model. The displacement curves of the upper edge vs. pressure for different materials are shown in Fig. 2, where dashed lines represent the analytical solutions.

Figure 2: Displacement-force curves of various constitutive models for a clamped force-controlled uniaxial tension simulation.

A clamped plate under pressure simulation is used to test the ability of the presented shell models to capture the membrane and bending deformations together. In this case, a rectangular plate with length \times

width \times thickness = $20 \times 20 \times 1 \text{ mm}^3$ is clamped with fixed boundaries, and a uniform distributed pressure is exerted on the whole plate (Fig. 3). The plate is modeled as either an incompressible or compressible (Poisson's ratio=0.3) shell. For the neo-Hookean model: elasticity modulus = 0.3 MPa. MR model: $c_1=4 \text{ MPa}$ and $c_2=8 \text{ MPa}$. GOH model: $a_4=10 \text{ MPa}$, $b_4=5$, $a_6=30 \text{ MPa}$, $b_6=5$, and $\mu=0.226$. Lee-Sacks model: $a=0.1 \text{ MPa}$, $a_0=3 \text{ MPa}$, $b_1=0.3$, $b_2=1$, and $\kappa=0.5$. The fiber directions for the GOH model are shown in Fig. 2, and the fiber is along $+45^\circ$ for the Lee-Sacks model. The displacement curves of the center node vs. pressure for different materials are shown in Fig. 2, where dots represent the analytical solutions.

Figure 3: Displacement-pressure curves of various constitutive models for a clamped plate under pressure.

A patient-specific trileaflet aortic valve is created from CT data. (Fig. 4a) For each leaflet, one edge is fixed where the leaflet is attached to the aorta, and the other is left free. The leaflets are modeled as incompressible neo-Hookean material with an elasticity modulus of 1.25 MPa, shell thickness of 0.4mm, and density of 0.001kg/m³. A realistic transvalvular pressure gradient is applied on the ventricular side of the leaflets, and a penalty-based contact algorithm is applied between the leaflets. The opening and closing states of the aortic valve are shown in Figs. 4c and 4d.

Figure 4: The patient-specific aortic valve under real pressure. (a) FEA model (b) pressure curve (c) opening state (d) closing state. Color denotes the first invariant of the right Cauchy-Green deformation tensor \mathbf{C} .

DISCUSSION

Our results demonstrate a reasonable agreement between model predictions and analytical data (Figs. 2 and 3). The patient-specific aortic valve also opens and closes as expected. In the future, we intend to expand the capabilities of the present shell formulation for performing vascular and valvular fluid-structure interaction (FSI) simulations.

HEART RATE IMPACT ON PLAQUE DEPOSITION AT THE CAROTID ARTERY BIFURCATION

Ramita Sajankila¹, Esha Navaneethakrishnan¹, Elvan Dogan, MS¹, Amir K. Miri, PhD¹

¹Department of Biomedical Engineering
New Jersey Institute of Technology
Newark, New Jersey, USA

INTRODUCTION

Atherosclerosis, caused by plaque buildup in the arteries, has been the primary cause of heart disease and 50% mortality rate of all deaths in the United States [1]. It has been shown that when an artery splits into two different counterparts, there is an increased chance of plaque materials' deposition near the bifurcation area [2]. The wall shear stress and blood flow rate in an artery have been shown to directly impact the atherosclerotic plaque build-ups at the bifurcation of an adult artery, where a lower wall shear stress results in a higher plaque formation rate [3]. We need to understand the mechanisms of plaque deposition in the arteries to improve our treatments. In this work, we will perform one case study to quantify the effects of cardiovascular exercise intensity on the rate of plaque deposition near the bifurcation area of the carotid artery by using the ANSYS (FLUENT software) simulation and theoretical modeling to analyze a 3D model of artery's blood flow. The increased wall shear stress and maximum blood flow velocity through the carotid artery during the intense exercise model were used to validate the model. The results of this work can be used for further modeling a potential treatment for such patients.

METHODS

The numerical tool ANSYS FLUENT (Canonsburg, PA) was used to simulate a selected geometry of carotid artery bifurcation (Patient, Ref. [5]). The GrabCAD package was used for this study. Geometry, meshing, boundary conditions, and other elements were identified in the simulation, except for the rate of blood flow into the inlet of the artery (**Figure 1**). Our first case was a blood flow of ~ 120 beats per minute (BPM, heart rate), representing moderate cardiovascular exercise. Our second case was a flow of 180 BPM to represent intense exercise such as running [4]. The fluid flow is considered to be laminar Carreau flow, with a density of 1060 m³/kg. The geometrical parameters of the ANSYS simulation are listed in **Table 1**. The right CCA mean diameter and the ICA mean diameter refer to the dimensions of the bifurcated artery geometry that was used for the purposes of this study, i.e., to observe the intensity of cardiovascular exercise on plaque deposition near the bifurcation area.

The problem information is summarized as:

Table 1: Properties and Parameters from Ref. [5]

Parameter	Value
Right CCA mean diameter (5)	6.52 mm
ICA mean diameter	5.11 mm
External carotid artery (ECA) diameter	1.42 mm

Figure 1: Geometry of 3D carotid artery bifurcation

The governing equations of the mathematical problem are listed below.

Navier Stokes Equation

$$\rho \left(\frac{\delta u}{\delta t} + u \cdot \nabla u \right) \quad (1)$$

$$-\nabla p + \mu \nabla^2 u \quad (2)$$

Continuity Equation

$$\nabla \cdot u = 0 \quad (3)$$

Boundary Conditions

$$v_{\text{wall}} = 0 \quad (4)$$

The mathematical descriptions for the two cases were adapted from a model proposed by Sinnott et al., outlining the flow model of a bifurcated artery through a grid-free method [6].

Case I - 120 BPM:

$$v_{inlet}(t) = 0.5 \sin [4\pi(t + 0.0160236)] : 0.5n < x < 0.5n + 0.218 \quad (5)$$

$$v_{inlet}(t) = 0.1 : 0.5n + 0.218 < n < 0.5(n + 1) \quad (6)$$

$$n = 0, 1, 2, \dots$$

Case II - 180 BPM:

$$v_{inlet}(t) = 0.5 \sin [4\pi(t + 0.05235)] : 0.33n < x < 0.33n + 0.1453 \quad (7)$$

$$v_{inlet}(t) = 0.1 : 0.33n + 0.1453 < n < 0.33(n + 1) \quad (8)$$

$$n = 0, 1, 2, \dots$$

RESULTS

The results of the ANSYS simulations of blood flow through both the moderate and intense exercise models are displayed below.

Figure 2: Velocity profile of carotid artery for the two cases: (A) 120 BPM and (B) 180 BPM

The maximum velocity observed in the moderate exercise ANSYS model is 0.2188 m/s. The maximum velocity observed in the intense exercise ANSYS model is 0.3057 m/s.

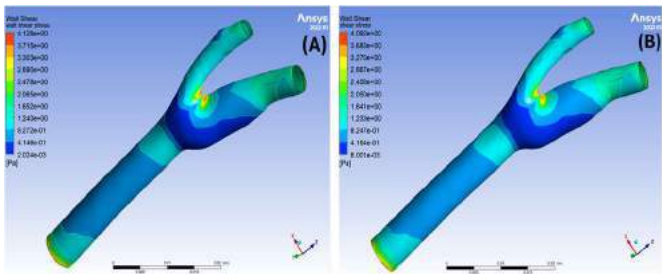

Figure 3: Wall shear stress of carotid artery for the two cases: (A) 120 BPM and (B) 180 BPM

The minimum wall shear stress observed in the moderate exercise ANSYS model is 2.024e-3 Pa. The minimum wall shear stress observed in the intense exercise ANSYS model is 8.001e-3 Pa. v_f for 120 BPM and 180 BPM was found from

ANSYS simulations to be 0.109 m/s and 0.159 m/s respectively.

DISCUSSION

The aim of this study is to observe the extent of the decrease of the rate of plaque formation over time in an artery when subjected to intense versus moderate exercise. As suggested by the results, it can be determined that the maximum velocity of the blood through the carotid artery at 180 BPM was higher than that of the artery at 120 BPM (**Figure 1**). Additionally, the minimum shear stress values at 180 BPM were also significantly increased in comparison to the 120 BPM model (**Figure 2**). Both of these results from the ANSYS FLUENT simulations indicate that the intense exercise model should showcase a lower rate of plaque formation over time. A higher shear stress of the blood on the wall of the artery theoretically results in any plaque that is formed being “washed” off by the blood moving at a higher velocity inside the arteries in the 180 BPM model. Therefore, this demonstrated an approximate decrease in the rate of atherosclerosis due to intense exercise. Such results can be interpreted to suggest that higher intensity cardiovascular exercise, such as sprinting or intense cycling, for example, is increasingly efficient at preventing atherosclerosis than lower intensity exercise, such as walking. Furthermore, these results support a trend between an increased heart rate due to intense exercise and a lower risk of cardiovascular disease due to a reduced atherosclerotic plaque buildup over a given period of time. Regarding future directions, it may be useful to create multiple simulations of identical arteries at varying heart rates including plaque deposition, which would then may be used to compute the rate of plaque formation for each simulation in order to mathematically demonstrate a relationship between the rate of atherosclerosis formation to that of exercise intensity.

INTRODUCTION

Burns, diabetic ulcers, and infection lead to 8.2 million Americans suffering from chronic wounds every year¹. Split-thickness skin grafting is a method widely used in plastic surgery to treat such wounds². The procedure begins with the use of a dermatome to harvest a graft of healthy epidermis with a thin layer of dermis (Fig. 1A). The graft is cut into a meshwork of slits then stretched to cover a larger wound (Fig. 1B). Prediction of the area of wound coverage, S_{final} , is critical for surgical planning, and is typically done using the following formula for the expansion ratio, R_{exp} :²

$$R_{exp} = \frac{S_{final}}{S_{initial}} = 1 + \left[\frac{L^2}{4d(L + g)} \right] \quad (1)$$

where $S_{initial}$ is the initial area of the graft, and d , g , and L are the parameters of the skin graft meshing protocol (Fig. 1C). The term within the brackets is known in reconstructive surgery as the meshing ratio.

Equation (1) is derived by approximating the stretched graft as expanding into a configuration in which the slits become squares and the tissue ligaments do not stretch.³ The equation also ignores the material properties of the skin. However, the sliced skin ligaments do stretch to a degree, and the slits can adopt more complicated shapes in the stretched graft (Fig. 1B). Our objective was therefore to improve tools for surgical planning of split thickness thin grafting by validating and improving upon Equation (1).

We hypothesized that improving upon the predictions of shapes adopted by the opened slits would improve the estimate of the expansion ratio R_{exp} . To test the hypothesis, we created a finite element model of elastic skin grafts, all of which had the differing meshing patterns but the same meshing ratio, and compared the results to Equation (1) and to a new estimate of R_{exp} that we derived. model and change the length of the cut and verify our hypothesis by comparing the expansion ratio.

Figure 1: Split thickness skin grafting involves (a) harvesting, and (b) meshing prior to transplantation. Meshing is defined by the parameters shown in (c).

METHODS

Model derivation: To improve upon Equation (1), we rederived the formula by assuming that skin grafts stretch into the shapes shown in Figure 1. The skin was treated as incompressible and plane strain conditions were assumed. Treating each cut as a square after stretching, and considering a unit cell within an infinite sheet of skin, the revised version of Equation (1) was derived using straightforward geometric considerations:

$$R_{exp} = 1 + \left[\frac{L^2}{4d(L+g)} \right] \left(1 - (4 - 2\sqrt{2}) \frac{d}{L} + \sqrt{2} \frac{g}{L} \right) \quad (2)$$

Finite element analyses: A 2D finite element model of a complete graft material was created in the Abaqus finite element package (Dassault Systèmes, Vélizy-Villacoublay, France). The model began with a sheet of elastic material that was slit with prescribed values of the meshing parameters d/L and g/L (Fig. 2). The left and bottom boundaries were assigned symmetric boundary conditions, and the right boundary was displaced to a stretch of 12. The skin was modeled with an incompressible Ogden Model. Plane strain, quadratic interpolation elements were used. Standard convergence tests were performed, and convergence was achieved with meshes that had on the order of 120,000 degrees of freedom.

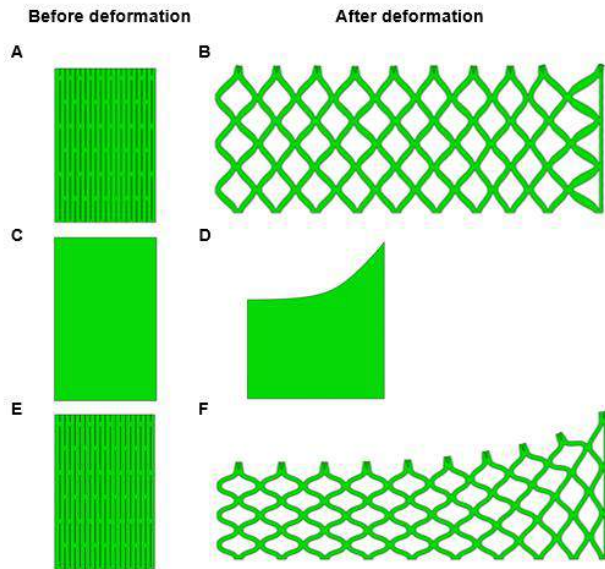

Figure 2: Finite element analysis results with linear and nonlinear Ogden models.

RESULTS

When the material undergoes large deformation, the linear analysis will lead to inaccurate results and the simulation is shown in Fig. 2A and B.

To compare the expansion ratio from formula (1) and formula (2), we used different parameter groups, which means at least one of d , g , and L was changed. The results are shown in Fig. 3A. The red bars mean the ratios are calculated by formula (2) and the blue bars represent the ratios calculated through formula (1). There is a big difference about ratios in group 5 and group 7. The parameters in these two groups show some similar points: (1) L has multiple relationships with d and g . (2) g has multiple relationships with d . In groups 2 and 3, blue bars are higher than red bars and d is greater than g in both groups. In group 7, the ratios are 3 from formula (1) and 3.47 from formula (2), and when the displacement is going to the maximum figure, the expansion ratio is 3.31 as the top point in the blue line in Fig. 3B and is closer to 3.47. In group 8, the ratio is 3.05 that shown in the red bar, and the ratio is calculated by the formula (1) is 3. These two ratios are very close and the maximum ratio in this group is 2.97 by simulation and shown as the peak point on the red line in Fig. 3B.

To verify the factor that affects the area expansion in our model, we created a cut-free skin model (Fig. 2C) and measured the expansion ratio of the skin with different magnitudes of deformation. The expansion ratio is constant as 1, which is shown as the purple line in Fig. 3B. The area of this model does not change after the stretching,

which demonstrates that the area change in our model is independent of the displacement.

We next applied this model to the skin with cuts and measured the area changes to study if the cut size and number affect the expansion ratio. The orange line shows the result with a model which simulates cuts changed to square (Fig. 2A and B) and the red line is the result of the Ogden model with small cuts in Fig. 3B. We can discover that the ratio in the small cuts Ogden model is always smaller than that in the linear model. When we use the big cuts with the Ogden model, the result is shown as the blue line in Fig. 3B. The ratio in this model is always larger than that in the model with small cuts.

Figure 3: The relationship between graft stretch ratio and displacement in different material models.

DISCUSSION

Skin is an elastic material with rubber-like material properties, an aspect that previous studies overlooked, leading to the assumption that each cut would become a perfect square when stretched at large deformations. Our analysis results show that in this case, the expansion ratio is greater than the result of the formula (1). Formula (2) will get a result closer to the simulation. When using the hyperelastic model for analysis, the analysis results are much smaller than those for linear materials. When using a small cut, the simulation result is lower than that of Equation (1). When using a large cut, the simulation results are higher than the results of formula (1). The formula (2) we spit out is also based on the cut becoming a perfect square after stretching. So, our formula cannot be completely consistent with the simulation results. But our results are closer to those of software analysis in large cut and linear analysis.

INTRODUCTION: Disc degeneration is characterized by elevated levels of pro-inflammatory cytokines [1]. Inflammatory stimulation of intervertebral disc nucleus pulposus (NP) can lead to a catabolic breakdown of disc extracellular matrix (ECM), acting as a positive feedback of further loss of tissue integrity and inflammation [2]. Using gain and loss of function approaches, we have also shown that actomyosin contractility mediates the effects of TNF α -stimulation on cell biomechanics and ECM biochemistry (GAG content) [3]. In the current study, we investigate the role of increased cell actomyosin contractility, with the RhoA activator drug, CNO3, on micro- and macroscale biomechanical properties of NP explants. We investigated changes in compressive micro-scale properties with atomic force microscopy (AFM) to determine local properties (point modulus) and spatial mapping of moduli (fast force mapping). We also examined viscoelastic response of NP explants to unconfined compression and modeled the behavior using nonlinear reactive viscoelasticity [4]. We hypothesize that inflammatory-induced changes to NP tissue biomechanics are driven by a loss of GAG content and that increasing contractility can mitigate the degradative effects of inflammatory stimulation of the NP micro- and macro- mechanics.

METHODS: NP Explant Culture: NP explant tissue punches were isolated from bovine caudal IVDs and cultured in 24 well-plates in a swelling restricted culture system [3]. Treatment: NP explants were cultured in one of the following groups for 14 days: (1) untreated, (2) 10ng/ml TNF α , (3) 1 μ g/ml CNO3, or (4) 1 μ g/ml CNO3 + 10ng/ml TNF α (n=5-7 per group). Stress Relaxation and Nonlinear Reactive Viscoelasticity: Cylindrical samples were subjected to 5 ramp-and-hold displacement profiles of 5% compression, for a total compression of 25%. To determine viscoelastic properties, stress relaxation data was fit to a Nonlinear Reactive Viscoelasticity model which models a solid material using a combination of strong and weak bonds. Strong bonds

are unbreakable and account for the elastic response of a material while the weak bonds break and reform into a stress-free state and account for the time-dependent non-linear response to loading. Both strong and weak bonds were modeled as uncoupled (nearly incompressible) neo-Hookean materials. Breaking and reforming of weak bonds was modeled using a Malkin relaxation function with a bond recruitment function dependent on distortional strain. The model computation and curve fitting of experimental data was performed using FEBIO. The resulting material parameters μ_e and μ_a (shear moduli of the strong and weak bonds, respectively), τ_1 and τ_2 (shortest and longest relaxation times constants), and F (recruitment function) were compared between groups. Atomic Force Microscopy (AFM): Explants were cryosectioned and samples were tested at specific points (point modulus) in the inner and outer part of the explant using an Asylum MFP-3D BIO AFM with spherical tip probes. Fast force mapping (FFM), a deflection-controlled feedback technique in which the AFM probe is oscillated at sub-resonance frequency, was also used to acquire maps of local elastic moduli and topography over 120x120 μ m regions. Curves were fitted to a Hertzian model to determine distribution of elastic moduli. Biochemical assays: Explant papain digests were assayed for GAG and collagen content using DMMB and OHP assay, respectively, and reported normalized to wet weight. Statistics: Data was analyzed by ANOVA with Fisher LSD post-hoc (GraphPad), with p<0.05 significant. Pearson correlations were used to identify relationships between biomechanical properties and biochemical content.

RESULTS: AFM: At the microscopic scale, TNF α stimulation significantly decreased the AFM point modulus of NP explants vs. untreated. (Fig 1A). FFM of explants showed qualitative differences in topography of interior and exterior areas of the NP explant (Fig 1B), however there were no significant differences in median modulus or surface roughness with location (not shown). Median modulus of TNF α

treated samples also significantly decreased vs. untreated (Fig 1C) in analysis of fast force mapping changes. Co-treatment of the NP explants with CN03+TNF α partially increased the median elastic modulus (FFM) compared to TNF α group (Fig 1C).

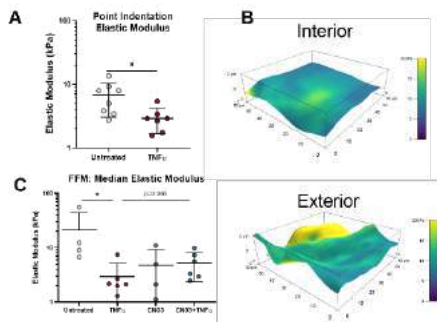

Figure 1: (A) AFM point modulus of untreated and TNF α explants. (B) FFM maps from interior and exterior locations of NP explant. (C) Median elastic modulus from FFM. * $p < 0.05$.

Model Results: At the macroscopic scale, nonlinear reactive viscoelasticity yielded excellent fits, with an average $R^2 = 0.96$ across all groups (Fig 2A). The dependence on distortional strain in the relaxation time τ_2 and recruitment F are shown in Fig 2B. Analysis of the parameter curve fit between groups demonstrated that TNF α did not have a significant effect on any of the viscoelastic model parameters (Fig 3). However, treatment with CN03+TNF α resulted in a significant increase in strong (μe) and weak (μa) bond moduli, and in relaxation time τ_2 compared to TNF α group (Fig 3). **Biochemistry:** While no significant between-group effects were observed in GAG and collagen content, significant relationships between biomechanical and biochemical properties were observed. At the microscale, AFM point modulus was significantly correlated with collagen content ($p = 0.019$, Pearson $r = 0.59$) and had a trend for correlation with GAG content ($p = 0.063$, Pearson $r = 0.47$). At the macroscale, elastic μe was also significantly correlated with collagen ($p < 0.0001$, Pearson $r = 0.92$) and GAG ($p = 0.007$, $r = 0.76$) content. Bond μa exhibited a trend in correlation with collagen ($p = 0.058$, Pearson $r = 0.59$) and GAG content ($p = 0.08$, Pearson $r = 0.55$). Both μe and μa were inversely correlated with water content, given the significant correlations found between water and collagen (Pearson $r = -0.93$) or GAG (Pearson $r = -0.70$).

DISCUSSION: The goal of this study was to evaluate biomechanical changes in NP explants with TNF α stimulation, to advance the understanding on extracellular matrix changes associated with a pro-inflammatory stimulus in NP tissue. Microscale analysis of point modulus using AFM demonstrated a significant loss in compressive properties with TNF α treatment. This was further verified by the results of fast force mapping that pointed to presence of a narrower distribution of compressive properties along with lower median modulus of TNF α treated explants. These findings are consistent with our prior findings of decreased GAG content and Alcian blue staining in TNF α treated explants [3]. Interestingly, the current study, found that point modulus was correlated with GAG and collagen content in the interior but exterior of the explant, which may undergo ECM disruption at periphery of the explant during longer term tissue culture. Treatment of NP explants with the RhoA activator, CN03, resulted in ~2 fold increase in explant microscale elastic modulus, however these levels remained below properties of untreated explants. Our prior studies showed that CN03 counteracted NF- κ B and downstream catabolic signaling [3], however that does not appear to fully protect the microscale biomechanics of the NP.

To examine effects on viscoelastic responses, we also curve fitted the stress relaxation test results to a nonlinear reactive viscoelasticity model, using a new numerical scheme developed by Ateshian and colleagues [4]. The bovine NP explants behaved nonlinearly with each additional stress relaxation step, consistent with prior IVD biomechanics studies [5]. In this model, weak bond recruitment was included as a function of distortional strain to achieve a good curvefit of the experimental data. In the model, strong bonds impart the elastic response while weak bonds break and reform into a stress-free state in response to loading. The process of bonds breaking and reforming is modeled as a reaction where loaded bonds are the reactants and bonds reformed into a stress-free state are the products of a reaction. The reaction is triggered by the evolving state of loading. The state of stress in strong bonds is a function of the total strain in the material, whereas the state of stress in weak bonds is based on the state of strain relative to the time that these bonds were reformed. We found that the relaxation time τ_2 of the reduced relaxation function needed to depend on the distortional strain to achieve good curve fits, further underscoring the nonlinear viscoelastic response of untreated NP tissue. We also modeled a distortional strain dependent recruitment function of the weak bonds. While the strong and weak bond moduli of the NP did not change significantly with TNF α , treatment with CN03+TNF α significantly increased the elastic and bond moduli, as well as relaxation time constant, suggesting that effects of CN03 are affecting both the elastic and viscous responses of NP tissue, which appear to be dependent on tissue water content. Future studies will examine detailed analyses of effects of CN03 on collagen and water content in NP, and examine contributions of CN03 alone on ECM biomechanics.

MULTISCALE COMPUTATIONAL MODELING OF *TGFBR1/2* KNOCK-OUT IN ADULT MOUSE AORTAS

Ana C. Estrada (1), Linda Irons (1), Jay D. Humphrey (1,2)

(1) Department of Biomedical Engineering, Yale University, New Haven, Connecticut, USA

INTRODUCTION

Vascular smooth muscle cells (VSMCs) are critical for the proper functioning and maintenance of the aorta, and dysfunction of VSMCs is responsible for the development of thoracic aortic aneurysms and dissections. Dysfunction of VSMCs is accompanied by changes in intracellular signaling, including altered gene expression and protein activation, as well as tissue-level growth and remodeling (G&R) of the affected vessels. Among the most critical signaling pathways in VSMCs is the TGF- β pathway, which acts through downstream Smad2/3 and MAPK signaling and is responsible for collagen synthesis and remodeling [1].

To better understand the role of TGF- β signaling on vascular G&R, our collaborators developed a conditional knock-out (KO) of TGF- β Receptor 1 (*Tgfr1*) and Receptor 2 (*Tgfr2*) in VSMCs of adult mice, with the KO initiated at 11 weeks of age. They found that while the KO decreased p-Smad2/3 activity, there was no significant change in the morphology of the vessels. However, when the vessels were perturbed with exogenous angiotensin II (AngII) infusion, they developed dissections, demonstrating an underlying vulnerability caused by the KO. The purpose of the present computational study is to understand how *Tgfr1/2* KO can lead to vulnerable but initially stable vessels. We used a multiscale G&R framework, which combines cell-level network modeling and tissue-level constrained mixture modeling, to simulate and analyze the effect of *Tgfr1/2* KO.

METHODS

We used a logic-based network modeling approach to capture the intracellular signaling of VSMCs. Interactions between species within the network were modeled using normalized hill-type functions for activation or inhibition. We built the network model by consolidating relevant signaling pathways reported in the literature. The model in this

study builds on the models used in Irons et al. 2022 [2] and Estrada et al. 2021 [3], and it includes added detail in the TGF- β signaling pathway. In total, the network model consists of 133 nodes and 210 reactions.

To capture tissue-level changes, we used a constrained mixture G&R model for a single-layered vessel previously developed by our group [4]. The G&R model accounts for changes in mass density production and removal of individual constituents, namely smooth muscle cells, collagen, and elastin. The model then integrates these mass densities over time to calculate the inner radius and thickness of the vessel under changes in hemodynamic load, such as blood pressure or flow. Using the method described in Irons et al. 2021 [5], we coupled the network to the G&R model by mapping the key inputs and outputs between the models. We mapped the network circumferential stress and wall shear stress inputs to the calculated change in circumferential stress and wall shear stress from the tissue-level model. We then calculate the mass density production and removal from the steady-state activation of relevant network outputs. The mean activation of collagen mRNA drives collagen mass density production, while mean MMP activation drives removal. Similarly, the network proliferation and apoptosis outputs drive smooth muscle cell mass density product and removal, respectively. We further mapped the contractility output of the network to the active stress calculation in the tissue-level model.

We optimized the wild-type material parameters of the G&R model and the Hill parameters of the network model using a nonlinear least-squares algorithm. We then simulated *Tgfr1/2* KO by gradually reducing the maximum activation of both TGF- β 1 and TGF- β 2 network nodes to 0.4 (where values are normalized to [0,1]) over the course of five simulated days and imposing a mild 15% pressure increase, as reported in the experimental data. To test vulnerability, we further perturbed the model by 1) increasing the pressure to 40% over baseline,

2) adding exogenous AngII as network input, and 3) combining the pressure and AngII perturbations. For each condition, we calculated the relative change in inner radius and wall thickness compared to the wild-type model at its baseline blood pressure (14kPa). We then analyzed the individual activation of network species after each perturbation to determine those with the greatest change compared to the KO alone.

RESULTS

We initialized the coupled G&R model using the mean reported dimensions and material properties of ascending thoracic aortas from wild-type mice in the experimental study and optimized the remaining parameters such that the model would 1) remain stable under constant hemodynamic load and 2) achieve a new homeostatic state with a 15% increase in pressure load. KO of the TGFR1/2 nodes with the optimized parameters resulted in no change to the inner radius and a 15% increase in thickness one week post-KO, consistent with the experimental data. We then performed a qualitative comparison of 68 individual network nodes and their corresponding transcripts from single-cell RNA sequencing performed in the experimental study. The coupled model accurately predicted changes in 55 of the 68 species, corresponding to 81% model accuracy.

To better understand vulnerability, we perturbed the optimized model by increasing the pressure by 40% or by stimulating the network with exogenous AngII, as well as a combined insult. Increased pressure led to wall thickening but mild changes to inner radius, while exogenous AngII infusion enhanced the wall thickening for each applied pressure condition. Comparing the network species with the greatest change from KO alone, we saw that mechanoregulation decreased with each perturbation but lysosome-related species, such as LAMP1/2, MITF, and Dishevelled (Dsh), a key protein in the Wnt/ β -catenin pathway, increased. The activation of these lysosome-related species suggests that these VSMCs may be shifting towards a more degradative phenotype, which has been previously implicated in the development of aortic dissections [3,6]. In order to test if the Wnt/ β -catenin pathway was a primary driver of remodeling due to pressure or AngII infusion, we next simulated inhibition of the Dsh node (based on [7]) during both pressure and AngII perturbations. We found that Dsh inhibition led to attenuation of the wall thickening comparable to that of KO alone (Figure 1), as well as reduced lysosomal activity.

Figure 1: Bar graphs showing the relative change in inner radius and thickness due to TGFR1/R2 KO, and KO combined with AngII infusion, pressure (P) increase, and Dsh inhibition

DISCUSSION

Using a multiscale G&R approach, we built a model of conditional *Tgfr1/2* KO in vascular smooth muscle cells. Our model incorporates a detailed network model of intracellular signaling coupled to a tissue-level constrained mixture model of vascular G&R. Despite a perturbation in a key pathway for cell and tissue maintenance, the KO vessels remain stable but vulnerable under baseline hemodynamic load. Both stability and vulnerability of these vessels highlight the necessary role of feedback between the network and G&R models. Feedback between the scales allows the coupled model to regulate changes in signaling and remodeling, such that mild perturbations in hemodynamic load and signaling lead to adaptive homeostatic responses, consistent with prior studies [2]. Gradual KO of the TGFR1/2 nodes yields changes in inner radius and wall thickness consistent with our experimental data. Additionally, the model captures a qualitative increase or decrease in 55 of 68 intracellular nodes compared to single cell RNA-sequencing data. For the signaling comparison, we assumed that changes in transcript expression correlate with changes in protein activity, acknowledging that the correlation is not guaranteed to be 1:1.

We then saw that increases in pressure had a greater independent effect on the thickness of vessels in the KO model, while exogenous AngII enhanced the G&R response for each pressure condition. Both perturbations resulted in increased activation of the Wnt/ β -catenin signaling pathway, which is also associated with activity of lysosome-related species, but this effect was attenuated by disrupting Dishevelled signaling. Experimentally, the KO causes a disruption in extracellular matrix structure and cell-matrix interactions. The concurrent increase in degradative activity within a disrupted matrix could be a potential mechanism for the vulnerability of the KO vessels.

INTRODUCTION

Traumatic brain injury (TBI), caused by rapid brain tissue deformation in response to sudden linear and angular accelerations of the skull, is a serious health condition that affects both military and civilian populations. However, the mechanisms linking mechanical insult and neurological injury, more specifically how skull motion is transmitted to brain motion during TBI, are not well understood. Recent work has highlighted that injury to the interface between the brain and skull is a relatively common consequence of TBI [1]. Methods to non-invasively probe the biomechanics of the brain and skull have been developed using magnetic resonance imaging (MRI) [2]. Test objects with known boundary conditions are, however, required to validate the ability to accurately characterize the biomechanical relationship between skull and brain. Prior work on biomechanical MRI phantoms have focused only on simulating the brain [3], mostly the deformation of the brain. However, the motion of brain relative to the skull has not been investigated yet. Here, we developed two skull-brain phantom models that can be used to evaluate skull-brain mechanics using tagged MRI. A key feature of these phantoms is the presence of slots that can be used to represent marrow in the skull.

METHODS

Two different biofidelic brain phantoms, namely, skull brain phantom (SBP) models, were developed using a cylindrical container: 1) SBP with attached (fixed) boundary (SBPa), where the container contains only a gel-based brain simulant that sticks to the container wall and 2) SBP with unattached (free) boundary (SBPu), where the simulant does not completely fill the container and is surrounded by a layer of water between stimulant and the container wall. The fabrication of these two models were divided into two steps, namely the mold and gel fabrication process. In the mold fabrication process, two identical cylindrical molds (outer diameter 5 inches, inner diameter 4 inches and length 8 inches) were 3D printed for both SBP models. The inside of the

mold represents the brain region whereas the cavities inside the wall represent marrow within the skull (**Figure 1a**). This design was chosen because in standard MRI acquisitions, bone provides almost no signal, but marrow inside the bone can provide excellent signal. However, the amount of marrow is not uniform throughout the skull. In both models, the bottom end cap had protrusions to fix the gel in the mold at that end, while the gel was kept free at the top end. To make it air-tight, the mold end was covered with a silicone gasket followed with an acrylic endcap tightened by nylon screws. A complete fabricated mold is shown in **Figure 1b**. A luer valve is added at SBPu model for adding water and removing bubbles from the mold.

Figure 1: a) Schematic of SBP mold and b) Fabricated mold

The gel fabrication process of these phantom models was modified based on previously reported methods [3]. Polyacrylamide (PAA) gel was used as a brain tissue simulant due to its easily tunable material properties, room temperature fabrication and high level of transparency for optical access. Briefly, 140.0 g of acrylamide (purity $\geq 98.0\%$) was dissolved in 1400 mL deionized water while stirring moderately to generate a 10% (weight/volume) solution. After the acrylamide was fully dissolved, 2.34 g of *N,N'*-methylenebis (acrylamide) (MBA, purity 99%) was added slowly while stirring the solution. Once the solution was homogenized, 1.22 g of ammonium persulfate was added to initiate

the crosslinking of the two monomers of acrylamide. Finally, upon the addition of 2.49ml of *N,N,N',N'*-tetramethylethylenediamine (TEMED, purity 99%), the solution was poured immediately into the molds following the addition of TEMED. For the SBPa model, the PAA solution was directly poured in the 3D skull and was allowed to cure and adhere to container wall, creating a fixed wall boundary condition. For the SBPu model, the PAA solution was first poured into an intermediate cylindrical mold (outer diameter 5 inches, inner diameter 3.75 inches and length 8 inches) with the inner surface covered with a Teflon tape, preventing gel from adhering to the cylinder wall. Once PAA gel was cured, it was then transferred to the 3D printed skull (inner diameter 4 inches), leaving a gap between the gel and the cylinder wall. Since water is widely used as an artificial cerebrospinal fluid, the gel of SBPu model was filled with water using a syringe through luer valve at least 1 hour before scanning. The water between the PAA gel and the cylinder wall created the free boundary condition in the SBPu model.

Figure 2: Neck rotation experiment performed on 2 SBP models. a) and c) showing 0° rotation (Purple line) representing resting position, whereas b) and d) showing 32° rotation (Yellow line) representing the position of impact, for SBPa and SBPu, respectively. e) representing the motion of gel in SBPu shortly after impact.

The head motion investigated in this study was neck rotation (rotation within the axial plane) using a previously described custom MRI-compatible device [4] used to constrain the motion of the head (or phantom), thereby facilitating a repeatable acceleration event within the MRI scanner. After the phantom was rigidly coupled to the head cradle using a strap, a cord was pulled to release a latch allowing an offset counterweight causing the head cradle to rotate clockwise at about 32° rotation (Figure 2). At that angular position, the counterweight impacted a padded stop (1/4" Sorbathane pad), which caused a rapid deceleration of the head cradle and phantom. An angular position sensor (Model MR338, MICRONOR, CA, USA) was coupled to the axis of rotation of the head cradle to provide measurements of angular position, velocity, and acceleration over time at 0.85 ms temporal resolution.

Figure 3: a) Mask region, b) marrow region, c) brain region and d) tagged image of SBP.

The tagged MRI study was performed using a 1.5 T Siemens Aera MR scanner. Data was acquired using a 1–1 Spatial Modulation of Magnetization (SPAMM) tagging pulse followed by 2D cine gradient echo acquisition using two axial acquisitions with orthogonal tag directions and the following acquisition parameters: FOV = 240×240 mm, matrix = 24×160, slice thickness = 8 mm, TR/TE = 3.18/1.68 ms and tag spacing = 8 mm. A single axial slice was acquired at approximately the middle of its long axis.

All MRI data processing was performed in MATLAB R2020a (MathWorks, MA, USA). A mask of the hydrogel portion of the phantom was created using ITK-Snap by registering the FLAIR image rigidly to the first frame of the tagged MRI data and applying the transformation matrix to the mask (Figure 3). Harmonic phase (HARP) analysis [4] with HARP refinement was performed to measure the displacement vectors between each frame and the first frame. Image axes were oriented with respect to the scanner. The maximum principal strain (MPS, largest eigenvalue of strain tensor) was analyzed from Eulerian strain tensors computed from the displacement vectors.

RESULTS

Video capture of both SBP models marked with vertical black lines showed significant rigid body motion in the SBPu at impact compared to the SBPa (Figure 2). The strain in the brain region for the SBP model in the neck rotation experiment was qualitatively similar to the results from an established sylgard phantom [5]. The MPS distribution for both SBP models at 9 different time points are shown in Figure 4. While in both models the strain was observed higher near the wall, the strain was quantitatively higher in the SBPa model (0.014) than the SBPu model (0.010) at the point of impact shown by the yellow box in Figure 4.

Figure 4: Maximum principal strain shown for SB Phantom with attached wall (a) and unattached wall (b) at first 9 time points (left to right). Yellow square represents the timepoint of impact.

DISCUSSION

The effect of impact forces was studied using two different phantom models and the results suggests that at the point of impact, the strain is larger with a fixed boundary. The lack of attachment to the container wall lessened the effect of impact force on brain in SBPu model. However, at later times after impact, strains were increased in the SBPu model due to a torsional wave originating at the fixed bottom boundary and propagating back and forth in the PAA gel. These models can be developed further by incorporating fat-water emulsion in the skull slots as a simulant for brain marrow.

INTRODUCTION

Microgravity related missions are becoming increasingly prominent in the current development of the space industry. With the increasing number of manned missions to the International Space Station (ISS) and the development of commercial space travel, it is important to address the various implications that arise in these microgravity environments. One such issue is the significant bone loss and decreased bone density observed in astronauts during extended periods of microgravity [1]. This bone loss, if left unchecked, can have severe consequences for the health and functionality of astronauts, as well as the success of future microgravity missions.

One promising solution to this problem is the use of low intensity vibration (LIV) as a countermeasure. Studies have shown that low intensity vibration can stimulate bone formation and improve bone density in both normal and microgravity conditions [2], [3]. However, the use of low intensity vibration in microgravity environments has been limited due to the lack of suitable bioreactors capable of providing the necessary stimuli.

Therefore, the goal of this study was to develop a vibrational bioreactor specifically designed for use in microgravity conditions. This bioreactor will be used on Space Tango's CubeLab platform [4] and enable the study of the effects of low intensity vibration on cells in microgravity, and potentially lead to the development of new therapies and treatments for use in space and other microgravity environments.

METHODS

This section describes the design and characterization of the vibrational bioreactor. The goal of this study was to create a bioreactor capable of achieving a target vibration acceleration of 0.7g at a frequency of 90 Hz, a signal regime we have shown to improve the growth rate and productivity of cells under simulated microgravity conditions [5]. We focused on three key components of the bioreactor: (1) the linear guide used to mount the payload and restrict the motion to

Figure 1 Thermal experiment setup

single dimension, (2) the characterization of the transducer used to induce vibration, and (3) the design of the well plates used to study the diffusion of a tracer molecule in the culture medium to ensure adequate medium change during the microgravity mission.

CubeLab Platform is a modular customizable laboratory developed by Space Tango that is designed for microgravity research on the ISS. It is a compact, self-contained laboratory that can be used to conduct a wide range of experiments in microgravity. We utilized the CubeLab 9U with a volume of 550 cubic inches.

Linear Guides are tested for their size and precision. Both the N drylin® N pre-loaded prism carriage and the Schneeberger NK1 2-95 were vibrated at 90Hz, 0.7g. Both linear guides are also compared to a regular roller guide used in the laboratory. The LIV is applied to a 1 kg steel payload for 20 minutes, and the acceleration is recorded through the MEMSIC CXL04GP3 accelerometer.

Transducer generates the mechanical vibrations that stimulate cells. Heat generated by the transducer can increase the temperature of the cell culture and negatively affect cell growth. To investigate this, thermocouples were used to track the temperature increase of the whole setup over the course of the vibration in a CubeLab. The transducer for this LIV bioreactor was selected as the PI-841.3.S0 from Physik Instrumente and the E-610 is its controller / amplifier. (Figure 1).

CubeWells Cells in culture require regular exchanges of media to maintain optimal growth conditions. In this study, we also aimed to investigate the speed of media exchange in the vibrational bioreactor. A customized microplate designed by Space Tango (will be referred as

CubeWells) and was initially filled with 8mL of water along with stereolithography (SLA) printed scaffolds encapsulated in hydrogels to mimic cellular constructs that will be used in the cell culture experiments (5x5x5mm). A simulated new medium—a mix of water and Royal Blue Icing Color dye—is pumped into the CubeWells at a rate of 0.9 mL/min. The media exchange is observed using a high-speed camera (1000fps, Photron FASTCAM MINI UX50) to see the diffusion of the dye and the movement of fluid in the CubeWells over the course of 5 minutes. Diffusion was quantified at five locations (Figure 4).

RESULTS

Linear Guides The results of the vibration experiment showed that the Schneeberger NKL 2-95 linear guide outperformed the N preloaded prism carriage by showing a consistent 1-axis acceleration over the 20 minutes of LIV. Although the Schneeberger guide is larger in size, it demonstrated a lower standard deviation for all axes when compared to the N preloaded prism carriage. Both guides can reach the targeted 0.7g in the direction of motion. However, when comparing the acceleration values in the other axes, the N preloaded prism carriage had more acceleration in both x and z, 0.4g and 0.1g respectively, compared to the Schneeberger guide.

Figure 2 Linear guides acceleration values over 20-minute LIV

Transducer Shown in Figure 3, the results of the thermal experiment on the actuator and controller setup during vibration indicated that the temperature of the system remained within safe limits for cell growth. The highest temperature recorded within the CubeLab was above 50 degrees Celsius, which was recorded at the controller. However, the ambient temperature of the air around the payload was less than 28 degrees Celsius over the course of the vibration. This suggests that the heat generated by the actuator and controller was dissipated effectively and that the temperature of the cells was not affected by the vibration.

CubeWells The results100% (8mL) media exchange indicated that after 3 minutes, the new media had reached the middle of the CubeWell, and after 5 minutes, 80% of the new media had reached the bottom of the microplate (Figure 4Error! Reference source not found.). dye over time, we were able to determine the diffusion of the new media in the microplate. The results showed that following the media change a recirculation would be required to completely exchange media for all of the scaffolds.

Figure 3 Temperature range of the ambient air inside the CubeLab during 25-minute of LIV

Figure 4 Diffusion rate of 5 locations in the CubeWell during 5-minute pump of new media

DISCUSSION

The results from this study suggest that the Schneeberger NKL 2-95 linear guide is more suitable for applications requiring precise and controlled vibration in a single axis with an acceleration of 0.7 g, while the N preloaded prism carriage may be more suitable for applications requiring multi-axis vibrations. The thermal data collected in this experiment provides information on the thermal behavior of the actuator and controller during vibration, useful for optimizing future bioreactors and evaluating safety and thermal load. The results showed that the temperature inside the bioreactor remained safe for cell growth and cells were not affected by the thermal behavior of the system. Finally, the results of the diffusion study showed that old media can be exchanged remotely 5 minutes with the current CubeWell design, however, additional re-circulation is needed for providing optimal media diffusion for cell growth. These results can be used to improve the design and operation of future vibrational bioreactors.

Overall, our study has provided valuable insights into the design and operation of an LIV bioreactor. This research could be used as a foundation to optimize the design of future bioreactors and provide a better understanding of microgravity's effect on cell growth. Further studies can be done to optimize the design and characterization of the bioreactor, such as finding the optimal vibration parameters for different types of cells and evaluating the bioreactor's performance under varying conditions such as temperature, humidity, and dissolved gas concentration.

INTRODUCTION

In cancer treatment, radiation therapy (RT) utilizes high-energy radiation to destroy cancer cells. Each year, more than half a million patients being treated in the United States receive radiation therapy [1]. Administering effective treatment to these patients is heavily reliant on accurately delivering radiation to the patient. Current methods rely on CT scans taken anywhere from days to weeks before the treatment. However, due to weight loss or tumor shrinkage in the time between imaging and treatment, and organ motion during treatment, this is not a fully accurate representation of the radiation delivered to the patient [2-4]. Serious side effects can arise from delivering radiation to healthy tissue, including nausea, radiation fibrosis and radiation pneumonitis, vomiting and diarrhea, or rectal bleeding and incontinence.

To avoid these effects, the radiation distribution within a patient can be measured in a method known as radiation dosimetry. *In vivo* dosimetry is currently possible using a variety of equipment; however, they are limited by their inability to measure in real time and collect information at a single point [5,6]. Currently, no method allows for real time 3D dosimetry mapping for radiation therapy. One proposed method to create such 3D dosimetry is X-ray acoustic computed tomography (XACT). This methodology utilizes the X-ray acoustic (XA) effect, which describes an acoustic wave emitted because of heat expansion by a target that has absorbed X-rays. However, this methodology is prone to issues in the signal-to-noise ratio (SNR) for endogenous targets, inhibiting its ability to translate clinically. By introducing a contrast agent to increase the SNR, the clinical efficacy of XACT can be drastically improved, shown in Figure 1a.

Recently, novel vaporizable endoskeletal droplets (VEDs) have been shown to increase the acoustic response to near-infrared photons during the photoacoustic effect. These droplets are primarily composed of liquid perfluorocarbon (FC) but have a solid hydrocarbon (HC) core, which allows for tunability of the vaporization temperature [7]. When

heated, interfacial mixing between the HC and FC phases facilitates vaporization of the droplet, resulting in a volumetric expansion of up to 125 times its original size [8]. To better understand the resulting temperature of the droplets when exposed to X-ray, we developed a model of the heat conduction through the droplet and into the surrounding water prior to vaporization. Using the model, we aim to determine the theoretical required dose and dose rate to vaporize the droplets.

METHODS

The model consists of three spherical domains, as shown in Figure 1b: a HC core with radius R_h , a FC shell with radius R_f , and a semi-infinite domain of water. The droplets are assumed to have radial symmetry.

Figure 1: (a) Schematic of contrast-enhanced XACT (b) Schematic of VED used in model, with hydrocarbon (HC), perfluorocarbon (FC), and water domains.

To model the conduction of heat, Fourier's law modeling one-dimensional heat conduction along the radius was implemented for each domain (Eqs. 1-3).

$$\frac{dT}{dt} = \frac{k_h}{r^2} \frac{d}{dr} \left(r^2 \frac{dT}{dr} \right) + Q \quad \text{for } 0 \leq r \leq R_h \quad (1)$$

$$\frac{dT}{dt} = \frac{k_f}{r^2} \frac{d}{dr} \left(r^2 \frac{dT}{dr} \right) \quad \text{for } R_h \leq r \leq R_f \quad (2)$$

$$\frac{dT}{dt} = \frac{k_w}{r^2} \frac{d}{dr} \left(r^2 \frac{dT}{dr} \right) \quad \text{for } R_f \leq r < \infty \quad (3)$$

For the model, it was assumed that heat was generated only in the HC core, given by Q in units of W/m^3 . The thermal diffusivity, k_i , where i indicates the domain, was defined as the thermal conductivity, α , divided by the product of the density, ρ , and specific heat capacity, \hat{C}_p , (Eq. 4) [9].

$$k = \frac{\alpha}{\rho \hat{C}_p} \quad (4)$$

Table 1 provides a summary of the values used to determine the thermal diffusivity of the three domains. For the model, the HC used was eicosane, due to improved vaporization compared to other HCs [10].

Table 1: Summary of the values used for thermal conductivity, density, specific heat capacity, and resulting thermal diffusivity.

	$\alpha [W m^{-1} K^{-1}]$	$\rho [kg m^{-3}]$	$\hat{C}_p [J kg^{-1} K^{-1}]$	$k_i [m^2 s^{-1}]$
HC	0.42	789	2133	2.50×10^{-7}
FC	0.50	1630	1087	2.82×10^{-7}
H ₂ O	0.61	1000	4186	1.47×10^{-7}

The following boundary conditions were implemented: using a semi-infinite ‘far-field condition’, water is 32°C far from the droplet (Eq. 5); at the interface between domains i and j , there is equivalent heat transfer (Eq. 6) and temperature (Eq. 7); all domains have an initial condition of 32°C (Eq. 8).

$$T(r \rightarrow \infty) = 32^\circ C \quad (5)$$

$$-k_i \left. \frac{dT_i}{dr} \right|_{r=R_i} = -k_j \left. \frac{dT_j}{dr} \right|_{r=R_i} \quad (6)$$

$$T_i|_{r=R_i} = T_j|_{r=R_i} \quad (7)$$

$$T(t = 0, r) = 32^\circ C \quad (8)$$

Applying the boundary conditions and the initial condition, the steady state solution was obtained for a value of Q such that the middle of the HC core was 33°C, which is the droplet’s observed temperature of vaporization. Using the value of Q , a corresponding dose rate, DR , was estimated (Eq. 9)

$$DR = \frac{Q}{\rho} \quad (9)$$

The total dose, D , to raise the HC by 1°C (the range of vaporization temperature for eicosane droplets) is determined by utilizing the heat capacity of the material (Eq. 10) [11].

$$D = \frac{\Delta T}{\hat{C}_p} \quad (10)$$

RESULTS

From the steady state solution, a heat map was produced for the VED, shown in Figure 2. From the steady state calculations, it was determined that a dose rate of around 85 Gy/s and a total radiation time of around 25 seconds is needed to bring the HC core to its observed vaporization temperature.

As a more representative solution to the heat conduction of an ideal droplet, a transient solution was calculated using an initial temperature of 37°C (shown in Figure 3) and a dose rate of 24 Gy/min, which is the highest achievable clinical dose rate of standard LINACs.

Figure 2: Steady state heat map of eicosane endoskeletal droplet with the HC core and FC shell outlined in black.

Figure 3: Transient heat map of eicosane endoskeletal droplet with the HC core and FC shell labeled in red vertical lines.

DISCUSSION

The results presented here indicate a large dose rate will be needed to raise the temperature of the droplet by 1°C. Using a more clinically relevant dose rate indicates an expected smaller increase in temperature of the HC, necessitating precise control of the vaporization temperature of the droplets. These findings highlight the need for a high-Z material that can more efficiently convert X-ray to heat, as well as the possible use of FLASH-RT, which is a novel type of RT that delivers high dose rates (> 40 Gy/s) [12]. Future models will explore these materials as dyes within the HC phase and their impact on the amount of heat generated per dose, as well as quantify in more detail the complexities of the interactions between X-rays and the droplets.

PIN LOOSENING IN EXTERNAL FIXATION: A FINITE ELEMENT ANALYSIS TO DEVELOP AN OVINE BONE TRANSPORT MODEL

Michael J. Poland (1), Yunzhi Peter Yang (2), Jeremiah T. Easley (1), Jeffrey Young (2), Holly L. Stewart (1), Chloe Brekhus (1), Christian M. Puttlitz (1), Benjamin C. Gadowski (1)

INTRODUCTION

Segmental defect repair remains a primary challenge in orthopedics. Bone transport distraction osteogenesis (DO) is a common surgical approach to bridge long bone critically sized defects. An osteotomy is performed adjacent to the defect to create a bony segment. The segment is then stabilized with external fixation and transported at 1 mm/day until it has crossed the bone gap (Figure 1B). After completion of distraction, the bone often must remain stabilized for more than six months. Consequently, long-term external fixation can lead to complications, such as pin loosening. The breakdown of the pin-bone interface can be attributed to an interplay of mechanics and pin-site infection. For example, increased pin flexion, caused by a weak construct, can irritate the bone and lead to increased infection risk. Conversely, infection at the pin site can weaken the bone, leaving it vulnerable to degradation from the pin [1]. Pin configuration A (Figure 2) was used in an ovine bone transport pilot study, but pin loosening resulted in premature termination of 2 sheep. The aim of this study was to optimize the external fixation construct to minimize stress at the pin-bone interface using finite element (FE) ovine metatarsal bone transport models.

METHODS

Computer Simulation

FE software (ABAQUS/Standard 2020) was used to model ten unique external fixator configurations. An approximated sheep metatarsal was modeled with elastic material properties ($E=18\text{GPa}$, $\nu=0.265$) and as a hollow cylinder with 7mm and 18mm inner and outer diameters, respectively. All external fixation components were modeled as stainless steel ($E=200\text{GPa}$, $\nu=0.3$), and all interfaces were modeled as tie constraints (Figure 1A). A 200N compressive force was applied to the superior surface of the simulated metatarsal at a 20° posterior-anterior angle to mimic the walking conditions of a sheep [2]. Rotation and displacement were constrained in all directions at the distal face of

the distal bone with an encastre boundary condition. Linear, hex elements were used to model the bone segments (1446 elements), pins (2100 elements), and frame (19538).

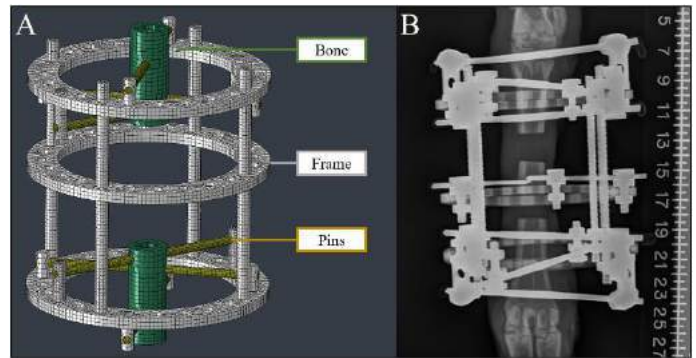

Figure 1: (A) Finite element model of simulated sheep metatarsal (green), external fixation frame (white), and fixation pins (yellow). (B) Radiograph of sheep metatarsal during the bone transport phase.

In Vivo Study

The results of the FE simulations informed the *in vivo* external fixator design where lower stress at the pin-bone interface indicated better performance. Pin configuration F was then used on two skeletally mature female ewes (IACUC #KP 1579). Pin pilot holes were drilled 0.1mm smaller than the pin core diameter. An osteotomy was performed to create a 2cm transport segment and a 3cm distraction gap. Seven days after the operation, distraction began at a rate of 1mm/day for 30 days followed by a consolidation period of 180 days. Biweekly radiographs were taken and analyzed for signs of loosening, such as radiolucency around each pin. Bandages were changed, pin sites were cleaned, and

the leg was palpated to check for loosening twice per week throughout the latency and distraction periods and once per week throughout consolidation. After sacrifice, micro-computed tomography (μ CT) analyses were used to measure the final pin site diameters in each specimen using the following parameters: Voltage: 70kVp, current: 114 μ A, integration time: 500ms.

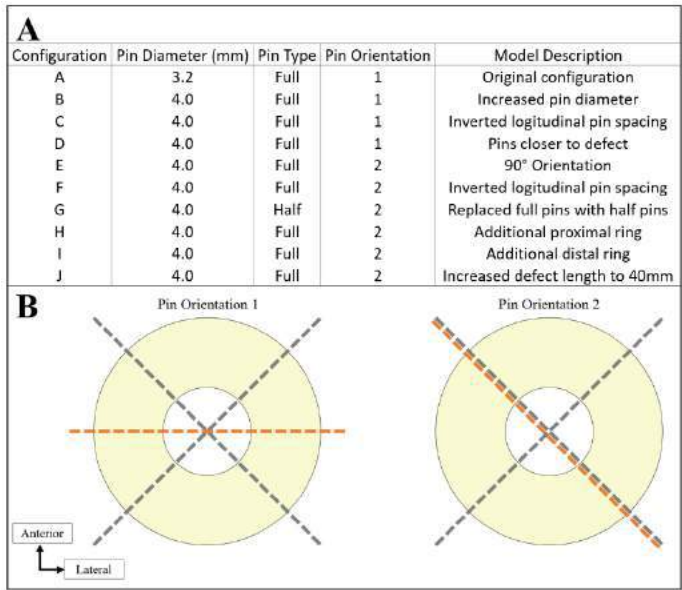

Figure 2: (A) Descriptions of the modeled fixation configurations. (B) Graphical representation of pin placement in a sheep metatarsal cross section

RESULTS

Computer Simulation

Maximum von mises bone stress (MVMBS) was approximately 25% lower for 4.0mm configurations when compared to 3.2mm configurations (Figure 3). Compared to configuration A, the use of 4.0mm half pins increased MVMBS by 40%. Moving pins closer to the defect resulted in the third highest MVMBS value at 34MPa. No other configuration altered bone stress by more than 7%. Maximum von mises pin stress (MVMPS) decreased by at least 52% in all models except for configuration G.

In Vivo Study

In vivo configuration F manual palpation demonstrated no qualitative signs of pin loosening throughout the duration of the study (217 days) in either sheep. In one animal, however, post-sacrifice micro-CT measurements showed a pin hole diameter expanded by an average of 2mm across one pin site. No other pin site in the configuration F animals had a measured diameter expansion larger than 0.2mm. Manual palpation of configuration A animals showed significant loosening after 30 days in 2 animals, and they were terminated early. Micro-CT measurements showed an average expansion of at least 3.5mm across all measured pin sites.

Figure 3: Pin and bone maximum von mises stress for each configuration

DISCUSSION

Pin diameter had the biggest impact on VMBS and VMPS, and further configuration modifications only marginally altered the stresses. The use of half pins in place of full pins erased any benefit of larger pin diameter. However, half pins only have one insertion point per pin and should be considered if infection is believed to be the main cause of loosening. Configuration D resulted in the third highest bone stress. This result is surprising because previous studies have shown that moving pins closer to the defect can increase fixation stability [3]. Therefore, this result may suggest that fixator stability and stress at the pin-bone interface are not always directly related. Configuration F was chosen for use in the *in vivo* study because it both resulted in low stresses at the pin-bone interface and had a higher axial pin spacing, decreasing the chance of fracture upon insertion. Stress may have been further reduced by increasing the pin diameter beyond 4.0mm, but the use of pin diameters greater than 30% of the bone diameter is not advised [3]. A larger *in vivo* sample size would be needed to investigate if the expanded diameter of the single configuration F pin site was a result of fixation mechanics. While it is believed improved fixation mechanics improved the outcome of the *in vivo* study, improved pin site cleaning may have also contributed to pin site longevity. High bone transport associated skin tension [3], tissue viscoelastic properties, and true anatomic geometry are not accounted for in this FE study. A future study could expand on this work by evaluating more configurations and loading conditions. Long-term ovine pre-clinical studies designed to improve the bone quality and rate of healing in bone transport patients would improve with better pin site longevity. The resulting external fixation construct from this work may be an effective model for future ovine DO studies.

INTRODUCTION

Patch augmentation of the aorta is a critical component of several pediatric cardiac surgical procedures, including repair of aortic coarctation with hypoplastic arch and the Stage I Norwood procedure for single ventricle palliation. During these procedures, an incision is made in the native aortic tissue and an autologous or commercial tissue patch is sewn in with a running suture line to achieve the targeted vessel geometry. Tissue-based patches are preferred for these reconstructions due to their ability to conform to the desired curvature and to better preserve aortic compliance; however, these materials are not as strong as synthetic alternatives and can be vulnerable to dilation or failure if used under inappropriate loading conditions.

Prior studies have characterized the mechanical behavior and failure properties of conventional patch materials, including pulmonary homograft, autologous pericardium, and various fixed pericardium products [1-3]. These studies typically report the ultimate tensile strength of the patch, determined through uniaxial tests of dogbone-shaped samples. While this type of test is well established and straightforward to perform, it does not reflect a realistic loading scenario for a surgical patch, which will be sewn into aortic tissue and pulled in all directions under a pressure load. Standard and bulge inflation tests better address the loading configuration, but they usually do not evaluate the sutured patch-aorta interface, which represents the weakest region of the patch.

In this study, we evaluated the failure strength of two common patch materials [4]: thick-patch pulmonary homograft (cryopreserved, cadaveric adult main pulmonary artery) and CardioCel Neo (fixed bovine pericardium) using three different test modalities. Unsutured and sutured patch samples were tested uniaxially to identify the effect of the suture line on failure strength, and patches were sewn into a porcine aorta to compare uniaxial failure strength to burst strength.

METHODS

Patch Materials

Each test modality was conducted for three different patch materials: porcine pulmonary artery, pulmonary homograft, and CardioCel Neo (Fig. 1). Due to known similarity between porcine and human large artery mechanics, porcine pulmonary artery was tested to supplement the limited pulmonary homograft sample size [5]. Samples were harvested from fresh, adult whole-heart specimens (Lampire Biological Laboratories, Pipersville, PA). Homograft is the preferred patch material for neonatal arch reconstruction, but its safety in older patients is not well documented. Two 30x30mm patches were retrieved from discarded OR scraps (LifeNet Health, Virginia Beach, VA, and Artivion, Kennesaw, GA). CardioCel Neo (LeMaitre, Burlington, MA) comes in a 0.3mm-thick sheet and is advertised to be stronger than the aorta and suitable for great vessel reconstruction. Two 50x80mm patches were retrieved from discarded OR scraps. All tissue was stored in normal saline at 4°C until use.

Uniaxial Failure Strength

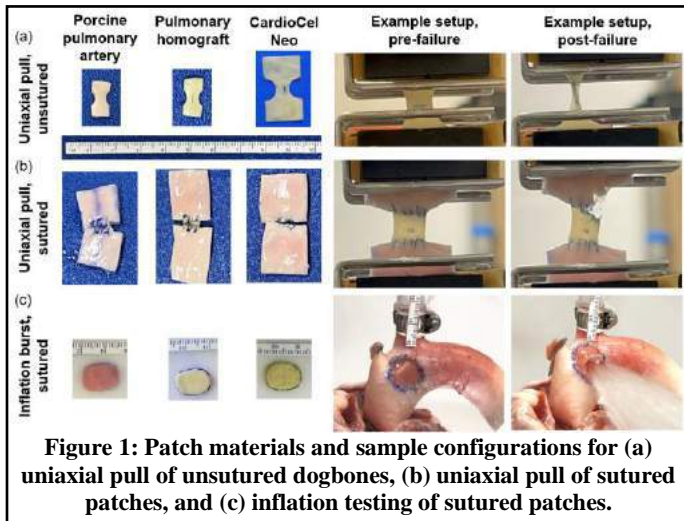

Uniaxial testing was conducted on both unsutured dogbone samples and sutured squares using a single-column Instron. Displacement was set to 10mm/minute, and force was recorded with a 50N load cell. Samples were held by 250N pneumatic clamps with sandpaper. Membrane tension at failure was calculated using the undeformed patch width for both sample types.

Unsutured Dogbone Samples

Ultimate tensile strength of the patch materials was assessed through uniaxial pull to failure of dogbone samples (Fig. 1a). Three axially aligned dogbones were cut from the porcine pulmonary artery to capture failure strength along the weaker direction of the vessel. Two dogbones were cut from each homograft patch for a total of four samples. Samples from both of these materials were prepared as

7.5x15mm strips with an 8mm punch used to create the narrowed central region.

For the CardioCel Neo, there was enough material available to prepare four dogbone samples from each of the two patches (n=8). Due to the significantly higher strength of this material, samples were cut to 15x25mm for increased grip area, and the punch was used to reduce the central region to <4mm width. Sample lengths were recorded as the distance between the grips after the samples were mounted and the Instron jogged to show 0.01N load.

Sutured Square Samples

To minimize the patch material needed for each sutured sample, 7.5x7.5mm squares were cut and sutured on either end to 15x15mm squares of porcine aorta (Fig. 1b). The 7.5mm edge length allowed 4 bites of a running 5-0 Prolene suture to be made into both the patch and the aorta with roughly 1.75mm bite spacing and 2mm bite depth. The two tabs of aorta were clamped into the Instron, and the mode of failure was recorded. Suture line failure was defined as either the patch or the aorta having suture pull-through from the needle holes into the edge of the suture line. Needle hole failure occurred when the patch or the aorta tore internally, originating at a stretched needle hole. Patch rupture was defined as a tear beginning at the free edge of the patch or internally without any continuity with the needle holes or suture line.

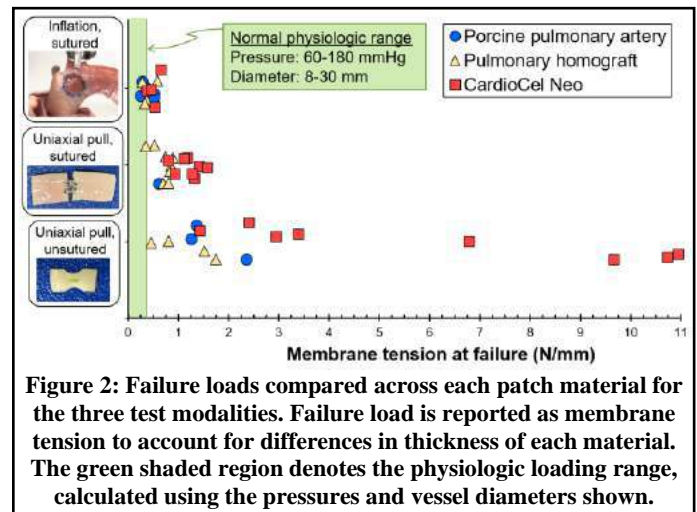

Inflation Burst Strength

To assess the importance of the loading state in patch failure, a series of inflation tests were conducted on patches sewn into porcine aorta models (Fig. 1c). For each patch material, a new porcine heart and aortic arch were prepared. An 11x15mm window on the anterior aspect of the arch was excised using an 11-blade scalpel. A sample of the same dimensions was cut from the patch material and sewn in using the same running 5-0 Prolene suture line as described in the previous section. T

A barbed fitting was clamped into one head vessel for connection to a pressure transducer. Another barbed fitting at the descending aorta connected to a saline bag, which was used to apply an impulse of pressurized water into the system. The other head vessels and the aortic root were clamped with curved forceps. A ruler was attached to the cannulated head vessel for diameter reading at the instant before failure, measured from recorded video. Peak pressure before failure was recorded. Changes to patch and aortic dimensions were used to estimate wall thinning at maximum pressure, and Law of Laplace was used to calculate failure stress. Failure was categorized using the same convention as in the uniaxial suture tests.

RESULTS

Failure strength, expressed as membrane tension, is compared across each patch material and test modality in Fig. 2. Uniaxial dogbone testing yielded the highest strength measurements for each of the materials, with the CardioCel Neo nearly an order of magnitude stronger than the homograft and porcine pulmonary artery. Inclusion of a suture line led to much lower failure loads across all materials, and testing in a pressurized environment led to lower strength measurements than in the uniaxial setup. Under burst testing, all CardioCel Neo failures occurred via suture line failure in the aortic tissue, leaving the patch fully intact. Three of the four homograft failures occurred at needle holes within the patch. Several inflation failures occurred within the adult physiologic loading range.

DISCUSSION

Mechanical strength of cardiovascular patch materials is of significant interest to surgeons as they reconstruct high-pressure vessels like the aorta, but most mechanical tests fail to evaluate the suture line, which is bound to be the weakest element of the patched repair. Our testing demonstrated a significant reduction in failure strength when a suture line was added to three different patch materials. None of the samples with a suture line failed far above the physiologic loading range, suggesting that aggressive control of postoperative blood pressure is essential for patient safety until wound healing begins. A next step for this study is to evaluate how different suture techniques can improve suture line strength.

ACKNOWLEDGEMENTS

The authors would like to thank Professor Tommaso Ranzani and graduate students Jacob Rogatinsky and Leah Gaeta at Boston University for providing access to, and assistance with, the Instron system used for uniaxial testing in this study.

NONLINEAR AND ANISOTROPIC MECHANICAL RESPONSE OF FISH SKIN

Sean T. Harrington (1), Frederick Sebastian (2), Rouzbeh Amini (1,2)

INTRODUCTION

In recent years, fish skin bandage substrates have been proven to be a viable treatment for severe burn victims [1]. It has been postulated that fish skin holds many nutrients that promote tissue regrowth in the epidermis [1]. It has been shown that the cellular responses (including gene expression and protein synthesis) in a wide range of cells depend on the mechanical stiffness of the extracellular matrix [2]. In the realm of wound healing, important processes, such as the migration and proliferation of the epidermal cells, heavily depend on the mechanical microenvironment in which the cells reside [3]. As such, to improve wound healing, identifying a favorable mechanical microenvironment is essential. Since the recent evidence have shown fish skin to be a promising burn dressing that improves wound healing, one could postulate that the mechanical response of the fish skin is like that of the native tissue. In this study, we aim to examine the feasibility of using a biaxial mechanical testing device to evaluate the mechanical responses of the fish skin. If this method deems appropriate, we will compare the results to human skin tissue in the future, to determine if the mechanical properties of the fish skin are a contributing factor to its proven performance as a burn dressing.

METHODS

Fish sample of haddock were acquired from a local fish market specializing in sale of freshly caught fish (John Mantia & Sons, Boston, MA). The skin samples were excised from the fish carcass (unknown sex) and stored in phosphate buffered saline (PBS) solution while the rest of the testing apparatus was set up. Storing in isotonic PBS was chosen because of the

similarity between the osmolarity of fish skin, and that of human skin [4].

The samples were then loaded into our custom-built biaxial testing apparatus [5] as shown in Fig. 1. Careful attention was taken to the sample orientation in relation to the anatomical direction of the fish body. In particular, axis 1 of the device was aligned with the dorsal-ventral (back-to-belly) direction of the fish body, and axis 2 of the device was aligned with the anterior-posterior (head-to-tail) direction of the fish body.

Figure 1: Biaxial Test Setup. Camera view depicting sample and four fiducial markers on the left, and testing apparatus with suture lines used to pull the tissue on the right.

The sample was then loaded under five loading protocols (Table 1) to allow for proper fitment of a constitutive model to the data. Nine preconditioning cycles were applied to each sample. The cross-sectional area of the sample in each axis were measured and denoted as A_0 for stress calculations. The positions of the four fiducial markers (Fig. 1), as well as the load applied to each axis, were recorded for each test.

Table 1: Loading protocols used in the biaxial testing.

Protocol Number	Axis 1 Stress	Axis 2 Stress
1	120 kPa	40 kPa
2	100 kPa	60 kPa
3	80 kPa	80 kPa
4	60 kPa	100 kPa
5	40 kPa	120 kPa

An internally developed image processing MATLAB script was utilized to obtain the positions of the fiducial markers at each timestep of the experiment. The positional data were then used to calculate the Green-Lagrangian Strain tensor \mathbf{E} [6].

$$\mathbf{E} = \frac{1}{2}(\mathbf{C} - \mathbf{I}) \quad (1)$$

where \mathbf{C} is the right Cauchy-Green deformation tensor. The load f_i at each timestep, in each direction i , was obtained from the load cells. Together with the cross-sectional area of the sample in each direction, the normal components of the First Piola-Kirchoff Stress tensor \mathbf{P} were calculated:

$$P_{11} = \frac{f_1}{A_o} \quad P_{22} = \frac{f_2}{A_o} \quad (2)$$

and the second Piola-Kirchoff Stress tensor was defined as

$$\mathbf{S} = \mathbf{F}^{-1}\mathbf{P} \quad (3)$$

with \mathbf{F} being the deformation tensor. After visual examination of the experimental data for the second Piola-Kirchoff stress versus the Green-Lagrangian strain, a Fung-type constitutive model identical to those of other biological tissues with similar responses was adopted [7]. The strain energy density function for this model was defined as

$$W(\mathbf{E}) = \frac{k}{2}(e^{\beta_1 E_{11}^2 + \beta_2 E_{22}^2 + \beta_3 E_{11}E_{22}} - 1) \quad (4)$$

where β_1 , β_2 , β_3 , and k are material parameters, obtained after fitting all five protocols simultaneously to the experimental data using MATLAB *fminsearch* function.

RESULTS

The stress-strain response of the fish skin was similar to the non-linear behavior of many collagenous human tissues (Fig. 2). In particular, the tissue displayed a toe-region where a small amount of stress led to a large deformation. However, the tissue became stiffer as the strain increased.

Further, the tissue response was highly anisotropic. Across all protocols, visual examination of the mechanical responses showed that the fish skin samples were much stiffer in the dorsal-ventral direction as compared to the anterior-posterior direction. In the first protocol, the stress on both directions were equal. In this protocol, the strain in the anterior-posterior direction was positive; however, the dorsal-ventral axis experienced negative strain, due to the Poisson's effect. The non-linear exponential Fung-type model fitted this single experiment reasonably well with the R^2 value of 0.98.

DISCUSSION

In this study, our goal was to identify if using a biaxial mechanical testing device is a feasible approach for quantification of the fish skin. We observed that this approach is indeed applicable to the fish skin. In our future work, we aim to increase the number of our samples, so that a meaningful comparison between our data and those published for human skin may be possible.

An anecdotal conclusion from our preliminary observation is that for greater effectiveness as a bandage substrate, it is perhaps advisable that the fish skin be oriented in a way such that the head-to-tail axis of the fish skin aligns with the axis of the most movement of the patient.

Figure 2: Biaxial mechanical response of the fish skin. S_{11} plotted in blue, S_{22} plotted in magenta along with the fitted constitutive model plotted in black.

Another important observation from our experiment was how similar fish skin behaves in comparison to an-isotropic human tissues. Fung-type model has been widely used as a phenomenological model in predicting the response of human soft tissue. As shown in Fig. 2, the constitutive model had an excellent fit with an R^2 metric of 0.98.

In summary, we observed that fish skin has a nonlinear and anisotropic mechanical response, qualitatively similar to those of human tissues. How similar the micromechanical environment of fish skin is to that of human skin needs to be identified in the future studies. Further research can also be performed to quantify microstructural architecture of the fish skin and its potential similarities to that of human native tissues.

MECHANICAL CHARACTERIZATION OF PORCINE TRICUSPID VALVE ANTERIOR LEAFLETS OVER TIME: APPLICATIONS TO EX-VIVO STUDIES

Julia Clarin (1), Dominique Dang (1), Lucas Santos (1), Rouzbeh Amini (1,2)

(1) Department of Bioengineering, Northeastern University, Boston, MA

INTRODUCTION

The tricuspid valve (TV) relies heavily on the mechanical behavior of its leaflets to ensure unidirectional blood flow and prevent regurgitation in the pulmonary side of the heart. Tricuspid regurgitation (TR) occurs when the leaflets fail to properly coapt, causing backflow of blood into the right atrium and reduced efficiency of the right ventricle. TR increases strain on the heart and can accelerate the development of serious heart conditions such as progressive right heart failure if left untreated [1]. Furthermore, high operative mortality rates and contrasting opinions on surgical approaches severely limit treatment options for over 1.6 million people in the US affected by tricuspid regurgitation [1]. The lack of safe and effective treatment options for TR highlights a critical need to better understand the complex relationship between TV biomechanics and function.

Recent approaches to characterize TV biomechanics include biaxial mechanical tests, ex-vivo experiments [2, 3] and computational simulations [4, 5]. We have previously investigated porcine TV biomechanics in our ex-vivo beating heart system [3]. Such a system enables us to isolate the mechanical behavior of the TV leaflets in whole hearts without requiring dissection of the valve apparatus, while also reducing the need for live animal studies. Ex-vivo experiments, however, often require relatively lengthy sample preparation and setup procedures. For example, preparation of whole-heart samples for our ex-vivo TV experiments may take up to 5 hours on average. Because the mechanical behavior of the tissue is essential to the experimental outcomes, preparation procedures must be performed efficiently to minimize degradation and maintain tissue integrity.

While tissue storage conditions (e.g., fresh versus previously frozen conditions) have been more extensively studied [6], the effect of preparation and setup time on the mechanical properties of the tissue has not been determined in TV leaflets. Therefore, we characterized the mechanical properties of the anterior tricuspid leaflet (ATL) over a relevant time scale to validate the accuracy of our fresh tissue experiments using the ex-vivo beating heart system. We evaluated porcine ATL mechanics by performing a series of biaxial mechanical tests over 5 hours. We hypothesize that the mechanical properties do not significantly change at our time scale.

METHODS

Healthy porcine hearts ($n=7$, approximately 6 months old) were obtained from Animal Biotechnologies (Tyler, TX, USA) within 24–36 hours of harvesting. To preserve freshness, hearts were shipped in chilled phosphate-buffered saline (PBS) and used immediately upon arrival. Tissue specimens were prepared immediately upon receiving the fresh tissue following procedures described in our previous publications [6–8]. Briefly, the ATL was excised from the heart with directional integrity maintained. ATL thickness was recorded as the average of five measurements. A square specimen (7.6×7.6 mm) was prepared from the center of the leaflet, and four glass markers were placed within the test region to quantify in-plane deformation using digital image correlation.

Specimens were mounted onto a custom biaxial tensile machine such that the radial and circumferential directions aligned with both axes [6–8]. Specimens were submerged in a PBS bath during testing to mimic physiological osmolarity and prevent tissue swelling [8]. The PBS bath and tissue specimens were kept at room temperature (21°C) to recreate the ex-vivo testing environment.

Based on our most recent ex-vivo beating heart tests (data not shown), the average time to run an experiment, from time of receipt to data collection, was approximately 5 hours. Thus, we performed biaxial mechanical testing over a period of 5 hours to capture potential changes in ATL mechanical properties that may occur during our experiments. Initial testing ($\text{time}=0$) began immediately after specimen preparation, and the following five tests were spaced out by 1-hour intervals. Specimens remained submerged in the room-temperature PBS bath in an unloaded state between tests.

Biaxial data were collected at all six time points using procedures consistent with our previous publications [6–8]. For this analysis, a stress-controlled equibiaxial loading protocol was used with a target stress of 120 kPa to ensure full engagement of collagen fibers and mimic physiological loading conditions on the ATL in a healthy heart [8, 9]. Positional data obtained from tracking the fiducial markers were used to determine the deformation gradient tensor and calculate the Green-Lagrange strain tensor. The cross-sectional area of the specimen and the forces applied by the actuator were also recorded. SB³C2023-582
Copyright 2023 SB³C Foundation, Inc.

tuators were used to then calculate the normal stresses in the radial and circumferential directions, represented by the first Piola-Kirchhoff stress tensor. Further details on stain and stress calculations can be found in our previous publications [6–8].

To provide a comparative measure of stiffness, the upper tangent modulus (UTM) was obtained by fitting the post-transitional linear region of the equibiaxial response curve (60–120 kPa) using a least-squares approach in MATLAB (Mathworks, Nantick, MA, USA). The circumferential upper tangent modulus (UTM_C) and radial upper tangent modulus (UTM_R) were defined as the slope of the fitted lines in the radial and circumferential directions, respectively. As described previously, the physiological stress on the ATL during systole was estimated to be 85 kPa using Laplace's law for a healthy mean right ventricular pressure of 25 mmHg [7]. Hence, the corresponding radial and circumferential strains at an estimated systolic stress of 85 kPa were obtained for physiological comparison.

Results were subjected to a one-way analysis of variance (ANOVA) to isolate the effect of time on the mechanical response of the ATL ($p \leq 0.05$). Radial and circumferential results were compared for each time point with a paired student's t-test ($p \leq 0.05$). Results are presented as mean \pm standard error of the mean (SEM).

RESULTS

The mean mechanical response of the ATL (mean thickness = $360 \pm 81 \mu\text{m}$) was determined using equibiaxial test data from all specimens ($n = 7$) at each of the six consecutive time steps. The mean mechanical response is represented by the averages of the first Piola-Kirchhoff stress and Green strain curves shown in Figure 1. Visual examination of the overall biaxial mechanical response does not reveal any major differences in radial or circumferential directions with increasing time (Fig. 1).

Mean radial and circumferential UTMs are shown for all time points ($t=0$ –5 hours) in Figure 2a. As previously described, the average stress on the ATL during systole was approximated to be 85 kPa in a healthy heart [7]. Thus, the corresponding strain at stress = 85 kPa represents an approximate physiological systolic strain, as shown in Figure 2b.

A one-way ANOVA revealed that mean UTM and physiological strain did not significantly change over time in either the radial or circumferential directions for the 5-hour test period. The overall mean UTM showed that specimens were significantly stiffer in the circumferential direction ($11.3 \pm 0.98 \text{ MPa}$) compared to the radial direction ($2.29 \pm 0.20 \text{ MPa}$) for $p \leq 0.05$. A similar effect was observed in ATL strains corresponding to the estimated systolic stress, in which mean radial strain ($27.6 \pm 2.9 \%$) was found to be significantly larger than mean circumferential strain ($7.37 \pm 0.85 \%$) for $p \leq 0.05$.

Figure 1: First Piola-Kirchhoff (PK) stress vs. Green strain average curves ($n = 7$) remained consistent in the radial (RAD) and circumferential (CIRC) directions for all time points (only four are shown for visual purposes). Shaded regions indicate SEM.

Figure 2: Mean (a) UTM and (b) estimated systolic strain did not significantly change in the radial (RAD) and circumferential (CIRC) directions over five hours ($p \leq 0.05$). Error bars show SEM.

DISCUSSION

Equibiaxial loading of the porcine ATL resulted in an anisotropic and nonlinear mechanical response that was stiffer in the circumferential direction, consistent with previous studies [7–9]. Importantly, there was no significant difference in the mean mechanical response of the leaflets over the course of five hours, as described by the UTM fitting in the radial and circumferential directions. The UTM was chosen as a measure of ATL stiffness to capture the mechanical response of the fully-engaged collagen fibers at physiological stresses. ATL strains corresponding to an estimated systolic stress value (85 kPa) further showed no significant change over five hours. Collectively, these observations support our hypothesis that the mechanical responses of the TV leaflets remain unchanged at a short time scale of five hours, especially as it pertains to ex-vivo setups [3, 7].

Despite our results, we must acknowledge potential changes in mechanical properties of our samples prior to experiments due to shipping time and conditions (in chilled PBS). In a previous study, we investigated the effect of short-term PBS storage on porcine ATLs that were obtained immediately after hearts were harvested. We found that two-hour submersion in PBS had no effect on the mechanical properties, as evaluated with equibiaxial testing [8]. As such, we expect the changes in the mechanical properties due to short storage in chilled PBS during the shipment to be minimal. Further, we did not characterize the ATL microstructure over time. Therefore, our results only indicate that the tissue-level mechanical response is not affected at a time scale relevant to our ex-vivo beating heart experiments.

Consistent with our proposed hypothesis, we observed that the mechanical response of the anterior tricuspid leaflet does not change significantly over a period of five hours. Thus, the outcome of ex-vivo studies that require sample preparation and manipulation up to five hours remain reliable.

TOWARDS HIGH SPATIOTEMPORAL RESOLUTION BLOOD FLOW VELOCITY FIELD MAPPING FOR MICE: A VALIDATION STUDY

INTRODUCTION

Mouse models offer many advantages in studying the contribution of hemodynamic forces to cardiovascular disease development, notably the simplicity of genomic manipulation to generate models of human diseases without other confounding variables [1], and the opportunity to follow the different stages of disease development in the same mouse. However, mice pose a significant challenge for blood flow studies that aim to quantitatively map flow patterns, because common flow imaging methods (e.g., pulse wave Doppler or MRI) provide only bulk velocity estimates [2] or velocity data with low temporal resolution, i.e., maximum velocity in mice is ~1 m/s with heart rate ~5-10 times faster than in humans [3], [4]. A quantitative, non-invasive medical imaging method to map blood flow velocity fields in mice would enable preclinical studies that are not possible currently, leading to new insights into disease mechanisms and treatments.

An alternative flow quantification method that can achieve non-invasive velocity field mapping is ultrasound image velocimetry (UIV) which applies particle image velocimetry (PIV) techniques to ultrasound images to track blood speckle or contrast agent displacement. In this way, UIV can produce instantaneous two-dimensional velocity fields. Both in vitro validations and in vivo studies have been previously conducted for UIV of human cardiac flow [5] but not yet in mice due to temporal resolution limitations in conventional ultrasound imaging. To capture images at higher frame rates, a commercially available imaging mode known as ECG-gated kilohertz visualization (EKV) is available, in which sub-sections of the targeted field of view (FOV) are scanned from different cardiac cycles and then combined into one image for each time point. This can produce higher temporal resolution (up to 10,000 fps) than conventional real-time ultrasound (maximum ~1,000 fps) without compromising image spatial resolution. This imaging mode has been used to capture fast-moving cardiac tissue in mice [6] but has yet to be used for UIV of mouse blood flow; it is therefore necessary to perform validation studies to test if UIV

can provide accurate velocity field information. As a first step to this end, the work presented here focuses on the validation of the technique using in vitro and in silico experiments with linear speckle or particle displacement.

METHODS

In Vitro Experiments: A straight fluidic channel with a circular cross-section was fabricated using high strength agar. The diameter of the channel was 1.2 mm, similar to that of mouse aortas. A blood mimicking fluid consisting of nylon particles with diameters of 5 μm [7] were used to produce speckle patterns in ultrasound imaging. Flow experiments were conducted by providing cross-sectional mean flow velocities between 14 mm/s and 550 mm/s (peak velocities 28 mm/s and 1100 mm/s, respectively) using a syringe pump. The ultrasound images were acquired using the Vevo 3100 (FUJIFILM VisualSonics Inc.) system with a 30 MHz linear array transducer. The ultrasound beam was oriented in two different directions to capture any angle dependency in flow imaging: perpendicular (Fig. 1A) and at a 60-degree angle (Fig. 1B) to the flow direction. The frame rate of EKV was varied between 1,000 to 10,000 fps. Velocity fields were measured from the EKV images using the MATLAB toolbox PIVlab [8]; a multipass approach was chosen with interrogation window (IW) sizes 180×180 px and 90×90 px with 50% overlap (for a FOV of 1440×316 px).

In Silico Experiments: In parallel to the in vitro experiments, in silico experiments were also conducted to understand and verify the effect of EKV reconstruction on UIV measurements in a controlled manner. Synthetic particle images with Gaussian intensity profiles were generated using PIVlab. Particle diameter was 25 ± 4 px and the image size was 800×600 px. The velocity field was linear at a 45° angle from the vertical image axis (Fig. 2); the horizontal and vertical (equivalent to the lateral and axial directions with respect to the ultrasound beam, respectively) components of particle displacement were both 3 px/frame. For EKV image reconstruction, each image sub-section (or

image strip) consists of particles from consecutive frames, thus particle movement is preserved within the region of the strip; however, particles *between* two neighboring strips are not correlated. The strip sizes were chosen to be 600 px in height, and the strip width ranged from 5 to 160 px. A smaller strip width corresponds to a higher EKV frame rate during ultrasound imaging. For PIV, a multipass algorithm was used, and the IW sizes were 160×160 and 100×100 px with a 50% overlap.

Figure 1: In vitro experiment setup when (A) the ultrasound beam was perpendicular and (B) at a 60° angle to the flow direction.

Figure 2: An illustration of the flow field displacements for the in silico experiments showing (A) particles in one frame vs. (B) particles in the next frame (the hollow circles represent new particles introduced due to non-zero displacement) after (C) a linear displacement at a 45° angle from the vertical (axial) axis.

RESULTS

In the in vitro experiments, speckle movement was captured for all flow speeds tested, including higher values close to physiological velocities in mouse aortas (Fig. 3); the higher the flow speed, the higher the required frame rate. To assess the accuracy of the UIV flow fields at different EKV rates, measured lateral (Fig. 4A) and axial (Fig. 4B) velocity components near the image strip edges were compared to ground truth values (based on pump settings) and UIV measurements of B-mode images. The results for a true cross-sectional mean lateral velocity of ~62 mm/s (Fig. 4A) and a mean axial velocity of ~14 mm/s (Fig. 4B) were chosen for demonstration because the velocities are small enough such that speckle movement could be captured by B-mode images (~300 fps) for comparison. The quantitative results show that as EKV frame rate is increased, the lateral velocity values obtained from PIV is increasingly underestimated, while axial velocity values remain relatively constant (i.e., greater errors for lateral velocity components at higher frame rates). The in silico data showed similar trends: a decrease in image strip width (equivalent to higher EKV frame rate) resulted in an increase in lateral velocity underestimation (Fig. 4C). This suggests that the effect of image strip width in EKV images is the main contribution to the observed bias error. The effect of strip width is then further highlighted in Fig. 5 using a heat map of in vitro UIV fields, in which the magnitude of lateral velocity vectors drops at the strip edges.

Figure 3: In vitro UIV flow fields for average cross-sectional velocities of (A) 400 mm/s and (B) 550 mm/s for EKV images captured at 8000 fps. The vector fields show that speckle movement was captured, with larger velocity vectors near the tube axis and smaller vectors near the walls; this qualitatively follows (C) the expected flow field which is lateral with a parabolic profile.

DISCUSSION

The validation results showed that although EKV images can capture speckle movement, using UIV for these images results in bias error for lateral velocity components. Due to EKV image reconstruction, there is a discontinuity of particles or speckles at the edges of each image strip. As a result, there is also a discontinuity in

lateral velocity magnitude. This effect is mainly due to the loss of matching particles or speckles at the edges of each strip: when particle lateral velocity is non-zero, foreign particles will be introduced at the strip edges at each time step. When there is a loss of matching particles between two IWs, the PIV cross-correlation peak is skewed towards zero displacement, introducing a bias error [9]. In the current study, when the IW size and particle displacements are fixed, as EKV frame rate increases (i.e., image strip width decreases), more strips and strip edges will appear in a single IW, introducing more foreign particles at each time step and thus increasing the loss of matching particles between frames. This explains the reason for increased lateral velocity underestimation as EKV frame rate is increased. In contrast, since the image strips are always oriented to be along the axial direction, there is no loss of axially moving particles, and thus the axial velocity components are insensitive to EKV frame rate.

To correct the bias error introduced by EKV reconstruction, the PIV cross-correlation function could potentially be multiplied by a weighting function based on the degree of particle/speckle loss prior to correlation function peak evaluation [9]. Upon implementation of bias correction in future work, further in vitro and in vivo studies will follow to eventually establish the techniques for mouse blood flow imaging.

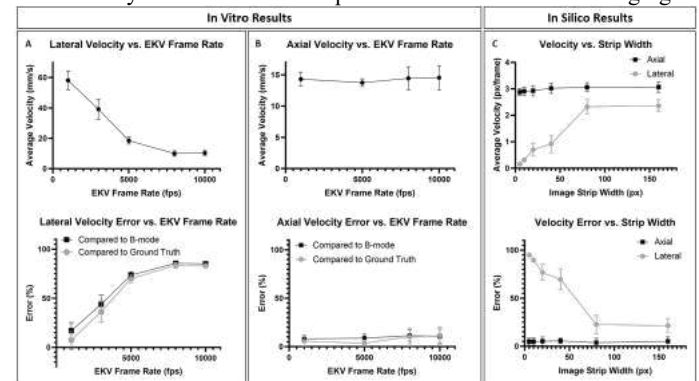

Figure 4: Measured in vitro velocity (near image strip edges) and its error vs. EKV frame rate for a true (A) lateral mean velocity of 62 mm/s and (B) axial mean velocity of 14 mm/s. (C) Measured in silico axial and lateral velocity components and the error vs. strip width. The data is presented as mean±SD; N=20.

Figure 5: Heat map of the UIV lateral velocity magnitude obtained using EKV images (in vitro at 3000 fps); the values drop at the image strip edges (indicated with white dotted lines). The true cross-sectional average velocity is ~30 mm/s.

INTRODUCTION

The temporomandibular joint (TMJ) is the articulation between the cranium and mandible and is necessary for chewing and communication. The TMJ contains a fibrocartilaginous disc, which acts to reduce friction and distribute contact forces throughout joint motion. Muscular and skeletal disorders of the TMJ complex are common and are often indicated by TMJ pain. Pain in the TMJ is estimated to effect 11.2 to 12.4 million U.S. adults according to a study conducted in 2018 [1]. Of those suffering from TMJ pain, 42% report high pain intensity, which can significantly impact quality of life to a degree similar to depression and heart attacks [2,3]. Disc excision is considered a gold standard treatment for advanced TMJ disorders [4] but has resulted in the conversion to total joint replacement in 11.7% of patients [5]. Unfortunately, there are no artificial TMJ disc replacements currently approved for human use, despite their promise as an intermediate treatment for TMJ disorders. We suggest that a robust artificial TMJ disc replacement will arrest joint degradation following disc excision and prevent the need for further surgical intervention. To this end we have performed a mechanical characterization of the ovine TMJ disc [6] and assessed the suitability of polyvinyl alcohol (PVA) hydrogels for TMJ disc replacement [7]. The results of these experiments suggest that PVA hydrogels are a promising candidate for TMJ disc replacement due to their compressive stiffness similar to the native disc, high toughness, and low friction. However, PVA hydrogels require tensile reinforcement to mimic the native tensile elastic moduli. Thus, the purpose of this study was to evaluate scaffold-based reinforcement of PVA hydrogels and to develop an implant design and surgical strategy for TMJ disc replacement.

METHODS

Tensile Reinforcement

Polypropylene (PP) angle ply scaffolds with a 300 μ m fiber diameter were created using a melt extrusion 3D printer. Scaffolds were

created with the following fiber angle (from primary loading direction) and center-to-center fiber spacing: 45° - 1.4 mm (n=6), 20° - 1.4 mm (n=6), 10° - 1.4 mm (n=5), 20° - 1.2 mm (n=6), and 20° - 1.0 mm (n=5). A melt electrowriting (MEW) 3D printer was also used to produce scaffolds (n=5) with a fiber diameter of 74 ± 4 μ m, fiber angle of 20°, and fiber spacing of 150 μ m. All scaffolds were embedded in a 25% PVA hydrogel and molded between two glass slides through six freeze-thaw cycles. One group (n=6) of tensile testing samples was also made from PVA alone. Dog-bone shaped tensile testing specimens were cut from the molded sheets using a scalpel and cutting guide. Physical measurements of each sample were taken using digital calipers. Testing coupons were preconditioned with 20 cycles to 0.08% strain followed by a uniaxial tensile test to failure at a rate of 0.08 strain/s. The sample elastic moduli were calculated using the tensile stress-stretch data. All tested groups were compared using a one-way ANOVA with post-hoc Tukey test, and results with $p < 0.05$ were considered significant.

Implant Design

Two implant attachment methods were assessed through uniaxial tensile testing. Sheets of 25% PVA hydrogel were affixed to a 3D printed substrate using a titanium plate and screws (n=7), or by a cross suture pattern (n=6) (Figure 1). Samples were subjected to a uniaxial tensile test to failure, and construct failure stress was calculated as the peak applied load divided by the sample cross sectional area. Failure

Figure 1: Implant attachment methods on testing fixtures.

stresses were compared using a t-test, a $p < 0.05$ was considered significant.

An iterative approach to implant design and surgical development was used to identify a final implant design candidate. Patient specific artificial TMJ disc implants were designed based on a computed tomography scan of the ovine TMJ, molded from 25% PVA using a 3D printed mold, and implanted in the corresponding ovine cadaveric TMJ by human and veterinary maxillofacial surgeons (all subjects were scanned and sacrificed as part of an unrelated study). Surgeons provided feedback about each design, which was then integrated in the next design iteration until a final implant design was approved.

RESULTS

Tensile Reinforcement

A summary of tensile testing results is provided in Figure 2. All hybrid constructs exhibited increased tensile elastic moduli in comparison to PVA alone. Hybrid melt extrusion scaffolds exhibited elastic moduli within the range of published values for the TMJ disc. The elastic modulus generally increased with a decrease in scaffold fiber spacing or fiber angle.

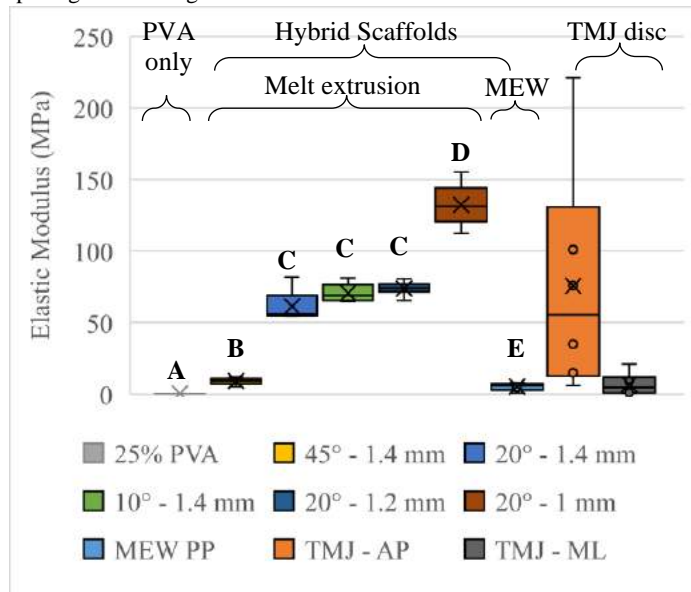

Figure 2: Comparison between the hybrid PVA-PP constructs, PVA alone, and native TMJ discs in the anteroposterior (AP) and mediolateral (ML) directions. Groups that share a letter were not significantly different. TMJ disc data were combined from multiple published sources [6, 8-12].

Implant Design

The failure stress of the PVA hydrogel samples attached using a cross suture pattern was $0.14 \text{ MPa} \pm 0.01 \text{ MPa}$ (mean \pm standard deviation), which was significantly less ($p < 0.001$) than the failure stress of the PVA hydrogels attached using a titanium plate: $0.23 \text{ MPa} \pm 0.02 \text{ MPa}$.

A finalized implant geometry (Figure 3) includes a 2 mm thick superior-lateral flange for attachment to the zygoma, and a 2 mm thick inferior-lateral flange for attachment to the mandibular condyle. Titanium maxillofacial reconstruction plates are used to secure these flanges using 1.9 mm diameter titanium screws. The shape and size of the TMJ disc component is modeled using the shape of the mandibular condyle. All implant sections are molded contiguously with the attachment flanges.

Figure 3: (left) Implanted TMJ disc replacement, and (right) 3D model of corresponding implant.

DISCUSSION

Tensile reinforcement of PVA hydrogels using 3D printed angle ply scaffolds increased the tensile moduli of the construct and allowed for more sensitive tuning of the anisotropic tensile elastic moduli within the range of published values for the TMJ disc across species [6, 8-12]. Using this technique, a mechanically mimetic scaffold can be created to match the anisotropic tensile behavior of the native TMJ disc.

The titanium plate attachment method was superior to the cross suture pattern in terms of failure stress. However, the failure stress of these attachment methods was far below the measured values for a 25% PVA hydrogel ($2.97 \text{ MPa} \pm 0.62 \text{ MPa}$) [7] which suggests that there is a large stress concentration at the implant attachment site. Further refinement of the implant attachment method will be directed toward reducing this stress concentration.

We have developed a patient specific PVA hydrogel TMJ disc implant that is easy to install through a translatable lateral surgical approach. However, rigorous preclinical assessment of these artificial TMJ disc replacement constructs is still necessary. Long term *in-vivo* experiments, paired with *ex-vivo* characterization of PVA hydrogel wear and fatigue properties are needed to predict the *in-vivo* lifetime of a non-degradable TMJ disc replacement. Experiments to investigate high-cycle wear on the artificial disc and strain life of the implant attachments are underway. An *in-vivo* pilot experiment in sheep is also in progress to assess the impact of an PVA hydrogel TMJ disc replacement compared to disc excision alone (current clinical standard). The goal of this pilot experiment is to evaluate the implants and their impact on the TMJ cartilage, chewing pattern, and diet over six weeks.

COMPUTATIONAL MODELING OF MACHINE PERFUSION OF THE HUMAN LIVER VASCULATURE

Daniel Emerson (1), Yoed Rabin (1), Levent Burak Kara (1)

(1) Department of Mechanical Engineering, Carnegie Mellon University, Pittsburgh, PA, USA

INTRODUCTION

Transplantation is the primary treatment option for people with severe liver diseases. One major barrier to liver transplantation is the absence of methods to properly store, transport, and transplant livers. The most commonly used method in liver preservation is static cold storage (SCS), where the organ is kept on ice, and preservation of the liver is limited to less than 12 hours [1]. Improvement to liver preservation techniques would help make liver transplantation more widely available and improve transplantation outcomes [2].

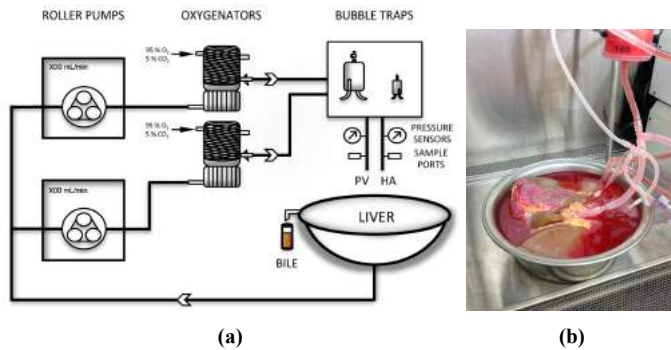

Figure 1: Schematic (a) and experimental apparatus (b) for subnormothermic machine perfusion from [3].

Development of new cryopreservation protocols is a highly complex multi-step process, requiring machine perfusion at varying temperatures, as well the loading and unloading of different cryoprotective agents (CPA). A schematic and experimental apparatus for machine perfusion at a fixed temperature is depicted in Fig. 1. Accurate computational models of the human liver would help researchers explore the complex cryopreservation design space, without the challenges and expenses associated with procuring real human livers. Researchers have created anatomical [4–6] and algorithmic [7–9] models of the liver vasculature. Both existing anatomical and algorithmic models have been primarily evaluated on their ability to match morphological metrics such as mean vessel length and diameter. None of [4–9] consider fluid flow through individual vessels of the liver, entering via the portal vein and out the hepatic vein. To this end, we aim to create a framework to generate variably complex models of the human liver and automatically simulate the perfusion of said models. It is important that our models behave consistently regardless of depth, and perfuse similarly to real human livers.

METHODS

Super Lobules: At a microscopic level, the liver consists of approximately one million highly regular collections of functional hepatocyte cells called lobules [10, 11]. Since it is not feasible to model the liver vasculature to this level of detail, we introduce the concept of a super lobule (SL): a collection of lobules which we model with a single lumped resistance. In our model we assume all super lobules to be of uniform volume and resistance. The notion of a super lobule allows us to create models of various depth that behave similarly by accounting for the contribution of its constitutive vessels with the assigned lumped resistance.

Space Colonization Algorithm: To generate the vascular structure of the liver, we build upon the space colonization (SC) algorithm introduced in [12, 13] where leaf venation and tree structures are generated with a biologically inspired iterative process. We utilize additions made to the algorithm in [14] to ensure the vessels explicitly reach the super lobules and trim non-critical vessels from the network. We make further modifications to the algorithm for modeling vascular trees. For example, we run the algorithm twice: first to generate known primary vessels in the portal and hepatic veins, and second to build the vascular network from this intermediate initialization to the super lobules.

Resistance Network: To simulate the flow through our vascular model, we consider a simple electrical analog model, where voltage and current are analogous to pressure and flow rate [15]. We model the resistance of each blood vessel according to the Hagen-Poiseuille equation. The Hagen-Poiseuille model is commonly used in simplified models of vascular flows in the liver [4, 6, 7, 16]. We can assign each vessel a resistance according to Hagen-Poiseuille with its radius and length. After prescribing pressure boundary conditions at the inlet and outlet, we can solve for the pressures and flows at every node and vessel in the model respectively. This is done by constructing a linear system of equations of the form $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$. There are three equations used to construct the coefficient matrix \mathbf{A} . First, we consider Ohm's law ($\Delta P = QR$); the pressure drop across all vessels and super lobules. Next, we consider Kirchhoff's current law ($\sum Q_{in} - \sum Q_{out} = 0$) at all nodes except the two boundary nodes. Finally, we enforce the boundary conditions as constant pressures at the inlet and outlet. The flows and pressures in \mathbf{x} are solved using an LU decomposition of the sparse asymmetric coefficient matrix \mathbf{A} .

While we can compute the resistance of a vessel based on its geometry, we do not have a deterministic way to compute the resistance of the super lobules R_{SL} to give our model the desired overall flow rate. We use the bisection method and repeatedly solve linear system with various values of R_{SL} and fixed pressure boundary conditions until our solution converges to the desired model flow rate.

Simulated Machine Perfusion: Using our complete model, we can visualize how CPA concentration varies through the model over time. At each time step, the inlet flow rate is multiplied by the time step to determine the volume of the fluid added. In each vessel the concentration of incoming fluid is combined with the concentration of the fluid already in the vessel, weighted by their respective volumes to determine the new concentration of a given vessel. Excess fluid is passed to downstream vessels according to ratio of cross sectional areas.

RESULTS

We consider the machine perfusion experiment detailed in [3] and pictured in Fig. 1. The portal vein (PV) inlet pressure is set to 5.8mmHg while the hepatic vein (HV) outlet pressure is left at 0mmHg. The steady flow rate at the inlet is 767mL/min. The initial diameter for both PV and HV is set to 15mm. The dynamic viscosity of the CPA is set to 3.5cP.

Figure 2: Nodal pressures (a,c,e) and vessel flow rates (b,d,f) for models with 25, 50, and 100 super lobules, respectively.

Results from simulations on models of varying depth can be seen in Fig. 2. We can observe consistency in the partition of flow across models of various depths. Models with more super lobules can provide more fine scale pressure and flow information throughout the liver, at increased computational cost, as detailed in Table 1. SC time refers to the amount of time to generate the vasculature with the space colonization algorithm. Matrix solve refers to the length of time to solve the linear system of equations once, and bisection solve refers to the total time to determine the model R_{SL} value by repeatedly solving the linear system.

Table 1: Model complexity based on number of super lobules.

# SL	SC Time (s)	Matrix Solve (s)	Bisection Solve (s)
5	9.21	0.00113	0.04
10	9.25	0.00265	0.08
25	11.72	0.0136	0.45
50	12.38	0.0427	1.32
100	20.36	0.158	5.03
250	60.21	0.896	27.65

We can also validate our models by examining how the model populates with CPA during simulated machine perfusion. Fig. 3 visualizes the perfusion of the liver, where red represents pure blood that is being displaced, and blue represents pure CPA that is pumped into the model. The color is interpolated between red and blue for vessels with mixed concentrations. We can note that in Fig. 3(b), the majority of small vessels have been populated with CPA, with the exception of a vessel in the top right corner. This observation can be seen in models of all depths, and matches well with what we known from machine perfusion experiments on real human liver. Perfusion of the liver is not a linear process and outermost regions, specifically the narrow, upper right portion of the liver take a disproportionately long time to fully populate with CPA.

Figure 3: Concentration of vessels in 25 SL model at (a) 50% and (b) 80% total concentration of CPA.

DISCUSSION

Overall, this work presents a novel adaptation and application of the space colonization algorithm to generate models of the human liver. All previous algorithmic models of the liver [7–9] have been generated using constrained constructive optimization [17]. With our notion of super lobules, we can create models of variable depth and fidelity, that all meet global pressure and flow boundary conditions. This approach allows the end user to trade model fidelity for computational cost depending on their needs. Furthermore, we observe that models of various depths behave consistently with each other, and in comparison to observations from experiments on real human livers, as opposed to the morphological validation seen in most prior works. It is also important to note the modeling simplifications made in this work. We simply consider steady Hagen-Poiseuille flow, we do not allow fluid to perfuse across vessel walls into the tissue of the liver, and we maintain a constant viscosity throughout the simulation. Nevertheless, this model serves as a preliminary step in the much larger goal of creating a computational model on which researchers can investigate and develop new cryopreservation protocols.

INTRODUCTION

In cardiovascular problems, growth and remodeling (G&R) is commonly triggered mechanically through fluid-structure interaction by a combination of pressure-induced intramural stress and flow-induced wall shear stress [1]. For example, it was hypothesized that G&R plays a key role in saphenous vein graft failure after coronary artery bypass graft surgery [2].

The constrained mixture theory describes mechanisms that drive G&R, capturing the different rates of turnover and material properties exhibited by individual constituents of the tissue [3]. However, this approach can be computationally expensive due to the need for tracking constituent configuration and perturbation history. This limitation was overcome by the recent concept of mechanobiologically equilibrated G&R [4]. This rate-independent theory can compute evolving homeostatic states efficiently by enforcing mechanical and mechanobiological equilibrium without the need to track the history of deposition and removal or to integrate evolution equations.

Previous implementations of the equilibrated constrained mixture model relied on an assumed form for intramural stress and flow-induced wall shear stress. To predict disease progression, we propose to combine fluid-structure interaction and G&R in a novel fluid-solid-growth (FSGe) framework using the mechanobiologically equilibrated constrained mixture theory, hence enabling efficient three-dimensional FSG simulations for patient-specific geometries.

METHODS

Our FSG model is implemented in our open-source multiphysics finite element solver svFSI (available at github.com/SimVascular/svFSI). In the following, we briefly outline the ingredients of our FSG framework. We solve the incompressible Navier-Stokes equations to obtain velocity and pressure inside the blood vessel. We pass local fluid pressure and wall shear stress to our 3D finite strain solid G&R model at the fluid-solid interface. As the solid model, we use a fast and efficient formulation of the constrained mixture theory that assumes that each G&R state is mechanobiologically equilibrated [4]. The shear-to-intramural gain ratio controls the relative importance of wall shear stress and intramural stress stimuli. Both fields are coupled in a partitioned scheme for separating the fluid and solid time scales (seconds vs. weeks).

Fluid: Incompressible Flow

Blood flow in the fluid domain is modeled by the incompressible Navier-Stokes equations,

$$\rho \frac{\partial \mathbf{u}}{\partial t} + \rho(\mathbf{u} \cdot \nabla) \mathbf{u} - \nabla \cdot \boldsymbol{\sigma}(\mathbf{u}, p) = \mathbf{0}, \quad (1)$$

$$\nabla \cdot \mathbf{u} = 0, \quad (2)$$

where \mathbf{u} and p are fluid velocity and pressure, respectively, with Cauchy stress tensor $\boldsymbol{\sigma}(\mathbf{u}, p) = \mu(\nabla \mathbf{u} + \nabla \mathbf{u}^T) - p\mathbf{I}$, density ρ , and dynamic viscosity μ . We calculate wall shear stress $\boldsymbol{\tau}_w$ as

$$\boldsymbol{\tau}_w = \boldsymbol{\sigma} \mathbf{n} - ((\boldsymbol{\sigma} \mathbf{n}) \cdot \mathbf{n}) \mathbf{n}, \quad (3)$$

with normal vector \mathbf{n} .

Solid-Growth: Equilibrated Constrained Mixture

We use a fast and efficient formulation of the constrained mixture theory that is based on the assumption that each G&R state is mechanobiologically equilibrated [5]. This rate-independent formulation eliminates time-dependency and directly predicts grown and remodeled states for given external loads and boundary conditions. Following the rule-of-mixtures, the solid Cauchy stress is calculated from constituent contributions as

$$\boldsymbol{\sigma}_h = \sum_{\alpha}^{e,c,m} \phi_h^\alpha \hat{\boldsymbol{\sigma}}_h^\alpha - p_h \mathbf{I}, \quad (4)$$

with Lagrange multiplier p_h , where subscript h refers to evolved homeostatic variables, and evolved mass fractions ϕ_h^α , namely elastin- and collagen-dominated matrix as well as smooth muscle. Our equilibrated stimulus function yields

$$\frac{\sigma_{Ih}}{\sigma_{Io}} - 1 = K_{\tau\sigma} \left(\frac{\tau_{wh}}{\tau_{wo}} - 1 \right), \quad (5)$$

with shear-to-intramural gain ratio $K_{\tau\sigma} \geq 0$, where subscript o refers to original homeostatic variables. The stimuli are intramural stress σ_I and wall shear stress magnitude τ_w , computed as

$$\sigma_I = \frac{\text{tr} \boldsymbol{\sigma}}{3}, \quad \tau_w = \|\boldsymbol{\tau}_w\|. \quad \text{SB}^3\text{C2023-586}$$

Figure 1: Velocity (top) with streamlines (green) and flow profiles (black) and pressure (bottom, blue), both with wall shear stress (red) in an asymmetric aneurysm (flow is from left to right).

Interaction: Partitioned Coupling

We couple fluid field \mathcal{F} and solid-growth field \mathcal{S} in a partitioned manner. We iterate between the fields, coupled by the interface displacements \mathbf{d}_{k+1} , until a convergence criterion $\|\mathbf{r}_k\|_2 \leq \epsilon_0$ is fulfilled:

$$\text{Update: } \tilde{\mathbf{d}}_{k+1} = \mathcal{S} \circ \mathcal{F}(\mathbf{d}_{k+1}), \quad (7)$$

$$\text{Residual: } \mathbf{r}_{k+1} = \tilde{\mathbf{d}}_{k+1} - \mathbf{d}_{k+1}. \quad (8)$$

We compare different methods to initialize the displacements \mathbf{d}_{k+1} in a new coupling iteration k . In the simplest case, we use a Gauß-Seidel scheme

$$\mathbf{d}_{k+1} = \tilde{\mathbf{d}}_k. \quad (9)$$

However, this coupling scheme is unstable for $K_{\tau\sigma} > 0$. The coupling scheme can be stabilized with static relaxation:

$$\mathbf{d}_{k+1} = \omega \tilde{\mathbf{d}}_k + (1 - \omega) \mathbf{d}_k, \quad 0 < \omega < 1. \quad (10)$$

While improving numerical stability, this coupling scheme typically converges slowly and is highly dependent on the choice of the relaxation parameter ω . A much more efficient scheme is obtained by dynamically choosing ω_k in each iteration k , e.g., through Aitken relaxation [6]:

$$\begin{aligned} \mathbf{d}_{k+1} &= \omega_k \tilde{\mathbf{d}}_k + (1 - \omega_k) \mathbf{d}_k, \\ \omega_k &= -\omega_{k-1} \frac{(\mathbf{r}_{k-1})^T (\mathbf{r}_k - \mathbf{r}_{k-1})}{(\mathbf{r}_k - \mathbf{r}_{k-1})^T (\mathbf{r}_k - \mathbf{r}_{k-1})} \end{aligned} \quad (11)$$

While easy to implement, Aitken relaxation can use only information from one previous coupling iteration. The Interface Quasi-Newton Indirect Least Squares (IQN-ILS) method can use information from up to q previous coupling iterations [7]:

$$\mathbf{d}_{k+1} = \mathbf{d}_k + \mathbf{W}_k \mathbf{c}_k + \mathbf{r}_k \quad (12)$$

$$\mathbf{V} = [\mathbf{r}_{k-1}, \mathbf{r}_{k-2}, \dots] \quad (13)$$

$$\mathbf{W} = [\Delta \tilde{\mathbf{d}}_{k-1}, \Delta \tilde{\mathbf{d}}_{k-2}, \dots] \quad (14)$$

We obtain the coefficients c_k by solving the minimization $\min_{c_k} \|\mathbf{V}_k \mathbf{c}_k + \mathbf{r}_k\|_2$ using QR-decomposition.

RESULTS AND DISCUSSION

The computational cost of our FSGe coupling scheme is comparable to a fluid-structure-interaction simulation with a hyperelastic solid material. We compare our coupled FSGe method to G&R models with different fluid approximations for pressure and wall shear stress [5, 8]. Our examples include aneurysmal formation (see Fig. 1), stenosis formation, and distortions of blood flow. We demonstrate the speed and robustness of our FSGe method for various Reynolds numbers and shear-to-intramural gain ratios. Simplified fluid dynamics in cardiovascular G&R models can provide a good approximation in many scenarios. However, we show that local fluid dynamics can significantly influence the long-term G&R state in blood vessels.

3D PASSIVE STRAIN MAPPING OF THE EMBRYONIC ZEBRAFISH HEART

Alex L. Gendernalik (1,2), David Bark (1,2)

INTRODUCTION

Congenital heart defects affect 1% of newborns, often with devastating consequences. However, the causes are poorly understood and only 20% have a known genetic etiology. Altered mechanical signaling or mechanotransduction may be one key contributor. The mechanical environment is spatially and temporally dynamic as the heart begins to function before it is fully formed through a complex coordination of processes. Abnormal mechanical feedback from the hemodynamic environment can lead to defective development of heart structures such as the chambers and trabeculae. We propose that the mechanical properties of the developing heart tissue play a fundamental role in the distribution of stress and the subsequent formation of heart structures. We use a novel technique to quantify the mechanical properties of the embryonic zebrafish heart through forced pressurization. Additionally, we develop strain maps to determine colocalization of strain or stiffness with early cardiac structures. Using this technique, we determine the conditions and material properties necessary for proper structure development.

METHODS

Zebrafish Embryo Production and Morpholino Treatment – Zebrafish were raised according to university IACUC guidelines. Adult *Tg(flk:mcherry)* and *Tg(myl7:eGFP)* transgenic zebrafish were crossed to produce embryos with fluorescent endocardium and myocardium, respectively. Embryos were incubated in E3 egg medium and 0.003% PTU to inhibit pigment formation. Embryos were removed from E3 media at the appropriate stage (2- or 3-days post fertilization) and transferred to media containing 30 mM or 40 mM 2,3-butanedione monoxime (BDM) for 2- and 3-day old embryos, respectively. BDM inhibits myosin ATPase to halt heart contractions. For RBC depletion experiments, Gata1 morpholino with sequence 5'-CTGCAAGTGTAGTATTGAAGATGTC-3' was injected at the 1-4

cell stage (approximately 8 ng in 1 nL injection volume) [1]. RBC depletion was confirmed at 1-day post-fertilization.

Pressurization and Imaging– Glass cannulas with tips pulled to ≤ 10 microns were used to puncture the zebrafish embryo skin and vasculature in the sinus venosus region. After cannulation, pressure was increased in 0.5 mmHg increments and 3D images were acquired using an upright confocal microscope at each pressure step.

Myocardial Strain Analysis – 3D image slices were segmented, aligned, and converted to 3D geometry using custom written code. Deformations were extracted and converted to Green-Lagrange strains using the unpressurized 3D heart image as a reference. Strains were mapped and analyzed in Paraview.

Finite Element Analysis – Finite element analysis was performed with custom code to estimate material parameters that best matched stress and strain observed during experiments. Boundary conditions were set such that the ventricular outlet was fixed, and the atrial inlet was allowed to deform.

RESULTS

Pressure vs. Normalized Volume plots (fig. 1) show that stiffness generally increases from two to three days post-fertilization. Strain was generally evenly distributed; however stiff focal points were present along the inner curvature of the ventricle. The atrium showed stiff areas at the inlet and atrio-ventricular junction. Strain patterns were observed in the ventricle at 2 days that were not present at 3 days. Finite element analysis shows that material parameters are on the order of 10 kPa. Morpholino knockout of RBCs resulted in strain patterns more similar to 2-day old persisting throughout development.

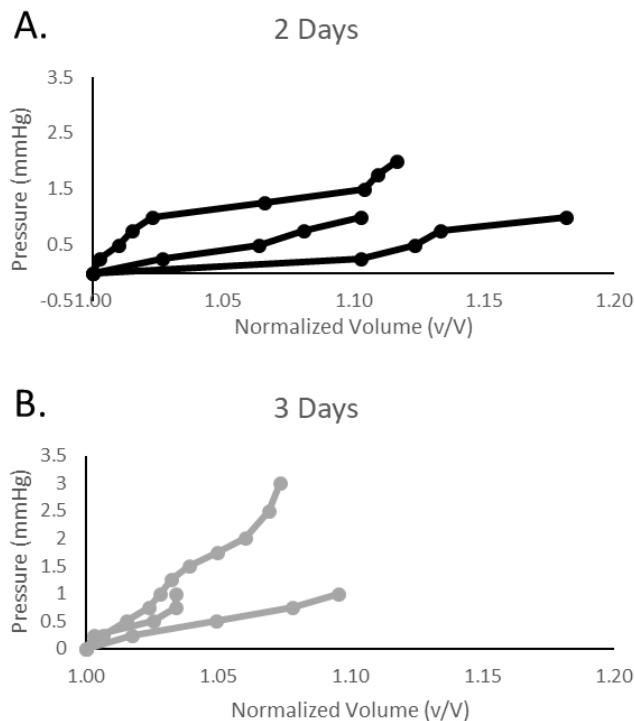

Figure 1: Pressure vs. Normalized volume (v/V) for 2-day (A) and 3-day (B) old zebrafish hearts.

Figure 2: 3D representation of strain magnitude (color) and direction for a 2-day old zebrafish ventricle.

DISCUSSION

We have developed a technique to visualize embryonic heart stiffness in 3D and determined a strain energy density function that represents

the material properties at 2- and 3-days post-fertilization. Additionally, using our strain mapping technique, we have located regions of high and low stiffness and have shown that these regions colocalize with areas of morphological changes or structure formation. Specifically, the ventricle inner curvature, AVJ, and atrial inlet were stiffer than the surrounding tissue at both 2 and 3-days. Patterns of ventricular stiffness observed at 2 days were no longer present at 3 days. During this period, structures such as trabeculae are forming. This suggests that trabeculae or hypertrophy of the ventricle helps to distribute deformation evenly across the ventricle.

CHATGPT AND THE FUTURE OF EDUCATION IN BIOMEDICAL AND MECHANICAL ENGINEERING

Sara E. Wilson (1,2)

- (1) Mechanical Engineering, University of Kansas, Lawrence, Kansas, USA
(2) Bioengineering Graduate Program, University of Kansas, Lawrence, Kansas, USA

INTRODUCTION

In November 2022, ChatGPT (<https://chat.openai.com/chat>), an AI (Artificial Intelligence) powered chatbot, was released by the company OpenAI. ChatGPT allows users to create generate text, code, and mathematical solutions using simple text based prompts. Across academic institutions, concern has been raised about the impact of this tool on academic integrity¹⁻³. In this paper, I will examine the potential impact of ChatGPT on academic misconduct in engineering and strategies that can be implemented to encourage learning and academic integrity.

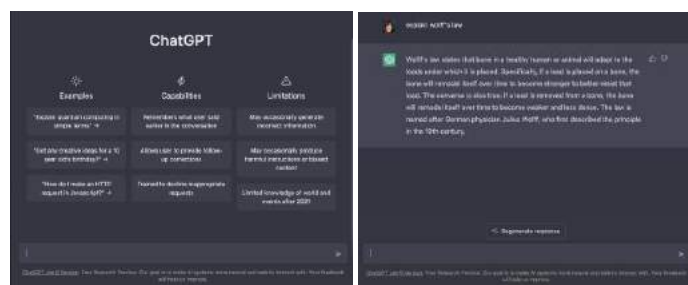

Figure 1 The chat GPT interface allows users to type in a simple text prompts and receive unique, real-text responses that would not be detectable by plagiarism checking software.

METHODS

To assess the impact ChatGPT currently has on biomedical and mechanical engineering education, a range of writing, problem solving, and coding assignment prompts were input into ChatGPT. The responses were assessed using rubrics. For writing, the AACU Value Rubric for Written Communication was used to assess responses⁴. For problem solving, the AACU Value Rubric for Quantitative Literacy was used to assess responses⁵. The rubrics assess competency across

different elements based on levels from benchmark (1) to Capstone (4). It is expected that a freshman student might be at a benchmark level (1) and should progress to capstone (4) at the completion of an undergraduate education. For computer code, a new rubric was created using these same four level across the categories of context (does the code address the prompt assignment?), code functionality and errors (does the code function without errors?), and commenting.

RESULTS

On a 1 to 4 scale, the writing samples generated by chatGPT scored a 2.7. Overall the writing samples had good grammar and addressed the writing prompt appropriately. The essays had generally good structure and a logical flow. The main weakness of chatGPT responses was in the use of literature citations. In general, the citation were few and many statements that should have been supported by a citation were not. Additionally the papers chatGPT chose to cite were fictitious. They looked like real papers and cited real journals but the papers cited could not be found on PubMed or Google Scholar.

For problem solving, ChatGPT scored between 1.3 and 3.2 on the value rubric. More advanced problems scored the lowest while simple math problems scored higher. For this exercise, ChatGPT did not get any math problem fully correct and even made mistakes on a basic differential equations problem for which there are functional solvers on the internet.

ChatGPT did the best at generating correct answers with coding assignments. In this work, coding assignments were presented in the prompt for C++ and Matlab. The average rubric score was 3.5. ChatGPT generated correct code for most of the lower level problems. ChatGPT made some errors in problem interpretation. It also placed functions improperly in the code in one problem. Finally, while

ChatGPT included commenting in the response, the commenting was sometimes sparse.

DISCUSSION

The use of ChatGPT by students to circumvent assigned homework in the classroom is a concern for engineering. From the findings here it is clear that ChatGPT (as it currently exists) could be used to generate writing assignments and code and to a lesser extent solved problems. This would be particularly true for lower level courses. There are several AI detectors currently being developed that can help to detect bot-created text. However these detectors are limited and a few small wording changes can make them fail to detect. Over time it is expected that AI-chatbots will continue to improve and it may be an arms race for the detectors to keep up.

To discourage chatbot use and to promote learning a number of strategies can be employed. The first of these is to talk about expectations and ethics in the classroom³. Another tool is create assignments that are not easily solved with chatbots. Assignments that have several levels, iterations of revisions, and scaffolding of work would be less conducive to chatbot solutions. Watkins suggests that one could even bring chatGPT into the classroom and have students examine the quality of responses and how they should be improved³. ChatGPT's AI is built off of materials on the internet, so more original and unique problems may also be less prone to chatbot answers. One can also move work to within the classroom (rather than homework) or ask for multimedia submissions rather than just code or written text². For my programming classes, I already do this by asking not just for code but also for flowcharts and video presentations of the code. Finally, one can discourage chatbot use by rethinking how points are assigned and grades are assessed.

As someone who teaches a freshman coding course, chatGPT is a serious concern. For my course, I am restructuring homework assignments and using in person grading to not only assess whether students have functional code but also do they understand the code they have submitted. In person grading will be time consuming, but will also allow for personal contact with students that may help with retention.

It is expected that AI will continue to evolve and chatbots will become more sophisticated very quickly. It will be interesting to examine if these scores improve even in the next few months before the SB3C conference. Other AI-driven tools are also coming online and we can expect this landscape to change rapidly.

GLUTARALDEHYDE CROSSLINKING OF COLLAGEN IS A TIME DEPENDENT REACTION ON THE ORDER OF 24 HOURS

Kimberly R. Kroupa (1), CV Sise (2), Jason Fan (1), Sinisa Vukelic (1), Gerard A. Ateshian (1,2)

INTRODUCTION

Glutaraldehyde (GTA) is a well-known chemical crosslinker, widely used in the stabilization of collagenous biomaterials. Its applications vary from the production of heart valves and vascular grafts [2,3], to immobilization of enzymes [4] and proteins for histochemistry and microscopy. This widespread applicability has motivated several efforts to characterize GTA mechanisms [studies on GTA and collagen, E], yet the chemical reactivity of GTA is not yet fully understood.

The primary reaction of GTA with collagen is accepted to be between the aldehyde groups of GTA and epsilon-amino groups of lysine or hydroxyprolines of collagen, resulting in the formation of quaternary pyridinium (PYD)-type crosslink. [4,5]. As such, in our lab, GTA has been used as a tool used to study collagen crosslinks in cartilage, where PYD-type crosslinks are most prevalent, as a model of cartilage pathology and osteoarthritis treatment.

Specifically, our previous work sought to identify and quantify changes in a Raman peak identified as being related to PYD crosslinks, introduced by GTA treatment of proteoglycan (PG) depleted cartilage explants [7,8]. These changes were then correlated to the increase in equilibrium Young's modulus E_Y induced by GTA, to yield new insights into the characterization of cartilage crosslinks. However, this method was limited by the high fluorescence background introduced by GTA, which overwhelmed the Raman cartilage signal only 30 minutes after exposure [10]. Further, it was observed that measurement of the modulus E_Y varied across a treatment group, according to how long after GTA exposure the samples were mechanically tested.

Together, these observations suggest that the reaction of GTA with collagen is time dependent. To examine this reaction and characterize its time constant, cartilage explants were digested of their proteoglycan content, leaving behind a nearly pure type II collagen matrix. These specimens were then treated with GTA for 120 s then washed. Repeated stress relaxation and cyclic strain tests, and confocal microscopy were employed to characterize the reaction over a period of 24 hours.

METHODS

Sample Preparation: Cylindrical cartilage explants were harvested from the condyles of four immature bovine knee joints (\varnothing 5 mm). Middle and deep zones were microtomed, resulting in a thickness of 2.71 ± 0.1 mm. Explants were digested of proteoglycans (PGs) using the protocol in [1]. PG depletion was verified using a DMMB assay.

GTA Treatment: Samples were exposed to 25mL of 0.2% GTA, prepared in phosphate buffer saline (PBS), for 2 min, then washed with 50 mL PBS for 5 mins.

Figure 1. PG-depleted cartilage explants are subjected to 40% strain, allowed to equilibrate, then 1% strain cyclic compression before and after GTA exposure.

Dynamic Testing: The stress relaxation protocol above was performed. After testing, the sample was allowed to recover, then compressed to 40% strain at $1 \mu\text{m/s}$, and again allowed to equilibrate for a minimum of 3 hours, resulting in a tare load of approximately 12 grams. Subsequently, a cyclic compressive strain of 1% was then applied onto

Confocal Imaging: Samples were treated with GTA, then sliced into 1 mm thick sections, submerged in PBS, and imaged on an Olympus Confocal microscope (laser 473 nm, 20 us/pixel, 1024×1024) at 5 min increments for 30 min, then 30 min increments up to 24 hours.

Stress Relaxation Testing: Explants were treated with GTA as outlined above, then tested immediately, 1, 2, and 24 hours after exposure in unconfined compression, by stress-relaxation test (10% strain at $0.5 \mu\text{m/s}$, 1800 s relaxation). Young's modulus E_Y was calculated from equilibrium load, displacement and sample geometry [10].

the specimen using a sinusoidal profile at a frequency of either 0.025 Hz (n=3) or 0.05 Hz (n=1) for 3 cycles, 15 minutes apart (Fig. 1). Samples were exposed to 25 mL of 0.2% glutaraldehyde for 2 minutes, then washed with PBS, all while held under constant compression at 40% strain in the testing apparatus. The cyclic compressive loading regimen detailed above was repeated immediately after treatment, then in 15-minute intervals, followed by 30-minute intervals, and so on, for 24 hours. Dynamic modulus was assessed as the difference from equilibrium tare load at 40% strain to maximum load during cyclic compression, normalized by the surface area of the sample and prescribed strain of 1%.

RESULTS

After enzymatic digestion of the explants, results of the DMMB GAG assay verified that 98% of PGs had been removed from the tissue, resulting in a nearly pure collagen type II matrix. Modulus E_Y prior to GTA treatment was found to be 36.9 ± 2.9 kPa. Preliminary confocal

Figure 2. (Right) Normalized average fluorescence of sample over >24h after exposure to GTA. (Left) Confocal images of representative sample before GTA, and 3min and 15h after. microscopy data used showed a monotonically increasing average fluorescence after exposure to GTA, before plateauing at 24 hr (Fig. 2). Repeated measurements of E_Y and corresponding sample height h after GTA exposure showed an increase in E_Y and decrease in h after the first test. Both values then remained constant (Fig. 3, Right).

Figure 3: (Left) Representative sample showing stress vs. time curves for 1% strain cyclic compression tests at 0.025 Hz over 24 hours. Smoothed. (Right) Sample height and E_Y repeated measurements after GTA treatment of PG-depleted cartilage over 24 hours. The height of the same did not recover after the first test. E_Y reached a final value at ~2 hours (n=4).

For each sample and corresponding set of cyclic strain tests, load-time curves were obtained and converted to stress-time curves using the axial surface area of the specimen (Fig. 3, Left). After GTA treatment, the maximum force exerted on the platen by the sample increased. The dynamic modulus was then calculated and plotted as a function of time after exposure to GTA, for both the 0.025 Hz and 0.05 Hz frequencies (Fig. 4). The dynamic modulus increased with time until 16 hours, when it began to plateau. The dynamic modulus was higher at the higher frequency of 0.05 Hz.

Figure 4: Dynamic modulus as a function of time for both frequencies: 0.025 Hz and 0.05Hz, on a logarithmic time scale. Average and standard deviation for 0.025 Hz (n=3) is shown.

DISCUSSION

The results of this study indicate that the reaction of GTA with collagen is time dependent, on the order of 24 hours, after exposure to GTA for only 120 s. Fluorescence, as measured with confocal microscopy (Fig. 2, Right), indicated that until 24 hours the compound will continue to form new bonds in the collagen Type II matrix, thus increasing the overall fluorescent signal of the sample. The increasing stress seen in Fig. 3, Left, indicates the sample is stiffening, as the same strain of 1% over time elicits a larger force exerted by the tissue, onto the platen. E_Y repeatability tests indicated that the modulus continued to stiffen until the second test at 2 hrs, then reached a final value. However, importantly height was not recovered after the first test (Fig. 3, Right). A change in height was also seen in the full load-time data for the cyclic testing. At later time points, >5hrs, when the platen moved upwards, the load exerted by the sample on the platen would frequently drop to zero (data not shown here). This indicates the sample height does not recover quickly, or at all, even at low strain values. Compression of the sample, as with these mechanical tests, may increase the proximity of binding sites on the bound GTA and collagen, speeding up the reaction, and causing the sample to crosslink completely while in a compressed state, unable to recover its original height.

Together, these observations suggest that the reaction of GTA with collagen is time dependent, where bound GTA continues to induce crosslinks with other GTA molecules and the collagen matrix, even after excess GTA has been washed away. To investigate if this reaction is producing mainly intermolecular crosslinks, or simply lengthening the GTA polymer chains between existing bound GTA, measuring resistivity to the enzyme collagenase could be used, as was done by Cheung et. al [9] in aqueous type I collagen. A reversible binding model can also be developed, to characterize this reaction and the type of bonds formed during it.

The dynamic modulus of GTA treated PG-depleted explants also increased on a similar time scale, reaching a maximum and final value around 24 hours (Fig. 4). The modulus was greater at the higher frequency. This, as well as increases in stress equilibration time of the PG depletion samples after GTA treatment, indicates that GTA could be changing the viscoelastic response of the tissue as well. In future work, this can be explored further with testing at additional frequencies, or with mathematical modeling.

CONFORMAL ABLATION OF ATHEROSCLEROTIC PLAQUE BASED ON MULTI-ELECTRODES AND NSGA II

Hongying. Wang, Ruizhe, Hou, Shiqing. Zhao, and Aili. Zhang

Department of Biomedical Engineering
Shanghai Jiao Tong University
Shanghai, China

INTRODUCTION

Atherosclerosis is a leading cause of mortality and morbidity worldwide. The plaque underneath the intimal will block the blood flow. The ablation of the whole plaque and intimal would cause restenosis. A novel radiofrequency balloon catheter with the integration of surface electrodes and cooling water inside the balloon was proposed, which could ablate the plaque while sparing the intima[1]. However, the plaque morphology varies in different lesions and patients [2]. Achieving precise conformal ablation of plaques with different morphologies while sparing the intimal is the key to achieving long-term patency of arteries and avoiding restenosis as much as possible.

For conformal ablation, optimization of the expandable and compliant electrode configuration design[3, 4] and multiple ablations with overlapping single-needle probe placements[5] are proposed in the radiofrequency ablation of tumors. However, the needle could damage the intimal and the combination of the multiple ablation session takes a long time, not suit for the endovascular ablation of plaque.

To achieve conformal ablation of atherosclerotic plaques underneath the intimal in a short time (~ 2 min), a conformal ablation strategy was developed with a numerical model and the non-dominated sorting genetic algorithm (NSGA II). The numerical model calculated the ablation results and was input into the algorithm. NSGA II searches the optimal parameter set, including the voltages of multiple electrodes, and the velocity and temperature of the coolant, by minimizing the thermal damage in the non-plaque region, especially the intimal region, and increasing the ablation coverage rate as far as possible.

METHODS

Numerical model: As shown in Figure 1, an annulus with thickness and inner diameter of 0.05mm and 2.9mm is used to simulate the balloon catheter, and the cooling water circulates inside the catheter. 12 electrodes were embedded in the outer wall of the catheter evenly, and the artery and the surrounding tissues are located outside the catheter.

Based on the clinical imaging data[6], the plaque was enclosed by four arcs, whose angle range from 91.7° to 154.8° and the thickness ranges from 0.83mm to 2.63mm, and the corresponding circumferential length ranges from 3.73mm to 11.15mm.

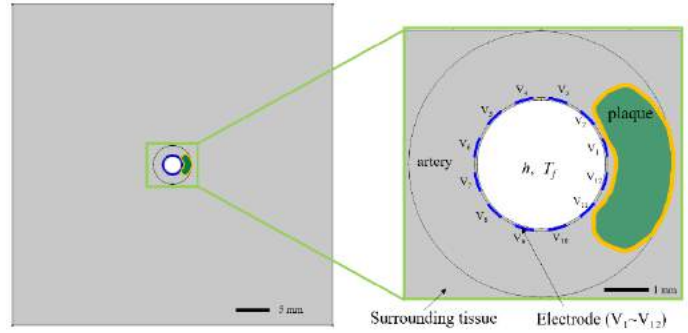

Figure 1: The two-dimensional geometric model for simplified calculation of strip multiple electrodes.

The quasi-electrostatic field equation (1) and the heat transfer governing equation (2) were used.

$$\nabla \cdot (\sigma \nabla V) = 0 \quad (1)$$

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) + \sigma (\nabla V)^2 \quad (2)$$

where V is the potential of tissue, σ and k are the electrical and thermal conductivity, respectively.

The convective condition was applied to the inner wall of the catheter

$$q = h(T_w - T_f) \quad (3)$$

where T_w and T_f are the temperature of the inner wall of the balloon catheter and the cooling water, respectively. h is the convective heat transfer coefficient is the function of velocity ($V/\text{m}\cdot\text{s}^{-1}$) and temperature (T/K) based on empirical correlation. In each electrode, the potential, V , is set to be $V_1 \sim V_{12}$. When one electrode isn't used, the insulation boundary condition is used. The initial temperature is set to

37 °C, and the outer surface of the phantom is set as thermal insulation to simulate *in-vivo* thermal treatment. The electrical and thermal properties of the artery and the catheter are the same as in the study [1].

NSGA II: NSGA II was chosen to search the optimal parameters (including $V_1 \sim V_{12}$, V_f , and T_f) for the ablation of different plaque morphologies with the merit of good performances in global optimization and fast convergence. The detailed algorithm flowchart is shown in Figure 2.

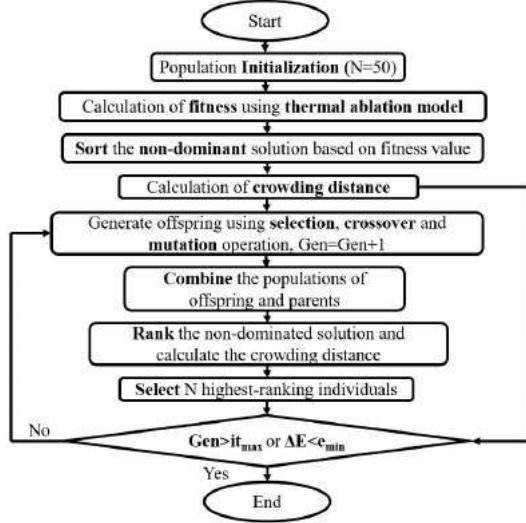

Figure 2: Algorithm flowchart for determining the optimal parameter set ($V_1 \sim V_{12}$, V_f , and T_f).

RESULTS

The optimal parameters were obtained and the optimized ablation results were good using the combination of multiple electrodes and NSGAII optimization (Fig.3). The over-ablation rate of intimal (ablation of intimal to the whole intimal) was 0% ~ 16.05%, the overall over-ablation rate (the area of over-ablation to the area of the plaque) was 2.52% ~ 9.60% and the coverage rate was 75.68% ~ 92.47% (see Table 1). The average values of the over-ablation of rate intimal, overall over-ablation rate, and coverage rate were 6.67%, 4.95%, and 84.92%.

Figure 3: The optimized ablation results for different plaque morphologies (a ~ i). The green region, red region, and blue region

represent the plaque, ablation area, and surrounding tissue.

Table 1: The three ablation indexes for different plaque morphologies.

Plaque	Parameters ($V_1 \sim V_{12}/V$, $T_f/^\circ\text{C}$, $V_f/\text{m}\cdot\text{s}^{-1}$)	over-ablation rate of intimal	Overall over-ablation rate	coverage rate
a	[24,4,27,N,N,N,N,N,N,0,24,5,9,4,8]	12.46%	3.00%	79.20%
b	[24,3,29,N,N,N,N,N,N,27,0,0,8,8,8]	6.85%	3.80%	88.40%
c	[26,32,44,N,N,N,N,N,N,N,16,0,9,21,5,4]	4.50%	5.03%	83.05%
d	[8,25,0,N,N,N,N,N,N,12,35,21,3,8,6]	2.07%	9.60%	86.75%
e	[13,0,N,N,N,N,N,N,N,N,N,N,43,30,7,4,2]	0	8.30%	75.68%
f	[9,0,N,N,N,N,N,N,N,N,N,N,23,21,29,5,5,4]	12.34%	4.56%	85.13%
g	[0,20,N,N,N,N,N,N,N,N,N,N,27,2,7,5,6,6]	0.84%	2.52%	84.78%
h	[33,6,N,N,N,N,N,N,N,N,N,N,0,26,6,5,9]	4.92%	4.95%	92.47%
i	[27,21,N,N,N,N,N,N,N,N,N,N,5,0,36,5,8]	16.05%	2.83%	88.83%

Note: N indicates that the corresponding electrode is not selected as the working electrode.

DISCUSSION

It demonstrates that the conformal ablation of atherosclerotic plaques with different irregular morphologies in a short time could be realized by the combination of multiple electrodes and NSGA II. The over-ablation rate is lower than 10% and the coverage rate was larger than 75% in the nine cases. In the future, the optimal strategies will be assessed with more different plaque morphologies and verified by the experiments. In addition, a three-dimensional model that takes into account the heterogeneity of different plaques will be developed to provide more precise guidance for the conformal ablation of atherosclerotic plaque clinically.

INTRODUCTION

The collagen microstructure of the cervix remodels during pregnancy to accommodate its biological function. As pregnancy progresses, collagen fibers become more disorganized, and, consequently, the cervix softens. Abnormal or early remodeling, however, can lead to preterm birth (PTB). PTB affects approximately 1 in 10 babies and has costly and long-term health consequences [1]. Methods of characterizing collagen organization in cervix tissue have the potential to predict the risk of PTB more accurately and earlier, allowing for timely medical interventions. Currently, cervical length serves as the gold standard for predicting risk of PTB despite its low positive predictive value [2]. Thus there is a need for improved methods for assessing collagen microstructure of cervix.

Second-Harmonic Generation (SHG) microscopy is a well-established technique for acquiring high-resolution images of the tissue microstructure but its clinical application has been limited due to its invasive nature [3]. In contrast, diffusion-weighted MRI (dMRI) is non-invasive and sensitive to changes in tissue microstructure [4], however, the relationship between collagen organization and dMRI metrics is not well established. Here we combine SHG imaging with simulations of diffusion MRI to explore the ability of dMRI to capture collagen remodeling due to pregnancy.

METHODS

Sample preparation. Cervices of 12-week-old Sprague Dawley rats were harvested and stored at -80C (two non-pregnant, two 15-days pregnant, two 17-days pregnant, and three 21-days pregnant). Excised tissue was thawed, embedded in optimal cutting temperature (OCT) compound, and cryosectioned transversely at mid-cervix (-20C). OCT was washed after sectioning and samples imaged immediately.

SHG imaging. A femtosecond laser (MaiTai DeepSee, Newport Corporation, USA), centered at 780 nm, illuminated the cervixes and a confocal microscope (Zeiss LSM 710, Germany) acquired 3D images of the samples

using a 40× 1.2 NA water-immersion objective. Two quantitative parameters, spherical variance (SV) and average out-of-plane fiber orientation (Φ), described the volumetric images. Briefly, Φ quantifies the average orientation of the collagen fibers relative to the imaging plane (the plane perpendicular to the cervical canals) and SV represents the dispersion of the collagen fibers in 3D, with values between 0 (unidirectional) and 1 (dispersed). Detailed descriptions of imaging and image quantification protocols are available in [3].

Diffusion MRI (dMRI) simulations. SHG image stacks (N=86) were binarized into a 3D volume consisting of collagen fibers and interstitial water domains. dMRI experiments were simulated by solving the Bloch-Torrey equation over the domain using the lattice Boltzmann method [5]. The collagen domain was modeled as not contributing to the dMRI signal (due to its low T2). A diffusion coefficient of 2.0 $\mu\text{m}^2/\text{ms}$ was used. dMRI scans consisted of a PGSE sequence with 64 directions, gradient duration of 10 ms, gradient spacing of 4 ms, and a b-value of 400 s/mm^2 . For each sequence, a non-diffusion weighted simulation was also performed. Both diffusion tensor imaging (DTI) and spherical harmonics (SH) approaches to analyzing the dMRI signal were considered [4]. The diffusion tensor was computed using custom Python code along with radial (RD) and mean diffusivity (MD), and fractional anisotropy (FA). Spherical harmonic coefficients up to degree four were computed using the pyshtools Python package.

RESULTS

A comparison of the simulated dMRI experiments for pregnant and non-pregnant cervixes shows a statistically significant ($p < 0.01$) difference in fractional anisotropy (FA), which is a measure of the degree to which water diffusion is restricted in one direction but not in others (Fig. 2a). Pregnant cervixes exhibit lower FA, indicating remodeling of the collagen fibers in the cervical tissue to be more disorganized. Structural metrics of

Figure 1: Overview of the simulation process. SHG image stacks (left) are binarized into 3D domains over which a dMRI experiment is simulated by solving the Bloch-Torrey equation, resulting in a map of the microscale signal distribution within the cervix tissue (center). The dMRI experiment is repeated in 64 directions from which DTI and spherical harmonic (SH) representations of the signal are computed. SH provides a model-free representation of the dMRI signal distribution on a sphere (right).

collagen orientation measured from SHG images are also correlated with FA. Both spherical variance (Fig. 2b) and average out-of-plane fiber orientation (Fig. 2c) have inversely proportional relationships with FA demonstrating that dMRI metrics are sensitive to structural variations in the collagen fiber orientations.

Figure 2: (a) Significant differences in fractional anisotropy (FA) exist between pregnant and non-pregnant rat cervix. FA also correlates with the structural parameters of (b) spherical variance and (c) average out-of-plane fiber orientation measured from SHG images.

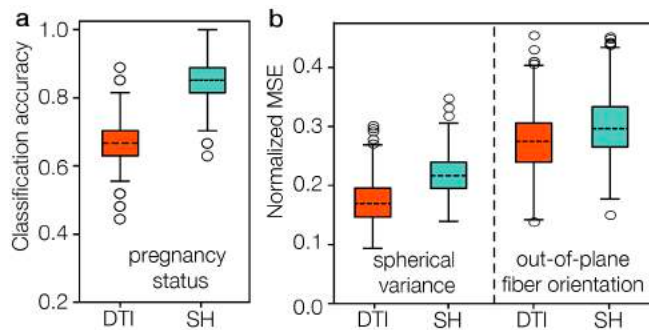

Figure 3: (a) Box plot of the performance of a logistic regression classifier trained to distinguish pregnant or non-pregnant status. Two classifiers were trained, one using traditional DTI metrics and the other using spherical harmonics (SH) coefficients. (b) Normalized mean-squared error of a linear regression model trained to predict spherical variance and out-of-plane fiber orientation. Models using both DTI metrics and SH coefficients were explored with the SH-based models outperforming the DTI-based models.

We next consider if dMRI can distinguish between pregnant and non-pregnant stages. A logistic regression classifier was trained to distinguish pregnancy status (Fig. 3a). Training was performed using 80% of the simulation data and model performance was evaluated on the remaining 20% of data. To generate a robust measure of model accuracy, each model was trained and evaluated 500 times with the training and testing data randomly

shuffled each time. Two types of models were trained. The first model used DTI metrics (FA, MD, RD, λ_1 , λ_2 , λ_3) while the second model used the spherical harmonics coefficients. Testing revealed that using only the first 9 coefficients yielded the best performance. All data were normalized to zero mean and unity variance prior to training. The SH-based model exhibits better performance, with a mean accuracy of 84% while the DTI-based model achieved an average accuracy of 66%. A similar training process using Ridge regression was utilized to predict spherical variance and out-of-plane fiber orientation (based on measurements from the SHG data) from the dMRI data (Fig. 3b). Again both a DTI-based and SH-based model were trained with the SH-based model achieving lower normalized mean-squared error in both cases.

DISCUSSION

Diffusion MRI of human [6] and mouse [7] cervix during pregnancy has shown FA decreases throughout pregnancy, which is in keeping with our results. In contrast to these previous studies, this study focuses on mechanistically establishing the ability of dMRI to reveal structural changes in cervix tissue during pregnancy due to collagen remodeling. By relating the simulated dMRI results with structural metrics of collagen organization, it establishes that FA is sensitive to structural features of collagen such as spherical variance and out-of-fiber orientation. It further shows that both DTI and more advanced models of dMRI such as those based on spherical harmonics offer specificity to these structural features. Additional data collection will enable the use of machine learning techniques to further refine estimates of microstructure from diffusion MRI. Establishing a non-invasive approach to quantitatively evaluate collagen structure *in vivo* during pregnancy may yield novel clinical diagnostic and staging tools for treating a range of pregnancy complications, in particular pre-term birth.

INTRODUCTION

Retinal progenitor cells (RPCs) are multipotent cells fated to develop into neural retinal cell types such as retinal ganglion, horizontal, amacrine, bipolar, and photoreceptors. Although RPCs are not known to be present in the adult mammalian retina, culturing them *in vitro* is important for screening therapeutic molecules, developing retinal cell therapies, and characterizing cellular mechanisms involved in retinal disease and regeneration. Immortalized RPCs originating from prenatal rodents are commercially available, but these animals do not have the same composition and distribution of cells within the retina compared to humans.¹ Although RPC differentiation from human pluripotent stem cells is well established, the differentiation process is cost-, labor-, and time-intensive (~30 days). In addition, achieving sufficient quantities of RPCs is challenging because the RPC stage is inherently transient; RPC proliferation slows substantially within 1-2 weeks as mature retinal cell types emerge.²

There is a critical need for readily accessible human RPCs that are capable of prolonged proliferation while retaining the ability to further differentiate into mature retinal cell types. The most common way to achieve prolonged proliferation in culture is to reprogram, or “immortalize” cells by genetically altering the cell to upregulate replication. However, this effect is quasi-permanent, and thus has been shown to reduce differentiation capacity, since maturation and proliferation are typically mutually exclusive.³ As an alternative to this traditional approach, our objective in this research paper is to generate and characterize a conditionally immortalized human RPC line that enters prolonged proliferation in the presence of a small molecule stimulus, then differentiates towards mature retinal cell types when the stimulus is removed. To accomplish this, we transduced human induced pluripotent stem cells (iPSCs) with a Tet-On SV40-T expression system, which is designed to cause inhibition of cell cycle regulators in the presence of tetracycline. The transduced iPSCs were differentiated to RPCs before being exposed to tetracycline, then phenotypic stability

and proliferative ability were characterized during subsequent passaging using principal RPC markers.

METHODS

Cell Culture and Transduction. Human iPSCs derived from a patient with no known ocular disease were cultured on ATCC cell basement membrane coating in mTeSR with primocin and were fed daily until transduction. DNA plasmids and lentiviral vectors were prepared by Vector Builder according to the simplified schematic in Fig. 1. iPSCs were transduced at an MOI of 1 and transduced cells were subsequently selected by adding puromycin and hygromycin to the culture media.

Figure 1: Simplified design of plasmids delivered by lentivirus.

Left: a ubiquitous promoter, RSV, is upstream of a tetracycline-inducible promoter (TRE), which drives expression of SV40-T, a known inhibitor of cell cycle suppressors. **Right:** RSV drives expression of a tetracycline-dependent transcription factor (rtTA), which, in the presence of tetracycline, binds to the TRE promoter to activate transcription of SV40-T.

RPCs Differentiation and Culture. iPSCs were differentiated into RPCs until Day 30 using a previously published protocol.² Briefly, iPSCs were dissociated into single cell suspensions using

accutase. Single cells were then aggregated to form embryoid bodies (EBs) using low adhesion v-bottom plates. EBs were cultured in mTeSR on Day 0 and slowly transitioned to neural induction media over 3 days. On Day 6, 1.5nM BMP4 was added to the media. On Day 8, retinal organoids (RO) were plated with the gradual addition of FBS. FBS was then gradually removed until Day 15 to allow for RO detachment. Transition to retinal differentiation media began on Day 16 and FBS was gradually increased until Day 22. On Day 22, 1X Glutamax was added. On Day 25, 100μM Taurine was added. This media was continued until Day 30 and used in subsequent culture maintenance and studies of RPCs. RPCs were separated into three experimental group after Day 30: RO, no dox (monolayer culture), and dox (monolayer culture). Doxycycline, which is in the tetracycline family was added to media (1μg/ml) for the dox group to induce SV40T expression. Dox group cells were then cultured for 10 passages before removal of dox (no dox P10 RPCs) to assess if dox removal has an impact on RPC gene expression and maturation.

Figure 2: Schematic of experimental groups and timepoints.

Gene Expression of RPCs. RNA was collected at Day 30 of differentiation and every other passage (P1, P3, P5, P7, P9) for dox group or every 5 days for no dox groups (Days 5, 10, 15, 20). cDNA was synthesized using Superscript VILO cDNA kit. IDT PrimeTime standard primers were used to assess gene expression of PAX6, SOX2, CHX10, and Ki67, in conjunction with PrimeTime® Gene Expression Master Mix.

Immunostaining and Confocal Imaging. Immunostaining was performed at the same time points as the gene expression study. Briefly, cells were seeded in chamber slides and fixed with 4% PFA for 30 minutes, followed by 3x10 minute washes with 1X PBS + 0.001 vol % Tween. Primary antibodies were diluted at 1:100 in immunoblock buffer consisting of sodium azide, Triton-X, BSA and donkey serum and incubated overnight at 4°C. This was followed by 5 more 1X PBS + Tween washes and 2hr incubation at 25°C with secondary antibodies diluted at 1:1000 in immunoblock buffer. Finally, the slides were washed 3 times and mounted using ProLong™ Gold with DAPI.

RESULTS

Qualitatively, we observed that transduced cells exposed to doxycycline were able to be passaged up to ten times, while cells in the no dox group were far less proliferative and thus were not passaged throughout the experiment. qPCR analysis (**Figure 3**) demonstrated that expression of SOX2, PAX6, and CHX10 (early retinal markers) decreased after dissociation into monolayers during culture. SOX2, PAX6, and CHX10 were also quickly lost during early passage in the Dox RPC group. Although Ki67 (a marker of proliferation) is relatively constant in ROs and no Dox RPCs, passaging of RPCs led to decreased Ki67 expression over time.

Preliminary immunostaining of SOX2, PAX6, CHX10, and Ki67 did not show protein expression in most retinal organoid time points and Dox RPCs passages. Some Ki67 seemed to be present for ROs at

Day 30 of differentiation (RO Day 0) and for Dox RPCs at P3 (**Figure 4**). In addition, some expression of Chx10 was observed in late passage (P9) Dox RPCs.

Figure 3: Gene expression analysis of RPC markers.

Figure 4: Immunostaining of RPC markers

DISCUSSION

RT-qPCR analysis revealed that after 30 days of differentiation from iPSCs, the RPCs expressed markers SOX2, PAX6, CHX10, and Ki67 indicating they were fated to develop into neural retinal tissue. The expression of Ki67 indicates ability of RPCs to proceed to active cell division. Its presence throughout late passages of Dox RPCs group indicates the possibility of sustained culture of these cells when conditionally immortalized. The co-expression of CHX10 and PAX6 is only present in neural retinal progenitor cells and thus the lost expression of these genes in Dox RPCs during early passages indicates that addition of doxycycline may not facilitate preservation of the retinal progenitor cell state.

Since immunostaining did not show expression of SOX2, PAX6, CHX10 and Ki67, future studies will include positive controls to ensure that the immunostaining protocol and chosen antibodies are functional. If positive controls do show staining of these markers, the differentiation protocol will be continued to a later time point before RPCs are dissociated into monolayer culture and doxycycline is added. Otherwise, the immunostaining protocol and antibodies will be revised.

In the future, experiments will also be performed to compare current data with control iPSCs that were not transduced. This will allow for assessment of leaky expression of SV40-T, which could affect the way iPSCs progress through differentiation. Other retinal cell markers will also be included to further characterize cell phenotype after doxycycline exposure.

INTRODUCTION

Fractures are one of the most common injuries worldwide with an estimated 178 million new fractures a year and 445 million prevalent fractures leading to billions of dollars in healthcare cost annually.¹ While most bone injuries regenerate well, 10-15% of normal fractures demonstrate impaired healing in the form of delayed- or non-union.^{2,3} Non-union rates increase to 50% of fractures when coupled with vascular damage or a high co-morbidity burden.⁴ Clinically, these non-unions are difficult and costly to treat as physicians are reluctant to intervene until 6-9 months without radiographic evidence of bone formation. There are currently no pharmacological agents approved to accelerate fracture healing or treat non-unions.³ Standard of care for addressing non-unions is surgical intervention to increase biomechanical stability and/or implantation of bone graft to promote healing. Injectable therapies are an exciting alternative to surgically implanted biologics for fracture healing. However, the translation of effective osteoinductive therapies remains challenging due to the need for safe and effective drug delivery. As such, there is an unmet clinical need for a controlled, localized, and non-surgical drug delivery system to treat bone fractures. Our objective is to engineer injectable polycaprolactone (PCL) nanowires loaded with beta nerve growth factor (β -NGF) to promote fracture repair.

METHODS

PEGDMA microrods were first fabricated to be used to demonstrate feasibility of the experiments. The microrods were fabricated as previously described through a process of photolithography.⁵ Prior to photolithography, the PEGDMA macromer was adjusted to have a 75% or 90% concentration to examine if the polymer network density affected protein loading efficiency and release. Following fabrication, the microrods were allowed to passively adsorb β -NGF protein for 30 hours in 4°C.

After loading, the microrods were spun down and the supernatant was collected to analyze NGF loading efficiency. This was done using a μ BCA assay and measuring the amount of NGF in the supernatant. NGF loading levels were calculated based on the depletion of NGF (eq 1) where X_i is quantity of drug added initially and X_t is amount of protein in the supernatant after 30 hours.

$$\text{Loading efficiency \%} = \frac{X_i - X_t}{X_i} * 100 \quad (1)$$

Nanowires were fabricated from polycaprolactone (PCL) polymers using a nano-templating technique.^{6,7} An anodized aluminum oxide (AAO) substrate with controlled pore size formed the template for nanowire formation. A PCL film was cast onto a glass substrate and heated to above melting temperature while in contact with the AAO template. This caused rapid nanowire formation into the AAO pores via capillary action. Following templating and cooling, nanowires were purified by membrane detachment and selective AAO etching with sodium hydroxide. Once released, the nanowires were sonicated, filtered, purified, and stored at 4°C as a suspension in water.

To functionalize the nanowires, a layer-by-layer (LbL) electrostatic assembly approach previously published was used.^{6,7} The PCL nanowires bear a strong negative charge following the alkaline etching method used in the fabrication process. Due to this negative charge, chitosan (positive charge) was used as the first layer to make positively charged nanowires. Chitosan was dissolved at 10 mg/mL in 0.25% Acetic Acid and incubated at 37°C for 15 minutes to fully dissolve. The solution was diluted in LbL buffer (25 mM HEPES, pH 7, 20 mM NaCl, 0.025% AcOH) to make a 2mg/mL chitosan stock solution. The nanowires were then reconstituted at 1 mg/mL in LbL buffer, and an equal volume of chitosan solution was added while sonicating. After 10 seconds of sonication, the nanowire-chitosan solution was removed and shaken at room temp for 30 minutes. The

solution was then centrifuged and washed with water. The nanowires now had a positive charge, and a subsequent layer of heparin (negative charge) could be added. First, β -NGF was loaded onto the heparin by incubating β -NGF solubilized in pH 6 sodium acetate buffer and heparin together at a 1:2 mass ratio for 30 minutes. The heparin-NGF solution was then added to the chitosan-nanowire solution at a 1:1 volume ratio and shaken at room temperature for 30 minutes. The nanowires were then resuspended in 500uL sodium-acetate pH6 buffer and 500uL of 2mg/mL chitosan in sodium acetate pH6 buffer was added. The solution was shaken for 15 minutes, spun down, and washed with sodium acetate pH 6 buffer. The nanowires were then spun down and supernatant was collected to analyze NGF loading efficiency using the same μ BCA assay as was done with the PEGDMA microrods.

RESULTS

First, PEGDMA microrods were fabricated and used to demonstrate feasibility of the release kinetic experiment. It was shown that the macromer concentration did not significantly affect loading efficiency (Fig 1A). The microrods were able to load over 2000ng of β -NGF (Fig. 1A), however less than 2% of the total protein was released over 168 hours (Fig 1B). This was later found to be due to physiochemical interactions between the protein and the microrods.

Figure 1: (A) Mass of β -NGF loaded into 16K microrods. (B) Percent release of β -NGF from PEGDMA microrods (n=3) over 168 hours.

To achieve a more linear release of NGF we next aimed to test whether PCL nanowires could be engineered with improved release kinetics. Nanowires were fabricated through a process of nano-templating (Fig 2). The nanowire width was controlled by the pore size of the AAO mold, while the length of the nanowires was controlled by varying the thickness of the polymer film. PCL nanowires were formed through capillary action after melting the PCL polymer and detached using sodium hydroxide. Nanowires with lengths ranging from 2-20 μ m have been fabricated, and a width of 200 nm has been consistently used thus far. PCL nanowires were functionalized through a layer-by-layer electrostatic assembly technique.

Figure 2: Polymeric nanowire fabrication technique. Nanowires are fabricated using an anodic aluminum oxide (AAO) template.

The same release experiment was performed with the PCL nanowires. The nanowires were able to successfully load 5 μ g of β -NGF with upwards of 75% efficiency and sustained first order release of the β -NGF over 8 days (Fig 3A). This data was generated using only a single layer of chitosan, further tuning of the NGF release kinetics to become more linear can be achieved by adding multiple layers of the electrostatic polymers⁶ (Fig 3B).

Figure 3: (A) 5 μ g NGF/mg was loaded with 75% efficiency onto nanowires followed by a single layer of chitosan. Sustained first order NGF release was observed over 8 days ($R^2 = 0.999$). (B) Hypothesized relationship of LbL layers and NGF release rates

DISCUSSION

Our results show that we can fabricate PCL nanowires, successfully load them with β -NGF, and deliver a sustained release. We were able to load 2.5 times more NGF on the nanowires compared to the PEGDMA microrods. This allows more NGF to be released locally into the fracture callus. Additionally, the ability to sustain first order release of the NGF over 8 days on the nanowires compared to the small amount released from the microrods shows that we were able to engineer a controlled delivery of this therapeutic.

While our results shown here are a good first step to addressing the clinical unmet need for a controlled and localized delivery system to treat bone fractures, these nanowires need to be further studied. Our next steps will be to add additional LbL layers to test the relationship between the number of LbL layers and NGF release rates. This will allow us to tune our nanowires for a more controlled release at specific timepoints during fracture healing. Following additional release kinetic studies, we will verify that the NGF released from the nanowires maintains bioactivity. This will be done using the canonical bioactivity test for NGF, the TF1 erythroblast cell proliferation assay.

In conclusion, the ability to deliver a therapeutic biologic to promote fracture repair without surgical intervention is the next step in fracture healing. Our developed nanowires can effectively load and release NGF in a controlled and localized way showing that this could be the next step to minimize delayed and non-unions.

CONTACT MECHANICS BASED FORMULATION TO EXAMINE THE ROLE OF CELLULAR ADHESIONS IN EPITHELIAL MECHANICS

M. Talukder (1), S. Kale (1,2)

INTRODUCTION

Epithelial tissue is one of the four major tissues in our bodies that covers all the internal and external surfaces and lines body cavities. Mechanical behavior of epithelial tissues coupled with the biochemical signaling is important in several physiological processes such as morphogenesis and wound healing as well as in pathological condition including cancer invasion. Understanding epithelial rheology is also necessary from a materials point of view for applications including organ-on-a-chip [1] and organoids [2]. The mechanical behavior of epithelia is governed by the complex multiscale architecture spanning subcellular to supracellular length scales. The dynamics of the subcellular constituents introduce complex time-dependent mechanical response of epithelia. On biologically relevant longer timescales, cortical tension and cellular adhesions that connect cellular mechanics control tissue mechanics, remodeling, and fracture behavior [3].

Several modeling approaches have been proposed to model the longer timescale epithelial mechanics governed by capillary forces and adhesion, vertex models [4, 5] being the most prominent approach. In vertex models, cell-cell adhesion is boiled down to an effective negative contribution to the cellular surface tension on lateral faces in contact. However, topological changes including fracture in the cellular network are introduced as additional rules in the model [6]. Consequently, the role of adhesion in epithelial remodeling, especially when the tissue undergoes fracture and neighbor exchanges, is not entirely clear from a modeling point of view. We address this gap here by developing a theoretical and computational framework that explicitly captures the cell-cell adhesion using a contact mechanics-based formulation. We demonstrate the effectiveness of the approach in examining formation of confluent tissues and mechanical response to external loadings.

METHODS

Morphological examination of epithelia has revealed that epithelial monolayers produce polygonal packings in confluent tissues with

polyhedral cell shapes [7]. Taking advantage of this observation, similar to a vertex model, we represent each cell by a deformable contour on a 2D space signifying the apical or basal surface as shown in Figure 1. The polyhedral shape of the cells is implicitly captured by introducing the cell height, h , as a model parameter. This description is accurate for a confluent tissue without the significantly higher computational burden of a 3D model [8], while the cylindrical shape approximation is less accurate for sparse tissues.

Figure 1: Kinematics of the deformable contour model of cell where φ maps points from 1D parametric domain to 2D physical domain of cell contour. Here, σ_{ab} and σ_l are the cortical tensions on the apicobasal and the lateral surfaces.

To formulate the model and obtain governing equations, we resort to Onsager's variational principle which provides a systematic approach to develop models for dissipative dynamics of soft biological materials involving coupled physical processes [9]. According to this variational framework, the dynamics of the system is governed by the balance of energetic and dissipative forces as well as the external forces. The forces are derived from potentials which account for all the relevant contributions from the underlying physics of the system. In this model, the power terms are due to apicobasal cortical tension, and cortical tension on the lateral surface of the cell. The energetic contributions include relatively weak bending stiffness of the cell contour to penalize

sharp corners by penalizing curvature. The adhesion between two cells is captured using the following form of the Morse potential

$$\varphi(g_n) = D \left\{ \left[1 - \exp\left(\frac{g_{min}-g_n}{l}\right) \right]^2 - 1 \right\}, \quad (1)$$

where g_n is the separation distance, D is the work of adhesion, g_{min} controls the minima location, and l controls the width. We follow the two-half pass algorithm [10] to capture cellular interactions. We include the dissipation from cortical viscosity and friction with surroundings.

The governing equations are obtained by extremizing the Lagrangian formed by all energetic, dissipative, and power terms with cell volume constraint. To discretize the extremized problem temporally, we use backward Euler method and to discretize it spatially, we use cubic B-spline finite elements. The key parameters of the model are cortical tension on apicobasal surface, σ_{ab} ; cortical tension on lateral surface, σ_l ; bending stiffness of cellular contour, k_b ; work of adhesion, D ; internal viscosity due to relaxation of actomyosin cortex, η_{int} ; external viscosity, η_{ext} .

Figure 2: Variation of equilibrium shapes with work of adhesion. Equilibrium shapes of (A) cellular doublet and (B) quadruplet at (i) $D = 0.25$ (ii) $D = 0.5$ (iii) $D = 0.75$.

RESULTS

To test the implementation of adhesion algorithm, we examine the equilibrium shapes formed by a cell doublet and a quadruplet. In both cases, we initialize the simulation by placing 2 and 4 circular cells respectively close to each other, such that they are within the interaction range of the potential. The cells interact through adhesion until they reach the equilibrium states as shown in figure 2. The increase in contact area with increasing work of adhesion is correctly captured by the model in both cases. The normalized parameters used for all the following simulations informed by representative properties of epithelia are $\sigma_{ab} = 1.0$, $\sigma_l = 1.0$, $k_b = 0.01$, $D = 0.5$, $l = 10.0$, $g_{min} = 0.1$, $\eta_{int} = 0.4$, and $\eta_{ext} = 0.5$.

Figure 3: Generation of confluent tissue from disparate cells (a) initial configuration of randomly placed circular cells (b) confluent tissue generated from the initial configuration.

To generate a confluent tissue, we initially generate a distribution of cells with initial radius of 0.6 in a biperiodic box of size 10 using random sequential addition with mutual exclusion to avoid overlap (Figure 3A). The cells are then expanded to increase the apical area until confluency with area fraction close to 1. The adhesive interaction between cells naturally results in a polygonal packing (Figure 3B). The

process involves two steps. First, cells are allowed to increase in volume at a fixed cell height to reach confluency. The cell heights are then allowed to relax such that the configuration reach the steady state.

Finally, we investigate the response of the confluent tissue to different loading conditions imposed by changing the size of the biperiodic box. The loading is applied at a rate slower than other relaxation timescales of the model. For a tissue subjected to uniaxial stretching (Figure 4A), we observe that the cells are first stretched similar to the overall stretch imposed on the tissue. However, at sufficiently higher stretch ratios, the cell-cell adhesion is compromised to form fracture in the tissue (Figure 4A-iv). A qualitatively similar behavior is observed for a confluent tissue subjected to equibiaxial loading (Figure 4B). The biperiodic box boundary conditions play an important role to avoid any boundary effects in these representative element simulations.

Figure 4: Evolution of the confluent tissue subjected to different loadings. (A) State of the tissue at the stretch ratio of (i) 0.108 (ii) 0.364 (iii) 0.678 (iv) 0.993 after a uniaxial stretch was applied at the rate of 0.033 in the horizontal direction. (B) States of the tissue at the stretch ratio of (i) 0.059 (ii) 0.215 (iii) 0.431 (iv) 0.603 after an equibiaxial stretch was applied at the rate of 0.033.

DISCUSSION

We have presented here a 2D deformable model where the cell contour acts as an active surface interacting with adjacent cells through adhesion potential. The contact formulation used to implement the cellular adhesion is shown to capture equilibrium configurations of multicellular assemblies. Importantly, the cellular rearrangements including fracture are naturally captured in the model without resorting to any rules for topological transitions. Thus, the modeling framework provides a promising way to examine the role of adhesion in epithelial remodeling events. Having demonstrated the capabilities of the model, we intend to investigate the role of the adhesion potential in governing cellular rearrangements and tissue fracture.

FORCE DIRECTION IS DIFFERENT FROM FIBER DIRECTION AT THE ANTERIOR CRUCIATE LIGAMENT ATTACHMENTS IN PORCINE KNEES

D. Ishii (1), S. Koseki (1), S. Sato (1), H. Fujie (1)

INTRODUCTION

The anterior cruciate ligament (ACL) has two types of insertions to the bone, namely direct and indirect insertions. The direct insertion is composed of fibrocartilage whose amount is greater at the femoral insertion than at the tibial insertion^[1]. It has been suggested that the difference in fibrocartilage amount was related to ACL force, although the details have not been clarified. For a better understanding of the mechanical function of the ACL insertions, it is crucial to analyze the ACL force on the insertions. Previous studies have also investigated the magnitude and direction of the ACL force during joint motion^[2-5], but the direction of force was determined with respect to the tibial plateau and sagittal plane^[3-5]. In this study, the direction of the ACL force was determined with respect to the attachment surface.

METHODS

Ten immature porcine knee joints were used; five for femoral and the remaining 5 for tibial analyses. A previous study reported that the porcine ACL has three bundles; the antero-medial (AM), intermediate (IM), and postero-lateral (PL) bundles^[6]. The AM bundle is located anterior to the tibial attachment of the lateral meniscus while the IM and PL bundles are located posterior to the attachment in the porcine knee. Therefore, in this study, we defined the fiber bundle consisting of the AM bundle as 'long fiber' and the fiber bundle consisting of the IM and PL bundle as 'short fiber' (Figure 1).

Each knee joint was fixed to the 6-DOF robotic system^[7] (FRS-2015, Technology Services) at full extension, 60°, and 90° of flexion. The ACL force in response to an anterior tibial load of 100 N was analyzed under the assumption of superposition, following a previously reported method developed by one of the co-authors^[2].

After the tests, the tibia for femoral analysis was disconnected from the clamp of the robotic system, and a metal rod having a sharp needle tip was fixed to the clamp. The needle tip was controlled to 3-dimensionally digitize 10 points randomly selected in the femoral

Figure 1: Femoral (a) and tibial (b) attachments of the long fiber (L), and short fiber (S) of the porcine ACL. Scale bar is 10 mm.

attachment areas of the long and short fibers, respectively. Principal component analysis was performed to determine the first, second, and third principal components from the 10 points' coordinate data for the attachment of each fiber. The planes of the long and short fiber attachments were obtained from the first and second principal components, while the directions of the attachments were determined from the third principal component under the assumption that the planes can be represented by 2D flat planes. In addition, the plane and direction of the entire femoral attachment were determined via principal component analysis from the total 20 coordinate data. The elevation was defined as the angle between the attachment direction and the sagittal plane of the femur, while the deviation was defined as the angle between the projection of the attachment direction onto the sagittal plane and the anterior direction of the femur, and both the angles were determined. Similar analysis to the femoral attachments were performed for the tibial attachments. The elevation angle between the attachment direction and the tibial transverse plane, the deviation angle between the projection of the attachment direction onto the transverse plane and the tibial anterior direction were determined.

Finally, the elevation angles of the ACL force between the ACL force direction and femoral and tibial attachment plane were determined.

In addition, the deviation angles of the ACL force between the projection of the ACL force direction onto the entire femoral and tibial attachment planes and a line perpendicular to the resident's ridge^[8,9] for the femoral side and a line found inside the ACL tibial attachment for tibial side (Figure 1) were determined. Statistical analysis was performed to analyze significant changes in the elevation and deviation angles of the ACL.

RESULTS

The attachment directions of the long and short fibers were completely different from fiber orientation, except for the tibial attachment of the short fiber (Figure 2). In those attachments, the attachment directions were tilted away from the ACL fiber direction.

Figure 2: Elevation and deviation angles of the attachments of the long and short fibers of the ACL. The elevation angles are represented with respect to the femoral sagittal plane (x-y plane) and tibial transverse plane (x-z plane), while the deviation angles are represented with respect to the femoral and tibial anterior direction (x-axis).

The elevation angle of the ACL force was less than 10 degrees except for the tibial attachment of the short fiber (Figure 3). The elevation angles were significantly decreased with flexion on the tibial side ($p < 0.05$ in one-way ANOVA), while a contrast tendency was observed on the femoral side. Note that the elevation angle at the tibial attachment of the long fiber was negative at 90° of flexion.

The deviation angles of the ACL force were significantly increased with flexion on the femoral and tibial sides ($p < 0.05$ in one-way ANOVA). The angles varied more on the femoral side than on the tibial side.

DISCUSSION

Previous studies indicated that the elevation angle of the ACL force was approximately 40 degrees from the femoral sagittal plane and the tibial transverse plane^[3-5]. The present study clarified that the

Figure 3: Elevation angle between the ACL force and the femoral and tibial attachment planes of the long fiber and the short fiber.

elevation angle of the ACL fibers from the attachment planes is less than 10 degrees and sometimes can be negative, except for the tibial attachment of the short fiber. Interestingly, the attachment directions were tilted away from the ACL fibers in those attachments. These results imply that the ACL force is transmitted to the femur and tibia not only through their attachments' area but also via bony-contacts of the fibers near the attachments as shown in Figure 4. We believed that this is the reason for the negative elevation angles observed in the present study. It is suggested that the bony-contacts of the ACL fibers play important roles in the structure generation and overall functions of the ACL insertions.

ESTABLISHMENT OF A VALIDATED FINITE ELEMENT FRAMEWORK TO PREDICT THE 3D, PATIENT-SPECIFIC ARTERIAL MECHANICAL ENVIRONMENT

Caleb C. Berggren (1), Y.F. Jack Wang (1), Lucas H. Timmins (1,2)

INTRODUCTION

Acute coronary syndrome (ACS) events remain the highest cause of death worldwide [1]. These clinical events primarily originate from atherosclerotic plaque rupture, with recent clinical data indicating that ACS is preceded by rapid plaque progression [2]. As such, there is great clinical need to predict rapidly progressing coronary atherosclerosis. Recent imaging advancements (e.g., intravascular ultrasound; IVUS) allow for the identification of plaque characteristics [3], yet current methods for predicting coronary artery disease (CAD) progression and ACS events that rely solely on imaging are insufficient.

As the local biomechanical environment plays a central role in coronary atherosclerosis development and progression, coronary plaque mechanics may provide an alternative metric to improve clinical prediction of CAD progression and ACS events. Data from patient-specific models has shown increased mechanical stress in vulnerable plaques compared to stable and non-ruptured lesions [4,5]. Although insightful, these models possessed several assumptions that may impact their clinical utility and were not validated. To advance the prognostic abilities of coronary artery computational modeling, it is essential that robust, accurate, and validated modeling strategies are established. Such validation has proved challenging and, to date, has not been performed.

To advance the clinical utility of biomechanics for managing patients with advanced coronary disease, this study aimed to develop and validate an IVUS-based finite element (FE) model to evaluate the patient-specific solid mechanical environment.

METHODS

IVUS Image Acquisition A 6-9 month old porcine carotid artery sample (Animal Technologies, Tyler, TX) was cut to ~30 mm in length and mounted on a custom biaxial mechanical testing device. The device allowed interrogation of the artery with an IVUS catheter (Philips Core Mobile, Eagle Eye Platinum) without impacting tissue loading. Prior to image acquisition and tissue loading, the vessel was preconditioned in

the circumferential and axial directions over 10 cycles to a maximum pressure and axial stretch ratio of 180 mmHg and 1.8, respectively. An axial stretch ratio of 1.5 was applied, and the vessel was pressurized to 2 mmHg to prevent vessel collapse. IVUS images were acquired via a pullback in the central 15 mm of the vessel at approximately 0.5 mm increments (Fig. 1A). In the center of the imaging volume during the pullback (i.e., at 7.5 mm along the pullback), IVUS images were collected at static pressures of 20-120 mmHg in 20 mmHg increments. (Fig. 1A). Subsequently, the applied pressure was returned to 2 mmHg and the pullback and image acquisition was completed. Following the acquisition, image data were spatially co-registered with the aid of a fixed reference object not contacting the vessel but within the imaging frames.

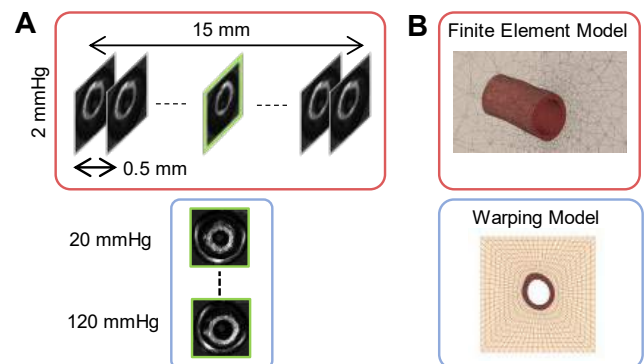

Figure 1: Image acquisition strategy (A) and model reconstructions (B) for finite element (red boxes, model shown with axial cut plane) and warping (blue boxes) models.

Experimentally-Derived Artery Strain Fields Hyperelastic Warping was employed to quantify tissue deformation from the acquired IVUS image data at lumen pressures of 2 (template image) and 120 (target image) mmHg [6]. The geometry was created from the IVUS-derived lumen and outer vessel boundaries extracted from the template image, and a perivascular (PV) tissue region was added for tethering (Fig. 1B). Domains were discretized with linear hexahedral elements. The artery was described as an incompressible neo-Hookean material (70 kPa shear modulus), and the perivascular tissue as a compressible, neo-Hookean material ($E = 50$, $\nu = 0.3$). Boundary conditions included an applied lumen pressure and fixing of the outer borders of the model (i.e., PV boundary) in all directions. Hyperelastic Warping was implemented via the warping module within the FEBio software suite [7] to determine the experimentally-derived strain field.

3D Forward FE Computational Model Lumen and outer vessel boundaries were extracted from all images acquired in the IVUS pullback at 2 mmHg (unloaded geometry). Surfaces were fit to the boundaries to define the artery model volume (Geomagic, 3D Systems). A block of PV tissue was added and encompassed the vessel (Fig. 1B). The artery and PV regions were meshed with linear tetrahedral elements (GibsonCode, TetGen), and were described by the same material properties as noted above. Applied boundary conditions included a lumen pressure of 120 mmHg, fixing the ends of the vessel and the PV outer surfaces in all directions. Data were post-processed to evaluate the FE-predicted strain field.

Data Analysis First principal Green-Lagrange strain (E_1) values were compared between the experimentally-derived (warping) and FE-predicted models. At 2 circumferential locations (0, 180°), strain data were extracted at 5 points through the thickness in the radial direction and absolute and percent differences were assessed.

RESULTS

First principal Green-Lagrange strains from both modalities demonstrated patterns characteristic of vascular tissues under loading, with higher principal strains at the lumen surface that decreased through the vessel wall. FE-predicted strains qualitatively agreed well with warping-predicted strains, as the locations of maximum and minimum strains occurred in similar spatial locations (Fig. 2A). Mean arterial strains were 0.29 ± 0.86 and 0.34 ± 0.73 for warping and FE models, respectively. Evaluating the data in more focal regions further confirmed the agreement between the FE-predicted and warping-derived strains. At 0° circumferential position, for example, FE-predicted strains decreased from 0.40 to .288 through the wall thickness, and the warping-derived strains decreased from 0.38 to 0.22. At the

180° circumferential position, transmural strain values for the FE-predicted and warping-derived ranged from 0.39 (inner) to 0.26 (outer) and 0.34 to 0.27, respectively (Fig. 2B).

DISCUSSION

Herein, we present a combined experimental-computational pipeline to validate FE predictions of the 3D coronary artery biomechanical environment under physiologic loading. Results demonstrate an agreement in the magnitude and location of maximum and minimum first principal Green-Lagrange strains between the FE-predicted and warping-derived methods. Moreover, agreement in transmural distributions of strain were observed between the two modalities. We acknowledge that the computational framework neglects several modeling considerations, such as the lack of pre-strain, only including 1 layer of the vessel, and isotropic material properties. Nevertheless, this study lays the foundation for future validation efforts that can incorporate a microstructurally-motivated strain energy functions for anisotropic materials. Indeed, FE model validation is critical to providing confidence in computational simulations and their integration into the clinical setting to guide patient management. These advances may enhance the prognostic capability for rapid plaque progression and ACS events.

PLASTICITY AND AVALANCHE FAILURE IN COMPUTATIONAL MODELS OF PULMONARY COLLAGEN-ELASTIN FIBER NETWORKS

INTRODUCTION

The lungs must withstand dynamic stretch associated with breathing and deep inspirations, accommodating a wide range of gas volumes from 1.2 L residual volume to over 6.0 L total lung capacity (TLC) in humans. Failure to sustain stretch and rupture of lung parenchyma cause enlarged airspaces and reduced surface area of the blood-gas interface, leading to ventilation-perfusion mismatching, gas exchange deficiency, and difficulty in breathing. Mechanical failure of the lungs is associated with emphysema progression, pneumothorax, barotrauma in diving-related injuries, and overdistension in ventilator-induced lung injury.

The structural integrity and mechanical function of the lungs depend on the organization of extracellular matrix proteins elastin and collagen, which exist as fibers crosslinked into an elastic network. Elastin fibers are taut under normal prestressed conditions, yet highly distensible—like a spring. Collagen is up to 100- to 1000-fold stiffer than elastin, yet wavy or tortuous at low lung volumes—like a string. Together, collagen and elastin form string-spring pairs that exhibit low stiffness at low stretch ratios and high stiffness at high stretch ratios [1].

A network of string-spring pairs may provide the lung with elastic recoil at low lung volumes as well as strain-stiffening to protect against overdistension at high lung volumes. However, it is unknown how microscale collagen-elastin interactions and network dynamics determine the emergence of TLC and the ability of lung parenchyma to withstand enormous volume change without yielding and failure. Previously, we collected experimental data of tensile testing in individual collagen fibers isolated from bovine lung tissue. In this study, we simulated equitriaxial stretching of elastin-collagen networks imbued with mechanical properties from our experimental data. We hypothesized that (1) no elastin fibers would fail before collagen fibers, and (2) no collagen fibers would fail or plastically deform before total lung capacity.

METHODS

A 3-dimensional network geometry mimicking a cube of lung parenchyma was constructed as a tessellation of truncated octahedra, each loosely representing an alveolus. Each edge (42,748 total) of the structure was represented by a parallel elastin-collagen fiber pair, permanently crosslinked with other fibers at each node (22,069 total). The initial structure was considered the resting configuration of the network with no stress at the boundary faces or internal prestress. Accordingly, every elastin fiber was assigned a rest length equal to its initial length, and every collagen fiber was assigned a rest length greater than its initial length. Elastin fibers were assigned a linear force-extension relationship, with failure occurring at 200% extension. Collagen fibers were assigned polynomial force-extension relationships designed to recapitulate a gradual recruitment “toe-heel” response followed by linear elasticity. Collagen fiber rest lengths were sampled from a microscopy-based waviness distribution [2]. Collagen stiffness was sampled from a log-normal distribution between 100- to 1000-fold stiffer than elastin. Strain thresholds for collagen plasticity and failure were randomly sampled from normal distributions, and plasticity was modeled by successive increases in rest length.

Incremental equitriaxial stretch was applied to the network by controlled displacement of nodes at the boundaries on all 6 faces. After each incremental stretch, the equilibrium configuration of the internal nodes was computed by numerically minimizing the sum of net force magnitudes acting on each node. Plasticity modifications to collagen fiber rest lengths—for fibers exceeding their respective plastic thresholds—were applied before each incremental stretch. Fiber failures were evaluated iteratively before each incremental stretch, such that the next stretch increment was not applied until no further failure events were detected. Network stresses were computed as the sum of force components normal to the boundary surface divided by the boundary face area. Pressure was approximated by the average normal stress across all 6 faces.

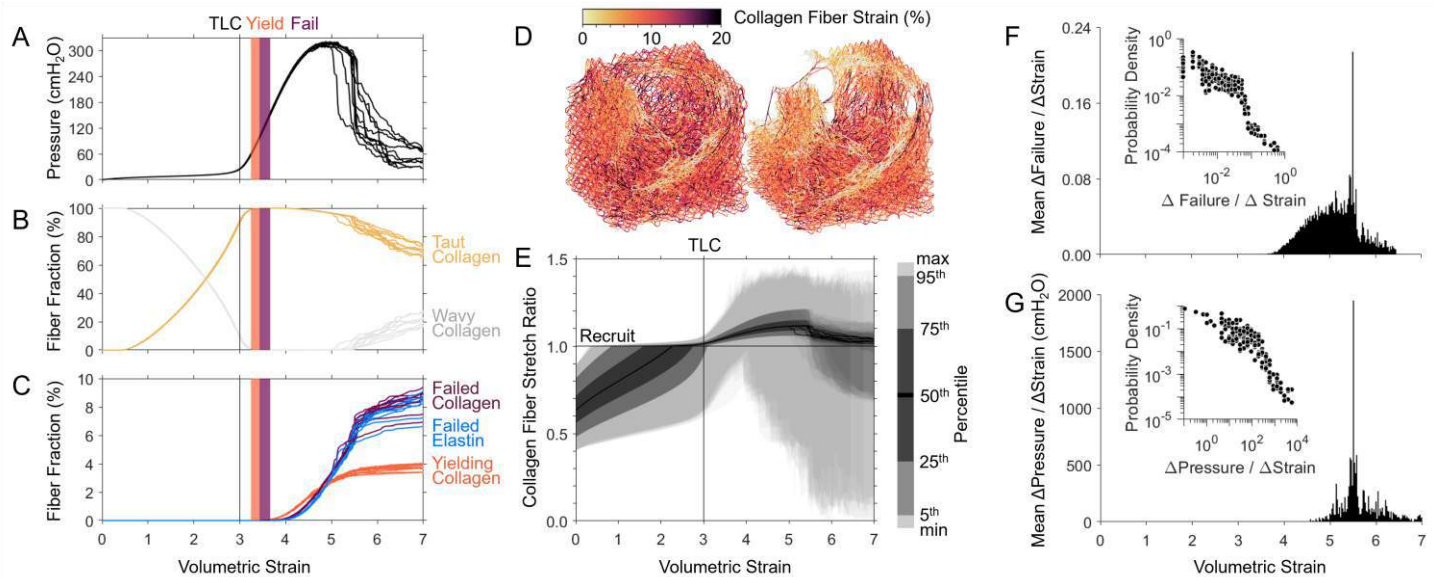

Figure 1: Summarized results from 10 collagen-elastin fiber networks during equitriaxial stretch. Shown at each incremental volumetric strain: (A) macroscale pressure, (B) fraction of collagen fibers recruited into a taut stress-bearing role from a wavy relaxed state, and (C) fraction of fibers plastic deformed or failed. Vertical bars indicate total lung capacity (black), onset of collagen yielding (orange), and onset of collagen failure (purple). (D) Example network during progressive rupture at volumetric strains 5.8 (left) and 6.2 (right). (E) Distributions of collagen fiber stretch ratios at each strain increment. (F) Average incremental fiber failure and (G) pressure drop at each strain increment, and (insets) probability density distributions on bilogarithmic scales.

RESULTS

Figure 1 shows macroscale stresses and microscale fiber status during simulated equitriaxial stretching of 10 collagen-elastin fiber networks. All simulations demonstrated an initial phase of fiber alignment, elastin extension, and gradual collagen recruitment. Collagen fiber recruitment initiated at 0.36 ± 0.04 volumetric strain. A strain of 3.00 was considered to represent TLC at 91.0 ± 0.5 % collagen recruitment and 26 ± 1 cmH₂O pressure. TLC was preceded by a strain-stiffening transition at 2.80 strain and 77.5 ± 0.4 % collagen fiber recruitment. Collagen fiber plasticity initiated at 3.33 ± 0.07 volumetric strain with 99.5 ± 0.3 % collagen recruitment and 78 ± 13 cmH₂O pressure. The onset of collagen yielding was followed shortly by the onset of fiber failure at 3.56 ± 0.08 strain, 99.9 ± 0.1 % collagen recruitment, and 129 ± 18 cmH₂O pressure.

In general, elastin fiber failure lagged collagen fiber failure (Fig. 1C). The first elastin failure occurred 5.8 ± 4.5 iterations after the first collagen failure, corresponding to an additional 3.8 ± 3.0 % increase in volumetric strain and 32 ± 25 cmH₂O (27 ± 23 %) increase in pressure. Despite a relatively gradual accumulation of fiber failure, tissue failure occurred by avalanches in nearly all simulations (Fig. 1A), with a sudden decrease in stress (Fig. 1G) accompanying a cascade of fiber failures (Fig. 1F) initiated at one location or in close proximity and propagating across the network (Fig. 1D). When collagen fiber properties for stiffness, plasticity, and failure were homogenous, failure events were more uniformly distributed throughout the tissue and failure was graceful rather than catastrophic (data not shown).

DISCUSSION

The string-spring model of collagen-elastin interactions in the lung implies that the functional role of collagen is primarily protection against overstretch of delicate parenchymal structures [1]. In this study, inflation of lung parenchyma was simulated by equitriaxial stretching of an idealized collagen-elastin fiber network representing a small alveolar region. The model's TLC emerged at 3.0 volumetric strain with

strain-stiffening and nearly 90% collagen fiber recruitment. Compared to humans with 6-L TLC and 2-L functional residual capacity (FRC), the networks' initial zero-strain state might plausibly approximate FRC, albeit neglecting prestress. The onset of fiber damage and failure in the network occurred at pressures similar to those reported as thresholds for barotrauma and development of emphysema [3],[4].

Collagen fibers recruited throughout inflation to TLC (Fig. 1B) limit the stretch imposed on each string-spring pair as the bulk tissue inflates beyond the range of quiescent breathing. Once the collagen fiber in a string-spring pair becomes recruited, additional inflation of the bulk tissue results in almost no additional stretch of the pair until the vast majority of collagen fibers have been recruited (Fig. 1E). No collagen began yielding before over 99% of fibers were recruited, and only after collagen failure initiated did elastin fibers begin to fail. The probability density of incremental fiber failures and pressure drops exhibited approximately power-law distributions (Fig. 1F), similar to avalanches in airway recruitment [5] and arterial dissection [6].

In conclusion, computational modeling of collagen-elastin fiber networks supports the primarily protective role of wavy collagen as a "safety net" for lung parenchyma, and furthermore highlights power-law behavior during failure. Collagen plasticity may confer additional longevity—without plasticity, the networks are more likely to fail catastrophically, and at lower strains.

CHARACTERIZING THE BIAXIAL MECHANICAL PROPERTIES OF SKELETAL MUSCLES OF THE MOUSE HINDLIMB

Katherine R. Knaus (1), Rebecca Hardie (1), Jessica Huberts (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering, University of California San Diego, La Jolla, CA, USA

INTRODUCTION

Exercise prescription to increase muscle strength and function boosts mobility linked to positive health outcomes but is currently limited by the gap in knowledge of underlying biological mechanisms. This includes how skeletal muscle tissue state [1] – muscle mechanical, metabolic, and plastic capacity – mediates transduction of external exercise stimuli to the biological regulators of strength and remodeling. Muscle tissue state exhibits disparate changes during remodeling, but the contributions of underlying structural and mechanical heterogeneity to the gradients of tissue state changes are not well understood.

Multiscale structural organization of muscle's mechanical constituents is an important determinant of tissue state. Mechanical performance depends on both macro scale properties, including fascicle architecture and tendon morphology [2], and microscale properties, including fiber size and extracellular matrix composition [3]. Muscles exhibit nonuniform tissue displacements that can arise from morphological and material heterogeneity, demonstrated by computational modeling [4], suggesting that structurally determined muscle mechanical behavior could dictate the cell-level mechanical cues arising from a prescribed exercise. Understanding how changes in tissue state will affect the physiologic response to a given exercise requires an understanding of how both muscle morphology and material properties dictate the driving mechanical stimuli.

Mice have long been used as an experimental model to elucidate biological mechanisms, as the capability of genetic manipulation makes them ideal for study of gain or loss of function *in vivo*. Recent advances in experiment models of murine exercise have introduced possibilities to study muscle remodeling response to loading [5]. Computational modeling has the exciting potential to derive mechanistic insight from these murine models by exploring how differences in muscle tissue state give rise to variable mechanical cues. Such an approach would require characterizing both the structure and material properties of mouse hindlimb muscles engaged by the exercise paradigm.

Studies characterizing skeletal muscle mechanical properties are span many species, muscles, and scales [6] and of these, studies of murine muscle do not characterize tissue properties independent of whole muscle structure. Biaxial characterization of porcine muscle has been demonstrated to effectively characterize skeletal muscle stiffness [7], with potential to consider contribution of constituents that would reflect anisotropic changes in tissue state. Similarly characterizing mouse hindlimb muscle is difficult due to the animal size, but important in understanding the influence of variable tissue state characteristics when using murine models of exercise. Therefore, the goal of this work is to develop a method to characterize the anisotropic properties of murine hindlimb skeletal muscles

METHODS

All experiments were performed with the approval of the Animal Care and Use Committee at the University of California San Diego. Two six-month-old female C57BL/6 mice were anesthetized until cessation of breathing followed by cervical dislocation to ensure death. Immediately post-mortem the right and left biceps femoris posterior (BFP) muscle was harvested (Fig. 1A). This hamstring muscle was chosen as its superficial location allowed it to be isolated from other muscles of the hindlimb without damaging the tissue and its wide shape enabled a square sample of continuous muscle tissue to be excised. In the excised samples, muscle fibers were oriented in the longitudinal direction (length = 7.50 ± 0.76 mm). The axis in this direction was called the along-fiber axis while the perpendicular axis oriented in the transverse direction (width = 7.70 ± 0.58 mm) and called the cross-fiber axis. To robustly measure thickness, five measurements were taken within the center region of the sample using calipers (thickness = 1.78 ± 0.06 mm). Muscle samples were stored in a solution of 30mM butanedione monoxime (BDM) in phosphate-buffered saline (PBS) for approximately 60 minutes. Samples were removed from solution and five graphite markers were glued on the surface. Four custom-made

hooks were placed on each side of the sample (Fig. 1B) and mounted in the pulley system (Fig. 1C) of a Bose Electro Force planar biaxial testing device (TA Instruments, New Castle, DE). While kept in a temperature-controlled bath of PBS; markers on the surface of the sample were brought into the visual field of the optical tracking system for computing the deformation gradient tensor. The samples were preloaded equally to 2.5 g to align them with the suture and pulley-system and thus secure a two-dimensional mechanical test. The mechanical testing consisted of 10% stretch-controlled biaxial tests at 0.5 Hz with biaxial ratios of $x_1:x_2 = 1:0.5, 1:0.25, 1:1, 0.5:1, \text{ and } 0.25:1$, all recorded after 15 cycles of preconditioning each [8].

Figure 1: Biaxial testing setup for mouse hindlimb muscle tissue.

Biaxial loads and pixel coordinates of the outer four material markers on the surface of the sample were used to compute stress and strain components with respect to the along and cross fiber axes to characterize the mechanical properties of the mouse BFP muscle. Forces were normalized by the cross-sectional area of the samples to compute the first Piola-Kirchhoff (PK) stress tensor. The reference configuration was the preloaded state of the samples at 2.5g, post-preconditioning, prior to the equibiaxial cycles. From the marker positions, the outer four markers were used to compute the deformation gradient tensor throughout the biaxial test by interpolating displacement gradients relative to the tare-loaded reference state at the center of a bilinear Lagrange finite element. The last three cycles of each biaxial loading protocol were averaged to compute the representative loading and unloading curves (Fig. 2A).

Only the loading curves were used for the constitutive analysis. The Green strain tensor and the 2nd PK stress tensor were calculated using the deformation tensor and 1st PK stress tensor. Shear components were assumed to be negligible, so differentiating a strain-energy function with respect to the Lagrangian-Green strain yielded the 2nd PK

stress in the principal axes. The strain-energy function chosen was a 2D Fung-type constitutive equation [8]:

$$W(E_{11}, E_{22}) = c(e^{a_1 E_{11}^2 + a_2 E_{22}^2 + a_3 E_{11} E_{22}} - 1) \quad (1)$$

The four model parameters θ for each specimen were obtained via the least-squares method through the loading cycles (Fig. 2B). The goodness of fit for each specimen was determined from the coefficient of determination.

RESULTS

Mouse hindlimb muscle tissue exhibited anisotropic mechanical properties when subjected to biaxial loading conditions. Although peak stresses differed between the biceps femoris muscles tested, all samples exhibited greater stiffness in the along fiber direction than in the cross fiber direction (Fig. 2A). The 2D Fung model provided a reasonable fit to the experimental data (Fig. 2B) with R^2 values ranging 0.83-0.97.

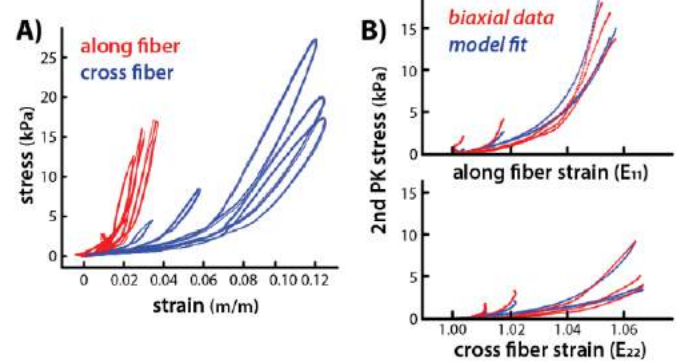

Figure 2: Representative biaxial loading curves and model fitting

DISCUSSION

These findings demonstrate an effective approach for using biaxial testing to characterize the anisotropic mechanical properties of a mouse hindlimb skeletal muscle. The greater stiffness along the fiber direction compared to across the fibers observed here is similar to what has been shown previously with biaxial testing of pig hindlimb muscles [7] and uniaxial testing of rabbit hindlimb muscles [9]. This method is currently limited to mouse hindlimb muscles from which a rectangular sample of continuous muscle tissue with a minimum length and width of 5mm can be excised. This method provides a means to characterize how muscle mechanical properties vary as a function of tissue state determined by intrinsic factors, such as sex and age, and extrinsic factors, such as exercise and diet. Such measurements will provide necessary contextual data to murine exercise models to understand the transduction of mechanical cues driving remodeling responses and will provide important inputs to computational models of mouse muscle contraction.

INTRODUCTION

Traumatic brain injury (TBI) is a leading cause of death and disability¹, but the mechanisms involved in its pathology remain unclear. It is currently not completely understood how motion is transferred from the skull to the brain, and there are many different models proposed for this mechanism². Quantifying the relative motion at the skull-brain interface will improve computational TBI models used by researchers and inform the design of protective equipment. One in-vivo measurement technique of relative skull-brain displacement is Magnetic Resonance Elastography (MRE)³, which is a non-invasive imaging technique. Standardization and development of better MRE actuators and methods of motion detection in the brain during MRE is important to maintain an acceptable octahedral shear strain-based signal-to-noise ratio (OSS-SNR)⁴, which is highly dependent on vibrational amplitude. Additionally, it has been shown that quantitative values of MRE, i.e., the magnitude of the complex shear modulus estimate ($|G^*|$), are sensitive to changes in OSS-SNR⁵, so MRE without acceptable vibration can present a challenge of both image quality, and elastogram accuracy. Previous work has simultaneously measured brain and skull motion using MRE⁶, and used an array of accelerometers embedded in a mouthguard to measure skull kinematics⁷. In this work, we aim to develop a measurement system that can accurately measure skull motion under MRI, and use it to understand the transmissibility of motion from the skull to the brain during MRE across a range of frequencies.

METHODS

Sequence and Processing Description: Whole brain coverage MRE⁸ at 2.5mm³ isotropic resolution with 16 phase offsets was performed at three frequencies on one healthy human subject using a Siemens 3T Prisma MRI scanner with a 48-channel head coil (Siemens Healthineers), and a custom pneumatic actuator. In order to capture wavefield images such that we can obtain a higher frequency response

resolution later down the post-processing pipeline, three custom MRE sequences were developed and utilized. The first used an effective encoding frequency of 40Hz (2 abutting 20Hz encoding gradients, TR=8013 ms, TE=113 ms, GRAPPA=3), and the second, an effective encoding frequency of 50Hz (2 abutting 25Hz encoding gradients, TR=6400 ms, TE=93 ms, GRAPPA=3). Settings were adjusted on the MRE hardware between each scan to not only apply the correct frequency, but also to adjust for decreases in vibration amplitude that occurs at higher applied frequencies. For processing, the difference was taken between the two phase images captured with opposite encoding directions, unwrapped using SEGUE⁹ and manual phase unwrapping, before being multiplied by the MENC value to obtain displacement in microns. We then performed a 16 point FFT on the displacement data to obtain the brain's frequency response with resolution half that of the effective encoding frequency. Using Freesurfer 7.0, a T1 structural scan of the subject was segmented into the whole brain, cerebellum, and corpus callosum (CC). Average frequency response was then calculated for each of these regions.

Figure 1.Figure 1. Visualization of experimental setup; custom MRE actuator pillow, mouthguard, and accelerometer array

Mouthguard and BIOPAC Accelerometers: To estimate skull kinematics, three MRI-safe, tri-axial accelerometers (TSD109C2-MRI, BIOPAC, Goleta, CA) were embedded in a 3D-printed mouthguard

array and attached to a boil-and-bite mouthguard that was fitted to the subject (Fig. 1). Accelerometers were offset in 3D to enable the calculation of rotational velocity from three sets of tri-axial linear acceleration data.

Calculation of the skull's motion parameters: Linear acceleration of the skull was recorded using the accelerometers. Rotational kinematic components of the skull and the linear kinematics of the center of gravity (CoG) of the head were unknowns that were calculated in the following analysis. We assumed the skull to be a rigid body which let us use equations (1-3) for each accelerometer^{7,10}.

Considering the position of the accelerometers with respect to the head and the predefined coordinate system, x, y, and z components represent the left-right (LR), superior-inferior (SI), and posterior-anterior (PA) directions, respectively. In these equations, three components of the linear acceleration of the CoG of the head (a_x^{CG} , a_y^{CG} , a_z^{CG}), angular velocities (ω_x , ω_y , ω_z) and angular accelerations (α_x , α_y , α_z) produced 9 unknowns. By solving equations 1-3 for each accelerometer, in which r_x , r_y , and r_z are the distance vector components from accelerometers to the CoG of the head, we found the unknowns at each timepoint.

$$a_x^{MG} = a_x^{CG} + (\alpha_y r_z - \alpha_z r_y) + (\omega_x(\omega_y r_y + \omega_z r_z) - r_x(\omega_y^2 + \omega_z^2)) \quad (1)$$

$$a_y^{MG} = a_y^{CG} + (\alpha_z r_x - \alpha_x r_z) + (\omega_y(\omega_z r_z + \omega_x r_x) - r_y(\omega_x^2 + \omega_z^2)) \quad (2)$$

$$a_z^{MG} = a_z^{CG} + (\alpha_x r_y - \alpha_y r_x) + (\omega_x(\omega_x r_x + \omega_y r_y) - r_z(\omega_x^2 + \omega_y^2)) \quad (3)$$

These linear accelerations and angular velocities are harmonic signals and can be written in the frequency domain using Fourier transformation. We calculated the FFT amplitudes of the angular velocity and linear acceleration at the CoG of the skull. FFT amplitudes of the displacement of the whole brain and its substructures were extracted from MRE images. To calculate the normalized transformation matrix of the angular velocity and linear acceleration for the brain, CC, and cerebellum, we divided the FFT amplitudes of the brain region displacement to the FFT amplitudes of the angular velocity and linear acceleration at the CoG in the dominant motion direction, and then normalized them. To elaborate more, during the MRE scan, the head was vibrated in the AP direction. Although there was vibration and consequently linear and rotational acceleration in other directions, the dominant linear acceleration was in the AP direction and the dominant rotational velocity was around the LR axis. We did these analyses for three different time ranges and to calculate the final normalized transformation matrix.

RESULTS

From the displacement in the brain calculated using MRE, the whole brain moves on average between 20-40 microns in AP direction

as shown in Fig.2. with the corresponding displacements shown in the frequency domain. In both transfer functions, in all regions, the first harmonic occurs at the frequency of 40 Hz and 75 Hz for encoding frequencies of 40 and 50 Hz, respectively (Fig.2). In the MRE vibration frequency of 40 Hz, a second harmonic is observed at the frequency of 80 Hz for the brain and the two other substructures.

DISCUSSION

In this study, we examined the relationship between the motion of the brain (which was estimated from MRE images) and the kinematics of the skull (through accelerometer-derived linear kinematics of the head). This relationship can give us further insights into the brain-skull dynamics. The displacement of the brain is almost the same for both vibration frequencies with a slightly higher value at 50 Hz. Considering the normalized transformation matrices, we observe a higher bandwidth for the vibration frequency of 50 Hz. This might be due to a better penetration of 50 Hz to the brain, which could be creating super harmonic motion at higher amplitudes compared to 40 Hz due to nonlinear effects. In the vibration frequency of 40 Hz, we observed a second harmonic with a relatively lower amplitude. In this encoding frequency, CC has the lowest amplitude in the rotational velocity normalized transformation matrix which might be correlated with its location in the brain. MRE waves attenuate as they move toward the deep regions of the brain, such as CC, which might cause less motion in these regions. Repeating these experiments for more encoding frequencies and analyzing the results for more regions of the brain, can improve our understanding about the broadband transmissibility between the skull and the brain, which could lead to a better understanding of TBI biomechanics.

INTRODUCTION

Ascending thoracic aortic aneurysm (aTAA) is a life-threatening condition whose etiology is still unknown, but the link between altered aortic hemodynamics and aTAA development is widely recognized. In particular, alterations induced by the presence of a bicuspid aortic valve (BAV) with consequent eccentricity of aortic inlet flow seems to play a role in the highest prevalence of aTAA cases in these patients, compared to subjects with a tricuspid aortic valve (TAV) [1]. In the state of the art, different groups have focused on the analysis of TAV and BAV influence on aortic hemodynamics by using patient specific geometries and inlet conditions [1,2]. However, perspective studies that investigate the evolution of hemodynamics patterns in presence of TAV or BAV phenotypes concurrently with aTAA progression are still limited.

Therefore, the main goal of this study is to investigate the role of inlet conditions eccentricity in the hemodynamics results at different stages of aTAA, accounting different configurations of TAV and BAV.

METHODS

The model representing different stages of a growing aneurysm in a virtual patient is built upon statistical shape analysis and Radial Basis Function morphing technique and has already been used in previous studies [3]. In this preliminary study, we consider two different geometries representing a baseline healthy aorta (A_{00}) and one stage of aTAA growth (A_{05}) (**Figure 1**). In particular, the baseline and the final stage of aTAA growth geometries are obtained by segmenting clinical CT datasets. The segmentation is performed by using the 3DSlicer software.

Transient computational fluid dynamics simulations are performed using Ansys Fluent (Ansys Inc.) pressure-based solver with 2-nd order schemes. The fluid domain is discretized with approximately 700 000 polyhedral elements. Blood is modeled as incompressible and Newtonian, with $\rho = 1060 \text{ kg/m}^3$ and $\mu = 0.00345 \text{ Pa}\cdot\text{s}$. The k- ω SST model is employed to account for turbulence.

Figure 1: Aorta segmentation with baseline and intermediate aTAA growth stage

PISO algorithm is used for pressure-velocity coupling and convergence is assured at every time step by reducing normalized residual of continuity, k and ω by 10^{-4} and of velocity by 10^{-6} . Outflow pressure boundary conditions are defined applying a 3-elements Windkessel model at each outlet, tuned to have a systolic-diastolic pressure of (120-80) mmHg. Windkessel parameters are computed so as to depend only on systolic-diastolic pressure and outlets dimensions. Since these values are equal for all the geometries, the same Windkessel parameters are imposed at each simulation [4,5]. In order to prescribe a time-space variant inlet velocity boundary, allowing to reproduce TAV or BAV aortic inlet condition, a specific user-defined function is implemented by considering the physiological data of Cao *et al.* [6]. In particular, an elliptic area is identified on the aortic valve plane, resembling the valve orifice. A paraboloid velocity profile is imposed inside the ellipse, while everywhere else velocity is set equal 0 as follows:

$$v_{in}(t, x, y) = \begin{cases} \frac{2 Q(t)}{\pi a_x a_y} \left(1 - \frac{x^2}{a_x^2} - \frac{y^2}{a_y^2}\right) & \text{if } \left(\frac{x^2}{a_x^2} + \frac{y^2}{a_y^2}\right) \leq 1 \\ 0 & \text{elsewhere} \end{cases} \quad (1)$$

where a_x , a_y are the ellipse semi-axis and x , y are the coordinates in a reference system centered in the center of the ellipse and aligned with its axis. $Q(t)$ is a prescribed volumetric flow rate waveform that resembles a physiological flow over a cardiac cycle (**Figure 1a**). All the simulations run for 7 cycles to achieve periodic fully developed solutions. For the result analysis, only data from the last cycle are considered.

Two different cases for the inlet conditions are here considered: a centered inlet condition ($a_x = 10.75$ mm, $a_y = 8$ mm) that describes a TAV patient and one type of eccentricity ($a_x = 6.7$ mm, $a_y = 5$ mm), reproducing a BAV patient. The corresponding inlet velocity profiles at peak systole are shown in **Figure 1b**. Either TAV or BAV inlet conditions are applied at each stage of aneurysm growth to evaluate hemodynamics evolution.

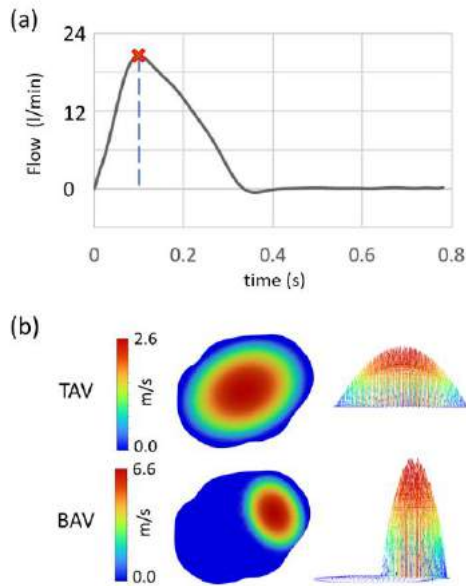

Figure 2: Flow rate profile used in the definition of inlet velocity (a), with highlighted the peak systole instant, with TAV and BAV inlet velocity profiles at peak (b).

RESULTS

Figure 3 shows an example of how the eccentricity of inlet flow and the presence of a bulge due to a growing aneurysm may affect the hemodynamics in the aorta. Observing velocity streamlines at peak systole we can see how the growing aneurysm has a negligible impact on the flow pattern, as A_{00} (**Figure 3a,b**) and A_{05} (**Figure 3c,d**) are compared. On the other hand, the inlet flow eccentricity has a huge impact on both velocity magnitude and flow recirculation. This is consistent with the fact that, having the same flow rate, the maximum velocity at the inlet in the BAV case is 2.5 times higher with respect to the TAV case due to the lower orifice area (**Figure 2b**). When dealing with cardiovascular pathologies, one of the main variables of interest are the Wall Shear Stress (WSS). **Figure 3e-h** shows the effects of eccentricity on the values of WSS in the ascending aorta at peak systole. As an estimation of the effects of eccentricity on WSS, **Table 1** reports the time averaged value of the area-weighted average WSS for the ascending aorta, where the aTAA bulge is observed. Consistently with the velocity increase, average WSS are ~2.5 times higher in presence of eccentricity for both the considered geometries. Both in BAV and TAV case a 7% increase in the average WSS can be observed in the aneurysmatic geometry, compared to baseline.

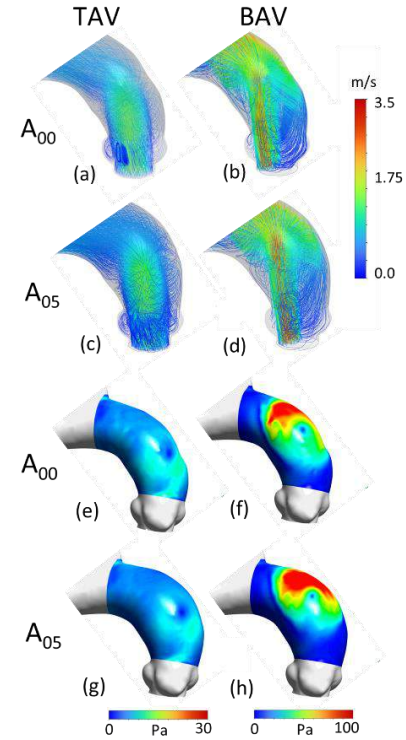

Figure 3: Streamlines of velocity (a-d) and WSS (e-h) at peak systole in the ascending aorta for the TAV (a,c,e,g) and BAV (b,d,f,h) analyzed cases, in A_{00} (a,b/e-f) and A_{05} (c,d/g,h) configurations.

Table 1: Time averaged values of area-weighted average WSS in case of centered (TAV) or eccentric (BAV) inlet flow, for both baseline and aneurysmatic geometries.

	TAV	BAV
A_{00}	2.98 Pa	7.41 Pa
A_{05}	3.18 Pa	7.91 Pa

DISCUSSION

In this study we investigated the effects that an eccentric inlet velocity profile has on aortic hemodynamics. In particular, TAV and BAV configurations have been considered and correspondent inlet conditions have been applied to evaluate hemodynamics in a virtual patient at different stages of aneurysm growth. The jet flow from our eccentricity model is the main responsible for higher velocities and WSS, as a consequence of impingement of the aortic wall, in agreement with previous findings [1,2], thus highlighting the necessity to account for the eccentric inlet flow when modeling aTAA hemodynamics.

INTRODUCTION

A confined enlargement of the aorta that mainly develops below the renal arteries is known as an abdominal aortic aneurysm (AAA). An 80% overall mortality rate makes AAA a socially significant cardiovascular disease. The clinical management of AAAs consists of assessing their maximum diameter using an ultrasound or computed tomography (CT) examination. The accepted thresholds for surgical/endovascular repair in the United States are a maximum diameter of 5.5 cm for men and 5.0 - 5.4 cm for women with a growth rate of 1 cm/year [1]. Furthermore, it is challenging to identify the normal growth pattern because of non-linearity associated with the change in diameter over time. To this end, the maximum diameter-based criterion has been challenged in recent findings [2] and alternative metrics have been proposed to assess the risk of rupture during AAA surveillance. These include growth rate, AAA volume, AAA wall surface area, and tortuosity. Growth rate appears to be an important metric for the clinical management of small-diameter AAAs [2]. In the present work, we estimated 12 geometric measures from longitudinal CT scans of AAA subjects under surveillance and assessed their ability to predict AAA growth rate using an exponential model.

METHODS

CT images in a DICOM format acquired retrospectively from 7 AAA subjects under surveillance were used as input to AAASc (an in-house MATLAB®-based semi-automated segmentation script) to create binary masks. Using the latter as input to AAAMesh (another in-house MATLAB®-based script for meshing), volume meshes were created for each AAA at each imaging follow-up (30,000-90,000 quadratic hexahedral elements). AAASc and AAAMesh validation were previously described in [3] and [4], respectively. Each AAA subject had multiple follow-ups performed during surveillance, which resulted in 23 CT scans obtained from Northwestern Memorial Hospital (Chicago, IL) and Allegheny General Hospital (Pittsburgh, PA) in

accordance with established Institutional Review Board guidelines. Patient consent was unnecessary since the review was retrospective and using existing medical records.

Growth rates

The exponential expression presented in [6] was used to calculate AAA growth rate according to Eqs. (1) and (2),

$$g = (e^{12r} - 1) \times 100 \quad (1)$$

$$r = \frac{1}{t} \ln \frac{X^{followup}}{X^{baseline}} \quad (2)$$

where $X(.)$ is the geometric measure, t is the time interval between consecutive scans in months, r is the logarithmic growth factor, and $g(.)$ is the growth rate of the measure. The Spearman's rho correlation coefficient was used to quantify the strength of the correlation analysis with growth rate, where a coefficient in the range of 1.00–0.90, 0.90–0.75, 0.75–0.50, 0.50–0.25, and 0.25–0.0, corresponds to a very high, high, moderate, weak, and no correlation, respectively [6].

Exponential AAA growth model and growth prediction

All geometric measures were examined to assess their ability for growth prediction using Eq. (3) [5, 6],

$$Y = \alpha \cdot e^{\beta t} \quad (3)$$

where Y is the measure or prediction, α is the mean value of the measure, and β is the mean value of growth rate. The follow-up measure can be

obtained using $T = \frac{\ln \frac{X^{baseline}}{\alpha}}{\beta}$ and $X^{follow-up} = \alpha \cdot e^{\beta(t+T)}$ where T represents how many months have passed since the aneurysm was last surveilled.

Table 1. Geometric measures used to predict growth rate.

V	AAA sac volume (mm ³)
V _{ILT}	Volume of intraluminal thrombus (ILT) contained within the AAA sac (mm ³)

D_{\max}	Maximum transverse diameter of the AAA sac (mm)
DDr	Maximum diameter to neck diameter ratio
S	Vessel surface area (mm ²)
T	Tortuosity
γ	Ratio of AAA ILT volume to AAA sac volume
H	Height of abdominal aorta (mm)
H_{sac}	Height of AAA sac (mm)
L	Centerline length of abdominal aorta (mm)
L_{sac}	Centerline length of AAA sac (mm)
DHr	Diameter-Height ratio; DHr is an expression of the fusiform shape of the AAA sac

RESULTS

As seen in Table 2, very high correlations were obtained for V vs. D_{\max} ($r = 0.97$), γ vs. V_{ILT} ($r = 0.91$), and L vs. S ($r = 0.90$) correlations for non-linear growth rate. V_{ILT} exhibited a high correlation with D_{\max} ($r = 0.89$), but had no correlation with T, H_{sac} , and L_{sac} ($r = 0.04$, $r = 0.11$, $r = 0.08$), respectively. D_{\max} was highly correlated with S ($r = 0.86$) but had no correlation with H_{sac} and L_{sac} . T has weak correlations with all measures except L ($r = 0.41$).

Table 2. Correlations of geometric measures using non-linear growth model.

Measure	V	V_{ILT}	D_{\max}	DDr	S	T	γ
V	1						
V_{ILT}	0.88	1					
D_{\max}	0.97	0.89	1				
DDr	0.65	0.52	0.65	1			
S	0.86	0.75	0.83	0.54	1		
T	0.29	0.04	0.30	0.62	0.44	1	
γ	0.71	0.91	0.73	0.44	0.60	-	1
H	0.37	0.45	0.37	0.14	0.72	0.16	0.40
H_{sac}	0.08	0.11	0.07	0.38	0.05	0.11	0.34
L	0.60	0.57	0.59	0.34	0.90	0.41	0.48
L_{sac}	0.12	0.08	0.10	0.34	0.10	0.22	0.29
DHr	0.71	0.58	0.72	0.48	0.42	0.36	0.39

To identify a growth curve that could predict AAA growth rates, growth curves were calculated using Eq. (3) for D_{\max} and V. Figures 1(a) and 1(b) show the exponential distribution of the growth based on these geometric measures, where the data was normalized with respect to the baseline measure ($t = 0$). The justification for using only these measures to predict growth rate is that the correlation of D_{\max} vs. V exhibited the highest correlation coefficient of all measures correlated. The non-linear growth model shows that both D_{\max} and V lie within one standard deviation of the mean for nearly all 23 data points derived from the serial CT scans.

DISCUSSION

AAA growth rate was estimated using a non-linear model and geometric growth analysis was performed successfully using an exponential function. There is considerable evidence that growth rate plays a significant role in predicting rupture risk in small AAAs. Aneurysm sac volume was postulated to be a useful metric for predicting risk of AAA in earlier investigations [2].

In the present work, we demonstrated the application of an exponential growth curve for maximum diameter and sac volume. For these, $\alpha = 1.08 \pm 0.08713$ for normalized D_{\max} and 1.20 ± 0.226 for normalized volume. Noteworthy is that α was calculated by using the

mean of the maximum diameters for all patients, while β was calculated as the growth rate using the first-order time derivative. Likely due to the relatively small population sample, which had 2-6 follow-up CT scans at 6-month intervals, the non-linear growth rate equation was not a good fit for the exponential model compared to [6]. Our results show a good agreement with the non-linear exponential model described in [5]. The exponential growth model presented herein could be used to make informed predictions of future AAA growth with as little as two CT scans during the surveillance period. Additional serial imaging data with a larger population sample is needed to corroborate the accuracy of the model.

INTRODUCTION

Antibodies (Ab) are a critical component in biotechnology and medicine as molecular recognition tools for diagnostic immunoassays or therapeutic applications [1]. Screening antibodies in relation to specific antigens (Ag) are imperative for an accurate diagnosis of disease and the development of vaccines [2]. The antigen-capturing activity of antibodies depends on the immobilization strategy. The antigen to be captured can be driven either by pressure or electrohydrodynamics. Electrohydrodynamic flows, such as electroosmotic flow (EOF), have advantages in microfluidics as they do not require mechanical pumps operating at higher pressures. Instead, EOF is driven by an external electric field under atmospheric conditions where the flow rate is directly proportional to the applied electric field [3]. In previous studies, we developed a numerical model and experimentally designed and tested a microfluidic device for efficient separation of fluorescence-tagged magnetic microbeads (mMBs) driven by EOF [3,4].

The *objective* of this study is to develop a numerical model of antibody-antigen reaction kinetics in EOF. As the Ag approaches the leading edge of the capture zone (the region in the channel wall (Fig. 1A) where the mMB-Ab complex is immobilized), the antibody-antigen complex (mMB-Ab-Ag) is formed and immobilized (Fig. 1B), as the Ag flows downstream in the microchannel.

METHODS

Following governing equations for EOF were derived based on assumptions by Krishnamoorthy et al. [5] and Comandur et al. [6].

- Conservation of mass: $\nabla \cdot \mathbf{V} = 0$ (1)
- Conservation of momentum: $\rho D\mathbf{V}/Dt = -\nabla p + \mu \nabla^2 \mathbf{V} + \mathbf{f}_e$ (2)
- Coulomb force: $\mathbf{f}_e = \rho_e \mathbf{E}$ (3)
- Poisson's equation: $\nabla^2 \phi = 0$ (4)
- Electric field: $\mathbf{E} = -\nabla \phi$ (5)

where \mathbf{V} represents the fluid velocity, ρ is the fluid density, μ is dynamic viscosity, ϕ is the applied potential, ϵ is the permittivity of fluid, and \mathbf{E} is the applied electric field. The momentum equation (eq. 2) includes the Coulomb force (eq. 3) exerted by the external electric field. The pressure drop term is zero because a constant pressure was maintained at the inlet and outlet of the channel during EOF. Poisson's equation (eq. 4) was then coupled with the momentum equation (eq. 2). The electric field in the channel was solved using Equation 5.

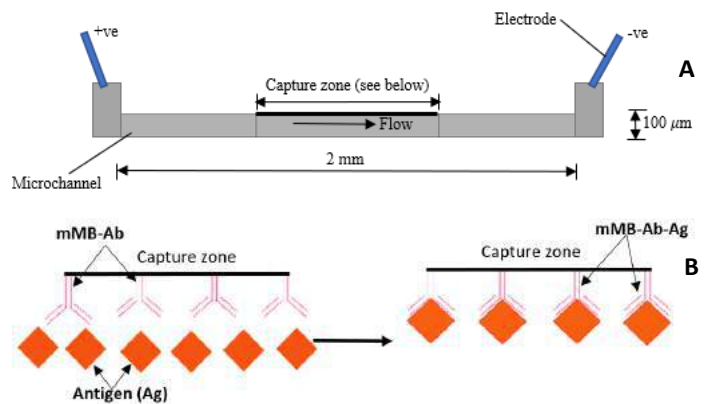

Figure 1: Schematic diagram of A) microchannel with capture zone, B) capture of Ag with immobilized mMB-Ab.

For the chemical reaction at the capture zone, a biomolecular, irreversible reaction (eq. 6) with a forward rate constant, k_f , and a negligible backward rate constant, k_r , was considered. The governing equation of the chemical reaction between the reactants is given in the Equation 7:

$$\frac{DC_i}{Dt} = D_i \frac{\partial^2 C_i}{\partial x^2} \pm k_f C_A C_B, \text{ where } i = A, B, C \quad (7)$$

where D_i and C_i are the diffusion coefficients and species concentration of A, B, and C, respectively. The negative sign corresponds to the depletion of reactants A and B, while the positive sign represents the formation of product C. Samples A and B can be replaced by any Ag and mMB-Ab. The process of anchoring the mMB-Ab molecules to a specified microchannel surface must maintain a balance between the need to reliably attach the mMB-Ab to the surface and keep them in a biologically active molecular conformation with high accessibility for capturing Ag from the solution [7]. Previous study has shown magnetophoretic separation in EOF using a magnetic field generated by a miniaturized magnet, and the capture efficiency of the mMB-Ab was evaluated [3]. In current formulation, the normalized surface density of mMB-Ab was specified at the capture zone of the microchannel, and the Ag was driven by an electric field.

Numerical Formulation. The size of the microchannel is length: 2 mm and height: 100 μm (Fig. 1A). The Ag is injected at the inlet of the channel and approaches the immobilized mMB-Ab at the capture zone (Figs. 1A and 1B). The length of the capture zone is 800 μm . A 2D computational geometry was developed (CFD-GEOM; ESI-CFD Inc., Huntsville, AL). Structured meshing was used with 9528 cells with an aspect ratio of 1.

The boundary conditions for driving the EOF, i.e., zeta potential ($\zeta = -95.6$ mV) and Debye layer thickness ($\lambda_D = 0.1$ μm), were applied to the walls of the microchannel. Based on the experimental data, a normalized surface density of the mMB-Ab at the capture zone is specified along with the concentration of Ag at the inlet. A surface reaction is applied for immobilized mMB-Ab. The surface reaction involves kinetic binding between mMB-Ab (exclusively on the surface quantified by a concentration expressed in moles/ m^2) and Ag in fluid volume (quantified by a concentration in moles/liter). Table 1 lists properties used in calculation.

Table 1: List of properties

Parameter	Value
Fluid density (ρ)	997 kg/ m^3
Dynamic viscosity (μ)	8.6×10^{-4} Pa.s
Relative permittivity (ϵ_r)	78.8
Rate constant (k_f)	10^7 L mol $^{-1}$ s $^{-1}$

RESULTS

Figure 2 shows that the mMB-Ab vs time plot at the leading edge of the capture zone remained the same for the first 0.2s and got depleted as the Ag entered the capture zone. At about 0.5s, the Ag in fluid got fully consumed by the immobilized mMB-Ab at the leading edge. Consequently, mMB-Ab-Ag is formed and remained immobilized at the surface.

Figure 3 shows the depletion with time of the mMB-Ab and mMB-Ab-Ag formation at the midway and trailing edge of the capture zone. The Ag concentration at the capture zone is very low. This is because any Ag that is near the wall reacts immediately with the mMB-Ab on the wall. This results in a near-zero concentration of the Ag at the wall while mMB-Ab still exists sufficiently.

DISCUSSION

A novel method was developed to capture electrohydrodynamics driven Ag by immobilized functional mMB-Ab at the channel surface for microfluidic immunoassays. This study found that the leading edge of the reaction shifts along the capture zone as the Ag reaches the

surface and mMB-Ab is fully consumed. The study suggests that rapid Ag detection can be achieved using this approach. This platform technology can lead to the development of a portable device for the detection of target cells, pathogens, and biomolecules.

Limitation. A capture zone binding surface was defined based on previous study [3], with a specified normalized concentration representing the immobilized mMB-Ab. In other words, Equation 1-7 can be simultaneously solved instead of sequential processing of Equation 1-5, followed by Equation 6-7.

INTRODUCTION

Diagnosing, surgical planning, and research for bone diseases are often performed using the gold-standard imaging technique of X-ray Computed tomography (CT). CT imaging enables high-resolution 3D imaging and reconstruction of bone to visualize and quantify aspects of cortical and trabeculae compartments. The highest resolution CT imaging available requires a long acquisition time, which increases the incidence of motion artifact, radiation dose, and cost. As such, a need exists to develop novel techniques for acquiring high-resolution CT images without compromising the accuracy of bone evaluation.

Deep learning (DL), a subset of artificial intelligence, might provide a computational way to maximize image spatial resolution and overcome CT limitations. DL is capable of generating high-resolution (HR) CT images from standard images that are routinely acquired at lower resolution (LR) [1]. A limited number of studies have demonstrated the feasibility of DL techniques for CT to improve the imaging of trabecular bone clinically [2] and preclinically [3]. However, DL's limitations to resolving smaller morphometric features on the length scale of intracortical porosity remain unknown. Likewise, other model frameworks, such as U-Net [4], could provide increased accuracy in this realm [3] given success in other image-based machine learning tasks. Furthermore, while standard metrics are used to evaluate DL models for image enhancement/quality, namely, structural similarity index (SSIM) and peak-signal-to-noise ratio (PSNR), whether these metrics translate to the conservation of bone morphology, textures, and quantitative metrics across resolutions remains unclear.

Thus, this study aimed to develop a DL model with U-Net framework capable of generating micro-CT (μ -CT) high resolution (HR) images from low resolution (LR) of mouse femurs even within small sample sizes. We hypothesized that DL-generated images would display enhanced image quality and preserve bone morphometry like HR compared to LR.

METHODS

Femurs and μ -CT. 16 femurs from 16 week old Diversity Outbred mice were imaged via μ -CT at 70 kVp and 200 μ A with 3 frame averages to obtain lower (20 μ m voxel) and higher (10 μ m voxel) spatial resolution (1000 and 2000 projections, respectively), while maintaining the same digital registration within a fixed Cartesian reference frame (i.e., x-y-z coordinates). 3D image arrays were converted to DICOM and subsequently into NIFTI format for developing DL model in Python coding language; python packages of Nibabel, Scikit-learn, Scipy, and PyTorch were used. Briefly, NIFTI files were imported and then exported as 2D images from a single imaging plane (traverses the femur entire length; Fig. 1), up-sampled via bilinear interpolation, and then grayscale normalized (max and min of entire training images).

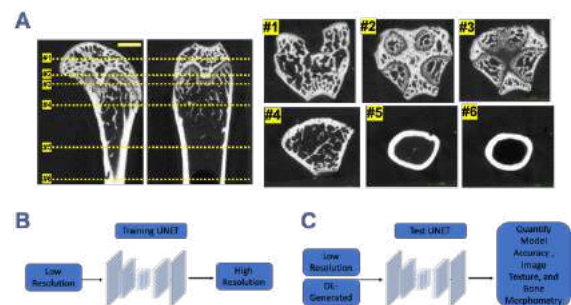

Fig. 1: (A) Example μ -CT images used to develop the DL model, showing the breadth of bone microarchitecture structures through the femur. (B) Schematic of DL training using UNET framework and paired low to high resolution images. (C) Schematic of testing pipeline used to evaluate differences in a trained model accuracies, bone morphometry, and image metrics between low resolution and DL-generated images.

Model Development and Evaluation: A total of 6000 images from 15 femurs (400/femur) were used for training/validation/test process (3375/1125/1500 images, respectively). One femur and the corresponding 2D images (400) were set aside as an external test set. A DL model with a standard U-Net framework was trained for 300 epochs using a 0.001 learning rate, batch size of 5, Adam optimizer, and mean squared error loss function on a GPU (~8hrs; A100-SXM4-40GB; Google Colab Pro). Model accuracy was assessed using PSNR and SSIM. To test the impact of different images (real or predicted) on standard μ CT (morphology) and image metrics (contrast and texture), 2D images from the test set were processed through BoneJ and Texture Analyzer plugins in ImageJ. BoneJ calculated the bone area fraction (i.e., bone area/total area; BA/TA) and thickness. Texture Analyzer calculated the image contrast and entropy.

Statistics. Confidence interval calculations and one-way ANOVA were performed to identify differences in bone and image metrics among groups. Significance was set at $p < 0.05$, and Bland-Altman plots were generated to visualize the differences.

RESULTS

The DL model could enhance the LR toward the HR based on qualitative (Fig. 2A) and quantitative DL metrics (Fig. 2B; test set PSNR mean = 38.4; test set SSIM mean = 0.92). The model could modestly resolve the smallest pores in the cortex and distal growth plate that can be seen in high resolution (Fig. 2A). Qualitatively, the DL-generated image appears to be denoised (Fig. 2A). Quantitatively, DL-generated and LR images have different image contrast and entropy to HR while having comparable BA/TA and thickness (Fig. 2C); except LR has increased thickness. Further, the DL-generated images had reduced confidence intervals for all metrics compared to LR; except DL images, entropy intervals were increased. On the external test, similar findings were seen in the DL-generated images and metrics as an internal test set (not shown); the model had decreased PSNR and SSIM as the images traversed from the cortical midshaft to the femoral head.

intervals = solid lines) highlight the differences in bone and image metrics between LR and HR (LR-HR; blue circles) and between DL generated and HR (DL-HR; red stars).

DISCUSSION

The present study trained a DL model with U-Net framework that successfully enhanced the resolution of μ -CT images of mouse trabecular bone and cortical boundaries and porosities. The DL model transforms an image as acquired via μ -CT at a comparatively low resolution to a virtual “higher” resolution. This study’s DL model, demonstrated with serial images from just 16 femurs, confirms and extends the use of DL techniques for enhancing image resolution in standard laboratory preclinical settings that utilize μ -CT imaging. Our DL model has shown improvement compared to another study that used deep convolution neural network frameworks in mice tibiae scanned via μ -CT (PSNR = 28.6; SSIM = 0.64)[3]. Advances in the current model might be due to differences in model framework, sample sizes, and bone microarchitecture. Similar to previous studies, our DL model was challenged by the smallest porosity in the cortex and spongiosa. Ongoing work aims to improve the DL model’s ability to resolve finer detail/smaller porosities and lacunae by increasing the number and variation of training images. Ultimately, it will be critical to determine the bounds and limitations of DL’s models to reveal features in CT images that are typically considered lost to lower image resolution.

In conclusion, this study demonstrates the initial success of using DL models to enhance standard μ -CT in murine femurs. Translation of these DL approaches to the clinical setting may provide improved image quality without changes in imaging protocol.

HISTOPATHOLOGY OF CAPSULE AND CARTILAGE PREDICT ELBOW BIOMECHANICS VIA MACHINE LEARNING

Michael A. David (1), Spencer P. Lake (2)

INTRODUCTION

Trauma to the elbow can lead to a debilitating disease of post-traumatic joint contracture (PTJC) in the afflicted joint and is associated with a loss of range of motion (ROM) and elbow function.¹⁻⁵ Elbow PTJC, most commonly manifesting as a decreased joint extension, is thought to be largely driven by the fibrotic changes to the anterior joint capsule and degenerate changes to other (e.g., cartilage) tissues.¹⁻⁵ Recent evidence has demonstrated that elbow PTJC is a whole-joint disease involving the anterior and posterior regions of the joint and multiple tissues (e.g., capsule, ligaments, cartilage).¹⁻⁵ Traditionally, histopathology is used to study cellular level details that can give rise to biomechanical changes measured *in vivo* and/or *ex vivo*. Unfortunately, it remains challenging to directly predict biomechanical function using only features observed in histological analysis; such predictive relationships could be used as diagnostic and prognostic biomarkers. Consequently, novel methods are warranted to integrate data from multiple tissues and data sources to establish predictive relations to study and treat elbow PTJC.

Machine learning (ML) is a rapidly evolving technique using computer-derived mathematical models that learn to accomplish tasks and find relationships between and within data. ML algorithms can be used to find predictive relationships between a set of inputs (in this case, histopathology scores) and outputs (i.e., elbow ROM). Recently, SHapley Additive exPlanations (SHAP) values have been used to glean insight into important input parameters that impact the model accuracy. Typically, a limiting factor in ML model development is the amount of data used for training; while oftentimes expensive and time-consuming to obtain, large datasets often yield improved accuracy of model predictions. Uniquely, our group has access to a historical database of histology and biomechanical data from several previous studies that used a preclinical animal model of elbow PTJC. Thus, this study aimed to develop predictive ML models linking histology features to elbow

range of motion, and to identify the most important parameter for predicting features of joint disease.

METHODS

Animals, Biomechanical Testing, and Histopathology: Data for ML model development was derived from prior studies using our group's rat elbow injury model of PTJC, histological scoring, and biomechanical testing (Fig. 1A)¹⁻⁵. Experimental groups included controls (i.e., age-matched uninjured and contralateral limbs) and injured rats with either no treatment, physical therapy (varying degree of immobilization + treadmill), or drug therapy (two dosing strategies of simvastatin or losartan) (Fig. 1B), which were assessed at 42- or 84-days post-injury. For ML model development, the input was histology scoring (e.g., cell counts and tissue thickness), and the output was a post-mortem biomechanical measure of elbow ROM. Our rat injury model leads to varying extents of ROM deficits at different timepoints post-injury and following different interventional treatments (Fig. 1B).

Fig. 1: (A) Schematic of a midsagittal section of the rat elbow used for histopathology scoring. Cellular and tissue evaluation by a pathologist was performed on the capsule and cartilage. Elbow range of motion was determined through *ex vivo* flexion-extension testing. (B) Previous data from our group's PTJC model highlight study groups and breadth of ROM used for model development.

Model Development and Evaluation: To predict elbow ROM, we used paired histological (averaged 3 sections/elbow) and mechanics data to evaluate multiple ML regression algorithms (n=58 elbows; 75/25 train/test ratio): Linear (LR), Support Vector (SV), Decision Tree (DT), Random Forest (RF), K-Nearest Neighbor (KNN), XGBoost (XGB), and one-dimensional Convolutional Neural Network (CNN). Model accuracy was assessed using R^2 values, absolute error, mean squared error, and root-mean-squared error. All model development was performed in Python coding language hosted on Google Colab; python packages of Scikit-learn and Scipy were used. SHAP values were used to identify key input parameters important for model accuracy. Pearson correlation analysis was used to evaluate correlations between input parameters and elbow ROM.

RESULTS

Correlation analysis revealed both negative and positive correlations between histology scores and elbow joint mechanics (Fig. 2). Overall, ML models were able to predict the elbow ROM from histological scores but with moderate accuracy (Fig 3A and B). Notably, RF and XGBoost consistently outperformed other models as assessed by all model metrics, albeit Linear and Support Vector models were also accurate. Absolute SHAP values identified a range of important histological parameters for predicting elbow range of motion (Fig 3C); the posterior capsule appeared to be consistently identified by all models as important.

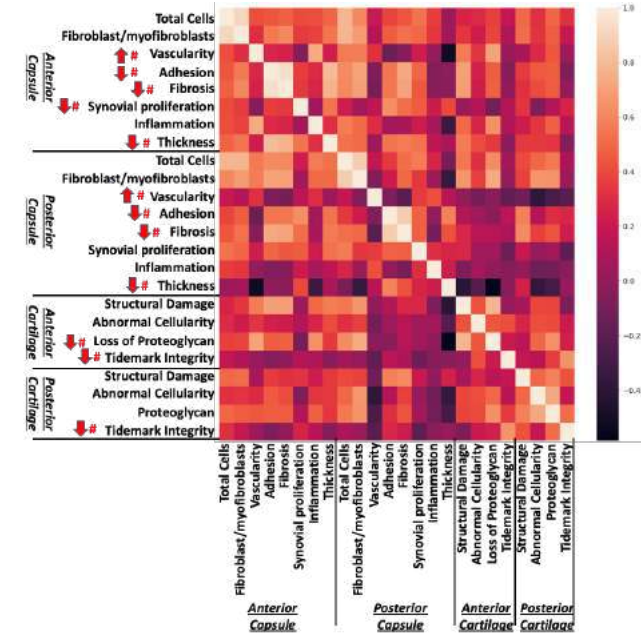

Fig. 2: Heatmap of Pearson correlation R^2 values for histological metrics; data that significantly correlated with elbow ROM shown as either negatively or positively correlated (arrows).

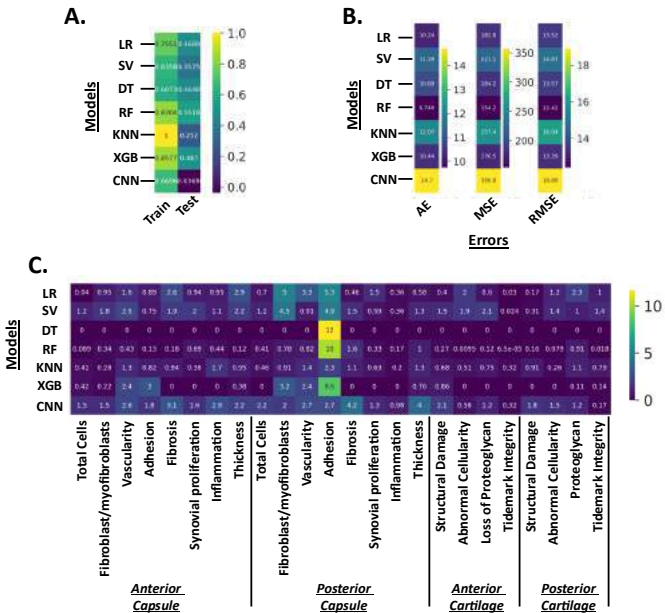

Fig. 3: (A) Heatmap highlighting R^2 values for train and test sets for each model. (B) Heatmap of model absolute error (AE), mean squared error (MSE), and root mean squared error (RMSE). (C) Heatmap of absolute SHAP values highlights the importance of different histological metrics in predicting elbow ROM.

DISCUSSION

This study demonstrated that ML models could predict elbow ROM from histopathology scoring of the capsule and cartilage with moderate accuracy. Each ML model performed to different accuracies, but Random Forest and XGBoost yielded the most accurate models (R^2 of ~0.47). Importantly, SHAP values gave insight into which histology parameter was key for the model. Interestingly, the posterior capsule was the most important tissue for prediction, particularly for thickness, adhesions, and fibroblasts/myofibroblasts. While these key parameters have been identified through previous preclinical and clinical studies, the larger impact of the posterior capsule over the anterior capsule is intriguing and requires further interrogation. ML models agnostically confirmed our intuition of elbow PTJC biology (i.e., important role of capsule tissue) while synthesizing vast information.

While the results of this first study to develop predictive ML models in the context of elbow PTJC are exciting, there is room for model improvements and next steps. For example, increasing the sample size to test the robustness of our model would be a critical step. We have access to additional paired elbows in our historical database; ongoing/future studies will enable even further increase in sample sizes. In addition, including more histological features and other evaluation metrics that are currently under development in our group (e.g., magnetic resonance imaging and computed tomography) might yield insights about novel relationships between multi-modal data.

In conclusion, ML models predicted elbow ROM from histopathology scoring of soft tissues. Ultimately, improving and expanding the use of ML for studying elbow PTJC might yield clinically relevant predictive relationships and lead to novel therapeutic strategies.

A TESTABLE MECHANISM FOR FORCE GENERATION AND MAINTENANCE IN THE TONIC SMOOTH MUSCLE

Suzanne E. Stasiak (1), Dhanajay T. Tambe (2), Hari Krishnan Parameswaran (1)

INTRODUCTION

Tonic smooth muscle (SM) regulates a wide range of vital body functions ranging from breathing, blood flow, vision, and reproductive functions, among others. Yet, despite its overwhelming importance in human health, the mechanisms that underlie force generation and maintenance in the SM remain poorly understood. Tonic SM can generate and maintain the force for durations over an hour. This force maintenance ability is currently attributed to a hypothetical state in the actin-myosin cycle of the SM, called the "latch phase," where myosin dephosphorylates but remains bound to actin^{1,2}. In the past 40 years, no study has been able to show experimental evidence that the latch state exists in the SM. Yet, this unproven concept is currently used to understand and interpret physiological data in diseases of the SM and taught in textbooks as *the* mechanism for force maintenance in SM. Here, we hypothesize that force generation and maintenance in the SM emerges as a result of a force-based mechanism where each cell in a confluent ensemble of SM cells use their contractile force to trigger Ca^{2+} release and force generation in other SM cells.

METHODS:

We measured cytosolic Ca^{2+} oscillations and force generated by human bronchial smooth muscle cells. Human bronchial smooth muscle cells were used for all experiments in this abstract. SM cells were serum starved for at least 24hrs prior to measurements.

RESULTS

Confluent SM cells build networks of cell-cell interactions as they constrict: Exposure to a contractile stimulus evokes cytosolic Ca^{2+} oscillations in the smooth muscle³. The period of these oscillations encodes the strength of the applied stimulus. Increasing dose of contractile stimulus leads to faster oscillations^{3,4}. Conversely, exposure to a muscle relaxant leads to reduction in oscillation frequency⁵. In a

recent study, we found that the Ca^{2+} oscillations in a connected ensemble of SMCs synchronize over a period of ~1 minute⁶. The time course of establishing synchrony in Ca^{2+} oscillations also corresponds to the time taken by the SM to generate steady state force⁷. Our analysis of Ca^{2+} oscillations in confluent ensembles showed that SMCs build dynamic networks of cell-cell interactions as they constrict (**Fig.2**). Isolated SM cells do not form such networks and isolated SM cells do not synchronize their Ca^{2+} oscillations⁶

Figure 1 SM cells build dynamic cell-cell interaction networks as they constrict. The number of interacting cell-pairs increase and reach a maximum of 55% of max possible cell pairs. Isolated cells do not synchronize their Ca^{2+} oscillations

Cell-cell interactions persist in the force maintenance phase:

To test whether cell-cell interactions play a role in the force maintenance phase of the SM contraction, we used monolayer stress traction microscopy⁹ to measure the *contractile moment* (M_{ii}) of each cell in a confluent ensemble of SM cells arranged in 300mmx100mm rectangular pattern. M_{ii} is a scalar quantity which indicates the strength of the contractile dipole of an SMC¹⁰. Measurements were made every 30 seconds for a period of 15 minutes. The time traces of M_{ii} for each cell in the ensemble is shown in **Fig.2A**. All cells in the connected ensemble contract in response to 10 μM histamine and the force generated by the cell reaches its maximum at ~1 min and levels off as

the cell enters the force maintenance phase. We *hypothesized* that If each SMC in the ensemble was maintaining tension independent of other cells through the “latch” or similar intracellular mechanisms^{1,11}, *fluctuations* around the steady state value of M_{ii} during the force maintenance phase ($t=5$ mins to 15 mins) should be uncorrelated, random noise. To test this hypothesis, we fit a polynomial curve to each M_{ii} trace to find the mean trend and isolated fluctuations in M_{ii} for each cell. The cross-correlation matrix is shown in **Fig. 2B** We find that fluctuations in contractility of SMCs in a confluent ensemble are strongly correlated, indicating that the SMCs are interacting with each other in the force maintenance phase.

Figure 2 (A) We examined the fluctuations in force in a confluent, ensemble of SM cells during the force maintenance phase of the contraction ($t=5$ mins to 15 mins). (B) We found that the fluctuations in force for individual cells in the ensemble are strongly correlated with each other. This shows that in a connected ensemble of SM cells, the cells are not maintaining tension independent of each other, using mechanisms that are intrinsic to each cell. Rather, the cells are interacting with each other during the force maintenance phase of the constriction.

SM cells can use their force to trigger force generation in other SM cells: One of the first steps in the chain of reactions that lead to force generation in the SM cell is the hydrolysis of membrane bound PIP2 to form IP3 and DAG. Here, we show that PIP2 can be hydrolyzed by a shear stress consistent in magnitude with stress exerted by a SM cell.

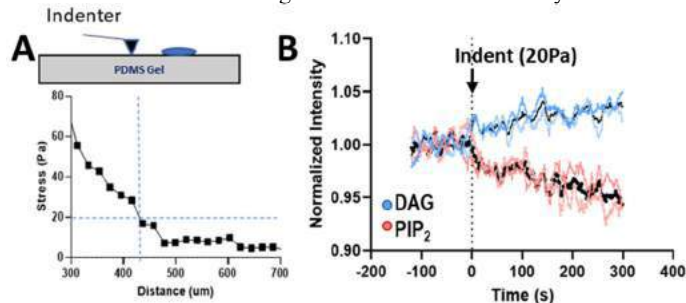

Figure 3: (A) We used an indenter to create a strain field on the collagen coated substrate. The indenter was positioned to apply ~20 Pa shear stress to an isolated SM cell. (B) The mechanical signal leads to an increase in DAG (blue) and a decrease in PIP2 (red). The black lines are average over $N=2$ trials. This data shows that PIP2 hydrolysis can be triggered by stress transfer from cell to cell.

We have confirmed that that the same applied stress leads to Calcium release and force generation in smooth muscle. We have also tested potential confounding effects of stretch activated Ca^{2+} channels by blocking their activity using Gadolinium. We found that that the stress-induced hydrolysis of PIP2 operates independently of stretch activated Ca^{2+} channels.(data not shown due to space constraints)

Mechanical signaling between SM may be sufficient for force maintenance in the tonic SM

Figure 4: During the force maintenance phase of an SM contraction, we calculated the conditional probability for the following sequence of events to be triggered in an SM cell: (1) Contractility of a cell decreases (2) PIP2 hydrolysis (Fig3) is triggered in that cell (3) The contractility of that cell increases. Measurements were made in 21 cells in a confluent ensemble. Overall, the probability that our proposed mechanism was triggered in SM cells in the force maintenance phase was 0.89 ± 0.17

Taken together, the results we present here indicate that force maintenance in the tonic Smooth muscle is an emergent phenomenon driven by mechanical interactions between SM cells. Further testing using inhibitory compounds is underway.

DISCUSSION:

Dysfunction in the smooth muscle including asthma and hypertension affect over 20% of the world’s population. In the US alone, the cost burden of these diseases exceeds \$200 billion dollars annually. Despite their overwhelming importance to human health, the mechanisms by which SM generated force and maintains it are not well understood. The current dogma holds that force generation in the SM is regulated solely by intracellular molecular mechanisms. In contrast, we propose that force generation and maintenance in the SM is a emergent phenomenon where SM cells use their force to regulate cytosolic Ca^{2+} oscillations and force in other SM cells.

INTRODUCTION

Three-dimensional echocardiography (3D ECHO) and magnetic resonance (MR) imaging are frequently used to evaluate heart functions in clinic. Magnetic resonance images have higher spatial resolution and are widely regarded as the gold standard for cardiac imaging. Conversely, while of 3D ECHO images as a lower spatial resolution than MR images [1], it is easier and cheaper to acquire. Many studies have used inverse finite element (FE) modeling with either 3D ECHO or MR images to estimate the contractile stress of the heart and quantify left ventricular (LV) function. A recent study has found that (LV) geometrical quantities such as, volume and ejection fraction estimated by these two imaging modalities are different [2]. It remains, however, unclear whether the contractile stress (contractility) estimated from inverse FE modeling based on these two imaging modalities are different. To address this issue, we develop an inverse FE modeling framework based on animal-specific LV geometries and volumes from 3D ECHO and MR images acquired from the same normal swine model to investigate if there are differences in LV function estimated based on these two imaging modalities. Specifically, we seek to determine whether there is a correlation of the contractility estimated based on 3D ECHO with those estimated from MR images.

METHODS

All experiment data were collected following the national and local ethical guidelines. Both MR and 3D ECHO images were acquired from seven normal swine model using a Siemens MR images scanner (Malvern, PA) and an iE33 ultrasound system (Philips, Andover, MA) with an X3-1 transthoracic transducer, respectively. Two-dimensional (2D) and 3D ECHO images were acquired with the animal placed in the supine position. The LV endocardial and epicardial surfaces were segmented from the MR and 3D ECHO images associated with the end-diastolic (ED) time point using MeVisLab (MeVis Medical Solutions AG) (**Fig. 1A**) and TomTec Imaging Systems GmbH (Philips Healthcare, Andover, MA) (**Fig. 1B**), respectively. The LV volume waveform in each case was obtained by calculating the volume of endocardial surfaces at all time points in a cardiac cycle. The 3D LV wall volume was reconstructed from the endocardial and epicardial surfaces (**Fig. 1C**) and meshed using tetrahedral elements. Myofiber orientation was prescribed to be helical with a transmural linear variation starting from a helix angle of 60 degrees at the endocardium to -60 degrees at the epicardium (**Fig. 1D**).

The computational framework consisting of a FE LV model is developed where the functional relationship between pressures and volumes is obtained by minimizing a Lagrangian function consisting of LV cardiac wall tissue potential energy function and terms associated with the enforcement of constraints on **1**) fixed end on the base, **2**) Robin-type boundary condition on the epicardial surface, and **3**) cavity volume. Total stress of the myocardium is decomposed into an active and passive component. Passive and active mechanical behaviors of the LV are described by Fung-type strain energy function and a modified time-varying elastance model, respectively. Active contractile stress P_a is determined from the second Piola-Kirchhoff stress tensor that is defined by the myofiber direction.

Figure 1: (A) MR images; (B) 3D ECHO of LV; (C) endocardial and epicardial surfaces of the LV segmented from 3D ECHO image; (D) myofiber direction prescribed for inverse FE modeling.

The LV geometry (based on ED) was unloaded with backward displacement method. Passive parameters are then manually adjusted to match the pressure and volume measured at ED point. In the inverse FE modeling framework, the regional contractile stress is optimized until the model predicted pressure-volume loop (PV loop) match with the experimental measurements. Since LV pressure cannot be acquired from imaging techniques, the same LV pressure waveform from a healthy swine is used in all cases. All computational frameworks are implemented using the freely available open-source library FEniCS. Optimization in the FEniCS-adjoint uses inverse FE framework to minimize the difference between simulation and experimental measurements [3].

RESULTS

Fig. 2 shows a comparison of the regional wall thickness, PV loops, regional, global contractility and active tension estimated from 3D ECHO and MR images. Myocardial wall is thicker in basal area whereas thinner in apex in both 3D ECHO and MR images (**Fig. 2A**). The largest difference in wall thickness estimated from 3D ECHO and MR images is located at the apical lateral (#16). The model predicted PV loops from inverse FE modeling show good agreement with the respective experimental measurements from 3D ECHO and MR images (**Fig. 2B**). The percentage difference between measurement and simulation data is less than 10% for volume and pressure in all cases. Mean regional contractility in each AHA region over 7 cases (**Fig. 2C**) was larger based on MR images than that based on 3D ECHO. The peak value of regional contractility (**Fig. 2C**) and time to peak contractility (**Fig. 2D**) are consistent between 3D ECHO and MR images in basal (#1-6) and apical regions (#13-16). Region 9 has the largest difference over 16 regions in both contractility (37%) and time to peak contractility (25%). Maximum contractility estimated from 3D ECHO images (279 mmHg) is larger than that estimated from MR images (227 mmHg) (**Fig. 2E**). The comparison of active tension waveform (**Fig. 2F**) is consistent with maximum contractility, which is 265 mmHg in 3D ECHO and 215 mmHg in MR image. LVEDV and LVESV estimated from 3D ECHO are positively correlated to those estimated from MR images with 0.327 and 0.315 for their gradients, respectively (**Fig. 2G**). The R-value for EDV and ESV are 0.731 and 0.453, respectively, which means EDV has strong positive linear association and ESV has small positive linear association. Correlation expresses a positive linear relation of active tension between 3D ECHO and MR images with a gradient 0.474 (**Fig. 2H**), showing higher active tension based on the geometry and volume from 3D ECHO than MR images in the same animal. Contractility shows a strong positive linear association with R-value is 0.843. **Fig. 2 G-H** shows positive gradients for regional distribution of wall thickness and active tension between 3D ECHO and MR images in LV. The difference in volume segmented from two imaging techniques does not affect the model predicted contractile function.

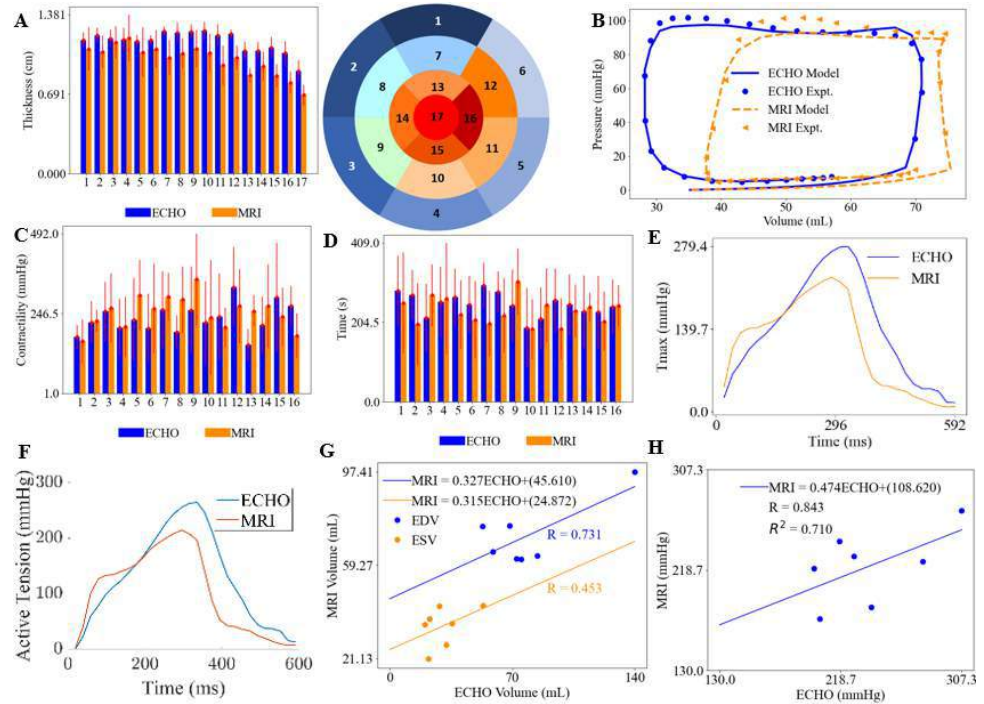

Figure 2: Comparison of (A) regional wall thickness of the LV and AHA Segments for each region; (B) Model predicted and experimentally measured PV loops; (C) regional maximal contractility and (D) time to peak contractility; (E) global contractility and (F) active tension estimated from 3D ECHO and MR images. Correlation of (G) end-diastolic volume (EDV) and end-systolic volume (ESV) and (H) contractility estimated from 3D ECHO and MR images.

DISCUSSION

In this project, an animal-specific inverse FE modeling framework was developed to estimate myocardial contractility in the LV based on 3D ECHO and MR images. To understand the relationship between 3D ECHO and MR images, the regional distribution of wall thickness segmented from images, LVEDV, LVESV, regional and global contractility and active tension predicted from inverse FE modeling were compared. The key findings from this study are as follows. **First**, ESV and EDV estimated from 3D ECHO are larger than that estimated from MR images with a positive correlation gradient 0.315 and 0.327. **Second**, global contractility and active tension estimated based on 3D ECHO is slightly larger than those estimated from MR images with a linear correlation gradient 0.474. The peak of regional contractility is comparable based on 3D and MR images. These findings shows that there is correlation in volumes based on the geometries segmented from 3D ECHO and MR images, and model predicted LV contractility is comparable based on 3D ECHO and MR images. There are some limitations in this work 1) the pressure measurements are not animal-specific, 2) the myocardial strain of the LV is not considered in the model.

BIOMECHANICAL FOLLOW-UP AND EVALUATION OF ANEURYSM GROWTH

F. A.M. Garbou, O. O. M. Elnamla, W. A.K.A. Saber, K. B. Kose (1),

INTRODUCTION

Cardiovascular diseases have the highest mortality and morbidity rates. Each year, cardiovascular disease (CVD) is estimated to be the cause of 32% of all deaths worldwide[1]. During blood flow in the circulatory system, the vessel wall is constantly exposed to mechanical forces and can play a role in the development of pathologies if the arterial endothelium morphology is abnormal. In an aortic artery with an aneurysm, these changes may result in a rupture of the endothelium. An accurate pre and post-operative risk of an abdominal aortic aneurysm rupture is an important guide for planning aortic aneurysm repair surgery. Clinical studies have determined the risk with maximum aneurysmatic diameter based on medical imaging technologies. [2] However, it is known that the risk is not necessarily reflected by the maximum diameter alone [3]. Therefore, additional information is required for accurate risk assessment of an aneurysm before and after surgical repair. This study was designed to numerically evaluate the remodeling in aortic aneurysm morphologies and underlying mechanical factors. This study compared the relationship between the changes in aneurysm morphology and hemodynamic parameters in patients who were scanned at regular intervals. In flow visualizations based on virtual aortic models obtained from computed tomography datasets of three different scans, it was determined that the endothelial segments with distinctive changes in wall shear stress distribution showed high consistency with the morphological change segments seen in the next periodic scans of the same patients.

METHODS

Five patients diagnosed with thoracic aortic aneurysms and aged between 70-75 were included in the study. Virtual aorta models were created from the CT images of the patients taken at

three-month intervals (Figure 1). Three-dimensional (3D) models were created with VTK algorithms and a model mesh for finite element analysis was created with Simmetrix libraries. Blood flow was simulated by computational fluid dynamics analysis and visualized in Ceetron Analyzer Cloud [4]-[6].

In this study, we focused on WSS visualization, a parameter that cannot be measured in the clinical setting but can be calculated by multi-physics algorithms. Blood was considered Newtonian fluid and boundary conditions were established from case-specific data obtained from the clinic [7]. The initial velocity gradient was obtained from the Doppler ultrasound reports of the patients.

Figure 1: 3D models of the aorta segmented from CT data obtained at regular intervals of the selected patient.

RESULTS

Numeric

Figure 2: The WSS distribution on the first scan of Patient A.

DISCUSSION

After this preliminary study, it has been observed that the most obvious effect of WSS on the change of endothelium morphology starts from the segments where dramatic decreases in WSS distribution are seen. The numerical analysis results were obtained in line with our hypothesis that shape change rates that may be encountered in the next scan could be predicted. This work was able to present significant findings on the evaluation of studies on aneurysm growth with in-silico methods and it is possible to strengthen it with more scan datasets.

NUMERICAL AND COMPUTATIONAL ANALYSIS OF ARTERY STRESSES CONSIDERING ACTIVE CONTRACTILITY

N. Goulbourne, Y. Li

Aerospace Engineering, University of Michigan, Ann Arbor, MI, USA

INTRODUCTION

Balloon angioplasty with stent deployment is an effective invasive therapy to treat atherosclerotic arteries. Vascular injury during balloon angioplasty with stent deployment is hypothesized to be the trigger of neointimal hyperplasia and phenotype change and migration of smooth muscle cells, which can lead to the subsequent restenosis of stented arteries. There are numerous research efforts focused on the optimization of balloon and stent design in an effort to reduce artery wall trauma, where the artery is treated as a passive material. Computational simulations have evolved as an attractive tool to study the mechanical performance of the artery, balloon, stent, and atherosclerotic lesion rupture over the last decade. Holzapfel et al. developed nonlinear strain-energy functions for characterizing the biomechanical response of arterial tissues and plaque during normal physiological loading and for simulating balloon and stent procedures [1,2]. Buffinton et al., Gastaldi et al., and Conway et al. studied the effects of plaque material, geometry, and stenting approach for artery bifurcation during stent angioplasty [3-5]. Other researchers have focused on the influence of the balloon configuration on the deployment of the stent and resulting wall response. There have also been numerical model results reported for fissuring, rupture, and dissection of the plaque and artery during the balloon angioplasty procedure. In all of these studies, the artery is modeled as a passive hyperelastic material and smooth muscle contractility is neglected. In the current work, we investigate the impact of this assumption on calculating artery and plaque wall stresses due to overstretch loadings.

We present a new coupled chemo-mechanical model to describe the active viscoelastic response of smooth muscle rich tissue in the arterial walls (media layer). The constitutive model is used in a thick walled arterial model to investigate the effects of smooth muscle contraction on artery stresses and quantify the role of active viscoelasticity in the mechanical response. Though previous simulations have shown that viscoelastic effects are minimally

important in the normal pulsatile response of healthy arteries for timescales on the order of a few seconds, our results show that the active viscoelastic behavior has a non-negligible effect on artery wall stress when longer timescale are considered. The current work focuses on the artery being overstretched on longer timescales for example during interventional surgical events.

METHODS

To model the mechanical performance of the artery wall being overstretched during events with time scales on the order of minutes we employ a two-layer thick wall model for the artery (the intima layer is assumed structurally negligible) and a three-layer thick wall model for the artery-plaque complex. The media layer consists of densely packed smooth muscle cells and the adventitia is collagen rich. Based on these characteristics, both layers of the artery are treated as incompressible and anisotropic; the plaque is considered isotropic. A comparison of the artery wall and plaque stresses for both active and passive materials was analyzed. Supra-physiological internal pressures and imposed diameter changes are prescribed as mathematical inputs to the model. Neither interventional tools such as catheters, balloons, nor stent deformation are modeled explicitly.

Accurate simulations of artery wall stresses are a valuable tool in designing medical devices and providing guidelines for surgical interventions. Reference [6] found that normal calcium oscillation of smooth muscle cells hardly affect artery mechanical behavior (3D cylinder simulations on an axisymmetric ring) for normal blood pressure cycles (period of one second). Medical and surgical interventions, however, are on longer timescales where the material viscoelastic response may be non-negligible and worth detailed consideration. The time of balloon inflation in balloon angioplasty procedures is from around half a minute to over one minute, which is on the same timescale as smooth muscle viscoelasticity.

The media layer model considers the active viscoelastic properties of the smooth muscle tissue. The adventitia is modeled as an anisotropic layer using an existing exponential form and an isotropic symmetric plaque layer is incorporated using Yeoh's model. Three types of plaques for various degrees of artery stenosis are considered in this work. The surrounding tissue is modeled as an outer pressure for a constant calcium concentration in the smooth muscle cells. The model material parameters are calibrated for swine common carotid artery. The wall and plaque stress distributions and corresponding deformations are calculated for healthy and diseased arteries for imposed displacements and tractions. The current findings are based on a ring model, so it is expected that further refinement of the results will occur for full 3D cylinder simulations – an aspect of future work.

The new strain energy function for the media layer is

$$\Psi_m = \frac{\mu_p}{2}(I_1 - 1) + \frac{k_1}{2k_2} \left(\exp(k_2(I_f - 1)^2) - 1 \right) + O_{imp}(AMP + AM) \frac{\mu_f}{4} \left(\frac{I_f}{I_f^v} - 1 \right)^2 \quad (1)$$

The strain energy function for the adventitia layer takes the following exponential form to describe the fiber reinforced anisotropic material

$$\Psi_a = \frac{\mu_{pa}}{2}(I_1 - 1) + \sum_{i=4,6} \frac{k_{a1}}{2k_{a2}} \left(\exp(k_{a2}(I_i - 1)^2) - 1 \right) \quad (2)$$

where μ_{pa} , k_{a1} , are modulus like material constants for the matrix and fiber, respectively, k_{a2} is a material constant for the fiber. Plaque is treated as an isotropic material and takes the form of the Yeoh model ($n=3$ in the current work)

$$\Psi_p = \sum_{i=1}^n C_{i0} (I_1 - 1)^i \quad (3)$$

where C_{i0} are material coefficients. The second Piola-Kirchhoff stresses for the media, adventitia, and plaque layers are obtained by taking appropriate derivatives of the strain energy density function in Eqs.1-3. We obtain the following expressions for the stress

$$\begin{aligned} \mathbf{S}_m &= \mu_p \mathbf{I} + \left[2k_1 \left(\exp(k_2(I_f - 1)^2) \right) (I_f - 1) + O_{imp}(AMP + AM) \mu_f \left(\frac{I_f}{I_f^v} - 1 \right) \right] \mathbf{M} \\ \mathbf{S}_a &= \mu_{pa} \mathbf{I} + 2k_{a1} \sum_{i=4,6} \left(\exp(k_{a2}(I_i - 1)^2) (I_i - 1) \right) \mathbf{M}_i \\ \mathbf{S}_p &= [2C_{10} + 4C_{20}(I_1 - 3) + 6C_{30}(I_1 - 3)^2] \mathbf{I} \end{aligned} \quad (4)$$

The parameters for the media layer are calibrated from isometric and isotonic tests. Parameters for the adventitia layer are for swine carotid artery and properties for the plaque are taken for human carotid artery (i.e. in the absence of experimental data for swine carotid artery plaque).

RESULTS

We calculate the stress distributions of the plaque-artery as functions of the normalized thickness and time for cellular (soft), hypocellular (mixed), and calcified (hard) types of plaque for the low activation level with a calcium concentration of 120 nM. Ramped displacement protocols are applied from $t_1 - t_2$, and the displacement held fixed from $t_2 - t_3$. Figure 1 shows the stress distributions for a stenosis ratio of 40% with and without considering active viscoelastic properties of smooth muscles (cellular plaque case). For the active case, the radial stresses increase to the peak values from $t_1 - t_2$ and then eventually go to the new steady state at t_3 , whilst the circumferential stress increases from $t_1 - t_2$, and continually increase $t_2 - t_3$, reaching a maximum at t_3 . For the passive case, stresses increase from $t_1 - t_2$ and are unchanged afterwards. The results show that active contractility of the media influences the mechanical responses of the plaque during artery overstretch.

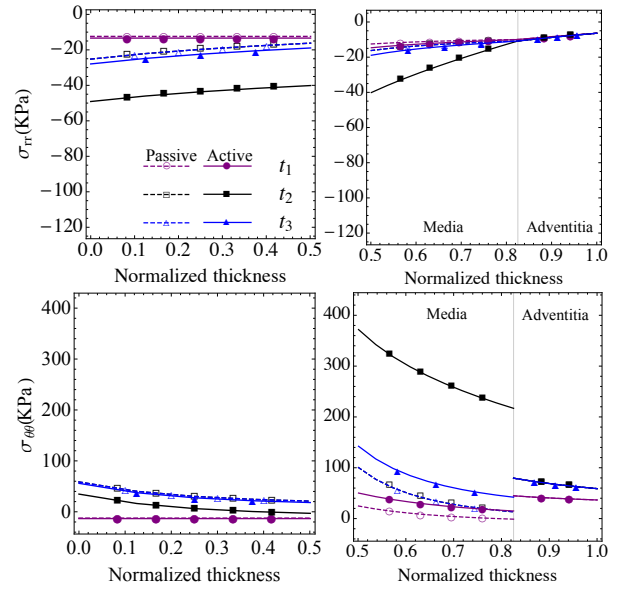

Figure 1. Stress distributions in the artery-plaque composite as a function of the normalized thickness. Active properties are denoted by the solid curves and passive properties given by the dashed curves (the legend applies for plots in the same row).

DISCUSSION

The results show that the magnitude of the stresses increases with plaque stiffness and for softer plaques there is greater cross-over viscous effects due to the interface coupling with the active viscoelastic media. When considering active viscoelasticity of smooth muscle tissue during artery overstretch, larger compression values in the plaque are predicted, which means that viscous effects are in fact non-negligible relative to the passive case.

INTRODUCTION

Hypoplastic left heart syndrome (HLHS) is a complex congenital heart defect in which the aorta and the left heart is underdeveloped, limiting systemic circulation. HLHS can be fatal if left untreated [1]. In children with severe HLHS, treatment involves multi-stage surgical palliation of the heart. The stage I, also known as the Norwood procedure, is performed during the neonatal period and consists of complex aortic reconstruction and incorporating the pulmonary artery (PA) augmentation with a surgical patch [2].

Despite significant improvements in surgical techniques, Norwood surgery remains a high-risk procedure [3]. A key factor is the sub-optimal reconstruction of the neo-aortic geometry and resultant disturbed hemodynamics that may play a factor in post-surgical complications (e.g., neo-aortic arch obstruction or aneurysm).

The goal of this study was to characterize the neo-aortic hemodynamics in patients who had undergone stage I Norwood palliation. Specifically, we focused on four representative patients with a range of neo-aortic arch geometries and used computational fluid dynamics (CFD) to evaluate abnormal hemodynamics in the neo-aorta.

METHODS

Clinical Data: MRI scans of four patients were acquired from an existing database at the Hospital for Sick Children who had previously undergone stage I and II procedures (see Table 1). Along with MRI, all patients received phase-contrast MRI (PC-MRI) at the ascending aorta, which was used to obtain inflow waveform for CFD simulations.

Table 1: Clinical characteristics of patients

	Patient 1	Patient 2	Patient 3	Patient 4
BSA (m ²)	0.57	0.50	0.59	0.53
HR (bpm)	81	104	116	103
Q _{inflow} (mL/s)	56	39	32	34

BSA=Body Surface Area; HR=Heart Rate; Q_{inflow}=Inlet flow rate.

CFD Simulations: The open-source SimVascular software package was used to reconstruct 3D aortic model from MRI, which were meshed into ~4 million tetrahedral elements with three boundary layers. Inflow rate at the neo-aorta was assigned based on PC-MRI derived flow waveforms. Flow through each outlet was characterized by the three-element Windkessel model with parameters adjusted through an automated approach to match the flow divisions determined by Murray's Law. CFD simulations were performed with 10,000 timesteps/cardiac cycle, run for 4 cycles to wash out initial transients.

Geometric Analysis: *Vascular Modeling Toolkit* (vmtk.org) was used to compute a range of geometric parameters, such as torsion, curvature, and diameter along the length of the aorta. Diameter was normalized to the inlet diameter to allow for inter-patient comparisons. All subsequent analyses are based on normalized diameter. Linear regression was performed for diameter vs. distance data to determine the line of best fit to the data.

Hemodynamic Analysis: CFD simulations were post-processed to compute three hemodynamic parameters: wall shear stresses (WSS), oscillatory shear index (OSI), and spectral power index (SPI). While the former two are standard hemodynamic parameters, SPI is a recently-proposed parameter that quantifies the extent of "turbulence-like" (high-frequency blood flow instabilities) in cardiovascular flows using a frequency-based approach [4]:

$$SPI = \frac{\sum_{n=n_c}^{+\infty} |Y[n\omega_0]|^2}{\sum_{n=1}^{+\infty} |Y[n\omega_0]|^2} \quad (1)$$

where $|Y[n\omega_0]|$ represents the Fourier transform of the velocity signal, ω_0 is the angular frequency of the signal, and n_c is the cut-off frequency. The cut-off frequency was set to 25Hz [4].

RESULTS

Hemodynamic Analysis: Figure 1 shows SPI maps that highlight regions of turbulent-like disturbances in the neo-aorta. Patient 3 and 4

had notably higher SPI in aortic arch and descending aorta compared to Patient 1 and 2. The velocity signals (see Figure 1 inset) taken from the descending aorta also show high-frequency flow instabilities likely induced by abnormal aortic arch geometry upstream.

Figure 1: Spectral Power Index (SPI) volume rendered maps showing regions of high-frequency disturbances. The inset shows velocity signal in descending aorta marked with X and a yellow circle.

Geometric Analysis: Figure 2A shows normalized diameter along the length of the aorta, and a best fit line from ascending aorta to mid-descending aorta (corresponds to X in Figure 2). Patient 1 had very high correlation coefficient, which indicates a smooth transition from ascending to descending aorta. Patient 2 and 3 showed mild deviation while Patient 4 had the highest deviation from the linear line. Figure 2B shows maximum diameter deviation from the linear fit line.

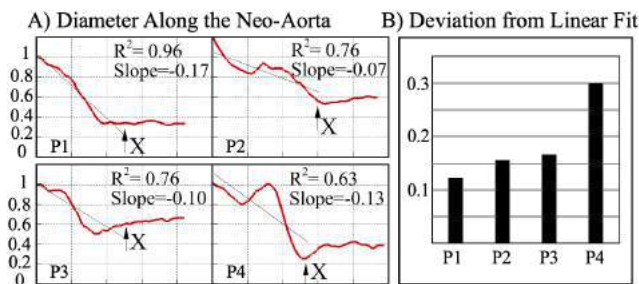

Figure 2: A) Normalized diameter along the length of the aorta and the line of best fit. B) Maximum relative diameter deviation from the linear fit line.

There was a high correlation between normalized maximum diameter deviation and SPI ($R^2=0.98$, Figure 3). No correlation was found between other hemodynamic parameters (i.e., WSS and OSI) and maximum diameter deviation.

Figure 3: Correlation between maximum relative diameter deviation and spectral power index (SPI).

DISCUSSION

Inefficient aorto-ventricular interactions are recognized factors in heart failure in HLHS children post-surgery. In this study, we have demonstrated that sub-optimal aortic arch geometry is associated with turbulent-like flows that are hallmark of various vascular pathologies (e.g., stenosis, aneurysms), and similarly, may contribute to neo-aortic complications, such as aortic coarctations.

We have introduced a novel parameter, namely, diameter deviation, to quantify the changes in aortic diameter compared to linear fit line, which is conceptually similar to coefficient of determination. Previous studies have used standard deviation of aortic diameter; however, standard deviation can be misleading since aorta may taper in healthy cases even with no surgical interventions [5]. In contrast, diameter deviation is not impacted by natural tapering of the aorta since it compares the local diameter against a linear fit line.

The two conventional hemodynamic parameters (i.e., WSS and OSI) evaluated in this study showed no correlation with diameter deviation. This is not surprising since both OSI and WSS were originally designed to quantify low-frequency oscillatory flow in atherosclerotic-prone regions. In contrast, SPI showed distinct regions of turbulent-like flows in the aortic arch. These turbulent-like flows are known to induce proliferative and inflammatory endothelial gene expressions compared to non-turbulent flows [6] and thus, may be implicated in neo-aortic pathologies.

Previous studies have focused on quantifying energy losses in neo-aorta using 4D Flow MRI [5]; however, those parameters are only able to quantify non-turbulent contribution and neglect turbulent-flow contributions characterized by high-frequency signals. In addition, those parameters are dimensionalized, and thus, make it difficult to perform inter-patient comparison. In contrast, SPI not only quantifies high-frequency instabilities as a proxy of turbulent kinetic energy but also provides a non-dimensional value, both of which allow for inter-patient comparisons.

There was a strong correlation between diameter deviation and SPI. These findings highlight that the presence of turbulent-like flow in the neo-aorta could be due to sub-optimal aortic reconstruction. This has important implications for surgical intervention. For example, surgeons tend to oversize the patch to support growth; however, having a large patch can be a double-edged sword since oversized patches could induce abnormal flow conditions (e.g., similar to P4). Previous studies have shown that native neo-aortic tissue can grow to compensate for a smaller patch, and will likely grow optimally to match hemodynamic demand. Hence, future studies should use optimally designed, patient-specific patches that minimize pathological blood flow in neo-aorta.

SIMULTANEOUS MEASUREMENTS OF TEMPERATURE AND BLOOD PERFUSION RATE DURING SURFACE COOLING TO EVALUATE COOLING PENETRATION IN HUMAN SHOULDER REGION

Jacob Lombardo, Md Jawed Naseem, Liang Zhu

Department of Mechanical Engineering, University of Maryland Baltimore County, Baltimore, Maryland, USA

INTRODUCTION

Shoulder injuries, including rotator cuff tears and tendonitis, have affected more than 600,000 patients each year in the US, and surgical repair is an effective treatment.¹ After the surgery, doctors recommend placing a cooling pad on the skin near the surgical site to reduce inflammation and to alleviate pain.²⁻³ However, cooling penetration depth is greatly affected by the unknown local blood perfusion rate. Uneven cooling on the surgical site are factors contributing to the discontinuous use of the cooling device by patients.

In this study, we performed experiments on volunteers to record temperatures and blood perfusion on skin surface under a cooling pad. The experimental data were used as inputs to a whole-body heat transfer model to extract heat transfer coefficients and dependence of blood perfusion on local temperature. Finally, tissue temperature fields were simulated to evaluate whether cooling penetrates into the repair site in the shoulder region.

METHODS

A commercially available cooling device was evaluated in this study. Shown in Figure 1, it consists of a container with good insulation, a pump to induce water circulation, and a cooling pad suitable for cooling on the shoulder. The cooling pad was wrapped on the shoulder of a human volunteer in a sitting position. An elastic belt was used to ensure good physical contact to the skin and an aluminum sheet was attached to the cooling pad to generate even cooling to the skin surface. A Laser Doppler Flowmeter (LDF, BLF-21D, Transonic System Inc., Ithaca, NY, USA) with a flat probe was used to estimate the local blood perfusion rate. The LDF gives a value with an arbitrary unit (AU); however, it can be used to evaluate local blood perfusion changes at a specific skin location during the cooling process.

Three healthy volunteers were recruited to this study with local IRB approval. The LDF probe was attached to the skin, then, the cooling pad was wrapped on the shoulder region of the volunteer. A thermistor bead sensor (0.8 mm dia., T-View system, Alpha Technics, Irvine, CA) was attached to the center of the cooling pad on the upper arm to measure the temperatures before and during cooling. Ice-water

mixture ($0.11 \pm 0.03^\circ\text{C}$, $n=3$) was circulating through the cooling pad and the total cooling time was 20 minutes. The oral temperature of the volunteers were also recorded before ($36.6 \pm 0.2^\circ\text{C}$, $n=3$) and after the cooling ($36.8 \pm 0.2^\circ\text{C}$, $n=3$).

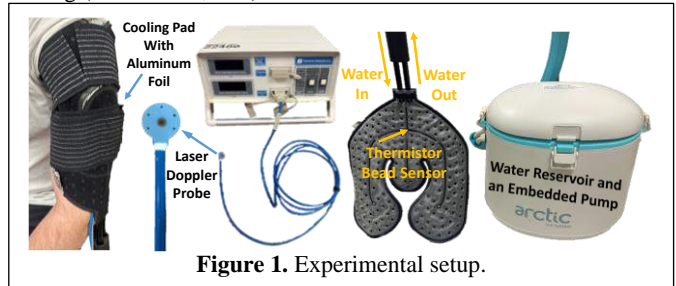

Figure 1. Experimental setup.

A physical model based on realistic measurements of a volunteer was generated. As shown in Figure 2, the body (70 kg and 1.78 m tall) consists of the brain, the internal organs, and the muscle for the rest of the body. The cooling pad is attached to the shoulder region. The thermal resistances due to convection and radiation with the surrounding air are lumped as an overall heat transfer coefficient h_{air} ($9.57 \text{ W/m}^2\text{K}$). The boundary condition of the cooling pad is also lumped as an overall heat transfer coefficient h_{water} , which will be determined from the measured temperatures during the cooling.

The Pennes bioheat equation⁴ is used to model both the steady state and the transient temperature fields of the body as

$$\rho_t c_t \frac{\partial T_t}{\partial t} = k_t \nabla^2 T_t + \omega_t \rho_b c_b (37 - T_t) + Q'''_{met,t} \quad (1)$$

Figure 2. A model of a human body.

where ρ is density, c is specific heat, k is thermal conductivity, ω is blood perfusion rate, and Q'''_{met} is metabolic rate. Both the blood perfusion rate and metabolism are coupled and assumed decreasing as temperature drops, using the following expressions:

$$\omega/\omega_0 = Q'''_{met}/Q'''_{met,0} = A^{(37-T)/10} \quad (2)$$

where subscript 0 refers to baseline value at 37°C. The coefficient A in Eq. 2 will be determined from the measured blood perfusion rate. All the simulations were carried out by COMSOL software.

RESULTS

Tables 1 gives the physical and physiological properties needed in the model. The air temperature, T_{air} , was recorded as 22.5°C. The baseline local blood perfusion rate and the metabolism used in the simulation are shown in Table 1.

Table 1 Physical and physiological properties⁵

Properties	Brain	Internal organ	Muscle	Blood
k , W/mK	0.52	0.52	0.52	0.50
ρ , kg/m ³	1060	1060	1060	1060
c , J/kg K	3800	3800	3800	3800
ω , 1/s	0.009	0.0021	0.00053	
Q'''_{met} W/m ³	9225	2460	535.5	

Figure 3. Blood perfusion rate decays with time during cooling.

Figure 3 gives the decaying trends of the blood perfusion rate measured by the LDF probe. The data were fitted with Eq. 2 to determine the unknown parameter A . The skin temperature was 34°C initially, then it decreased to ~27°C after the cooling pad was attached, leading to a blood perfusion rate as 50%-70% of the baseline value. After 20 minutes of cooling, the blood perfusion rate decreased to ~10%-30% of the baseline value. The determined values of A were similar among the three volunteers, varying from 1.45 to 1.9, suggesting blood perfusion decreases by 50-70% for every 10°C temperature reduction in tissue, based on Eq.2.

The recorded transient temperatures in the volunteers are shown by the symbols in Figure 4. Note that water temperatures in the reservoir only increased slightly during the cooling, by less than 0.5°C. The skin temperatures were around 27°C before water circulation, then decreased steadily to 3-5°C after 20 minutes of cooling. The experimental data were used as inputs to the simulation. While adjusting the h_{water} value (160-280 W/m²K), one obtains the best match between the experimental data and simulation predictions.

The final task of this study is to simulate the transient temperature distribution based on the recommended cooling setting by the manufacturer. The water in the reservoir should be ice-water mixture ($T_{water}=0^\circ\text{C}$) and the cooling time is set as 20 minutes. Figure 5 illustrated the baseline temperature contours (left), showing the maximal temperature of 37.3°C occurring in the brain and internal organ. After 20 minutes of cooling, one can see significant cooling penetration to the deep shoulder region (middle panel of Figure 5).

The transient temperature distribution along the vertical line in the upper arm region is also plotted in Figure 5 (right). The results show a relatively uniform temperature distribution inside the tissue

before the cooling, varying from 33°C at the skin to 36.5°C at the center. Once the 0°C water is circulating in the cooling pad, temperature decreases rapidly. Cooling penetration depth depends on the targeted temperature. If the targeted temperature is 27, 30, 33, or 35°C, then the penetration depth will be 19, 21, 29, or 35 mm, respectively. Considering that rotator cuff tear occurs at a relatively superficial region (just below the skin layer, <15 mm), it is highly likely that the surgical site and its vicinity can be cooled below 27°C.

Figure 4: Recorded temperatures by the thermistor bead sensor (symbols) and the simulation using an adjustable h_{water} .

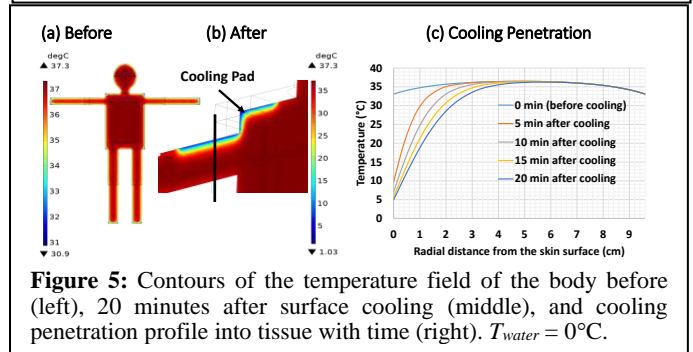

Figure 5: Contours of the temperature field of the body before (left), 20 minutes after surface cooling (middle), and cooling penetration profile into tissue with time (right). $T_{water} = 0^\circ\text{C}$.

DISCUSSION

The current study provides simultaneous measurements of temperature and blood perfusion rate at the skin surface of the shoulder region of human volunteers, leading to extraction of physical and physiological parameters needed to simulate temperature fields. The extracted parameters are within the range of normal physiology, and they are used to improve accuracy of theoretical simulations of tissue temperature fields under a cooling pad. Based on the simulation results, the model predicts a cooling penetration depth (<27°C) as 19 mm to the deep tissue region when ice-water mixture serves as the coolant. This penetration depth should be sufficient to reach the surgical repair site of rotator cuff tears or tendonitis and its surrounding tissue region (~15 mm in depth). Effective cooling may temporarily reduce nerve activity via disrupting the transmission of pain signals.²⁻³ This would be a cost-effective approach to decrease the usage of pain-killer medications, thus addressing the opioid epidemic crisis currently affecting many patients in the US.

INTRODUCTION

Pathological fractures due to bone metastases are a common occurrence for patients with advanced cancer [1]. Fracture rates are highest among those with multiple myeloma (43%), breast cancer (35%), and prostate cancer (19%) [1]. Typical treatments for such lesions include radiotherapy and various types of internal fixation, such as intramedullary nails or plates [2]; unfortunately, fracture risk in these patients is often uncertain, and doctors are forced to decide treatment plans based on visual observations of tumor size and location [2]. One way to quantify this risk is by creating patient-specific computational finite element (FE) models, which can be used to better advise doctors whether surgical intervention is necessary. The purpose of this study was to develop and validate a finite element technique to predict fracture risk using a canine radius model.

METHODS

Eight healthy radii (5 left and 3 right) were taken from canine patients euthanized for unrelated reasons. In the distal region of each radius, a cylindrical osteotomy with 25 mm radius was created to remove half of the bone width at the thinnest point and model the effect of a sarcoma, after which the samples underwent computed tomography (CT) scans with 1 mm slice resolution. For mechanical testing, samples were allotted to one of three loading conditions: three samples in cantilever bending (B1-3), three in torsion (T1-3), and two in compression (C1-2). Bending and compression samples were potted for fixation at the proximal end of the bone, while torsion samples were potted at both ends. Rosette strain gages were placed on the periosteal surface of the bone opposite to the thinnest region of the osteotomy. All samples were loaded to failure at a rate of 0.1 mm/sec or 0.5 degrees/sec, and yield load was determined from the resulting data. Finite element models were then created from the CT scans through a series of softwares, and loading and boundary conditions were added to replicate

the corresponding mechanical testing conditions of each sample (Figure 1).

Figure 1: Experimental setup (A) and location of loading and boundary conditions in the FE models (B). All samples had a boundary condition at the proximal end, shown by the yellow box. At the distal end, bending samples were loaded along the blue arrow, compression samples along the green arrow, and torsion samples with a moment applied to the area in the orange box.

Material properties for bone were generated using previously established relationships (Equations 1 and 2) between elastic modulus and density from CT scans for canine bones [3].

$$\rho = 0.9839 + 0.00049332 * HU \quad (1)$$

$$E = 1858 * \rho^{3.09} \quad (2)$$

For the medullary cavity, three different material definitions were tested: one using Equations 1 and 2 for elastic modulus, another with a hollow cavity, and a third with a constant isotropic elastic modulus of 0.02 MPa [4]. It was found that using 0.02 MPa (the effective elastic modulus of bone marrow) produced the highest accuracy and was therefore used in all models.

Simulations were run to the experimental yield load, and stiffness values taken from displacement versus force (or torque) were compared between experimental and finite element results. Finally, the computational models were used to predict yield failure using a maximum principal strain-based criterion [5].

RESULTS

The FE models accurately predicted stiffness, with all samples having less than 8% error and three samples being within 1% (Figure 2). For maximum principal strain, the average difference between finite element and experimental data was 809 $\mu\epsilon$ (11% error), the minimum difference was 235 $\mu\epsilon$ (1.9% error), and the maximum difference was 1858 $\mu\epsilon$ (31.6% error). When comparing loading scenarios, all bending samples yielded below 500 N, compression samples yielded between 800 and 1100 N, and torsion samples yielded between 3.8 and 7.7 Nm. Strain-based yield load predictions (Figure 2) differed from experimental data by an average of 98 N (28.8%) in bending, 207 N (21.9%) in compression, and 2.5 Nm (46%) in torsion. Paired t-test ($\alpha = 0.05$) comparisons (RStudio, Posit, PBC, Boston MA) did not reveal statistical differences between experimental and computational results for stiffness, strain, or yield load.

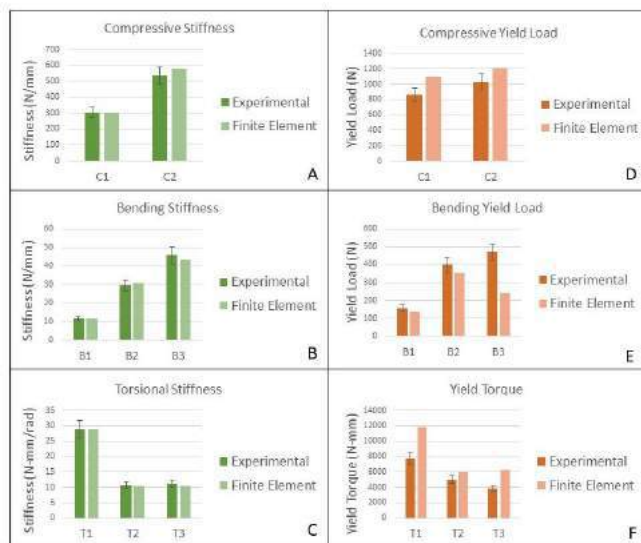

Figure 2: Comparison of experimental and finite element stiffness and yield load. Error bars represent $\pm 10\%$.

DISCUSSION

Overall, the finite element model showed high accuracy in stiffness predictions and moderate accuracy for strain and yield load. Some of the error in the strain-based yield load predictions likely resulted from not taking strain data at the exact location of the fracture, particularly for torsion samples, which exhibited spiral fractures that did not pass through the ROI.

Model validation was supported by statistical analyses, which showed no difference between experimental and FE data for stiffness, strain, and yield load, indicating no overall trends regarding over- or underprediction. Material property definition was an important aspect of the validation; by using an HU to modulus relationship for bone, differences in cortical and trabecular modulus were accounted for, while setting a homogenous modulus for bone marrow greatly reduced error from trying to extrapolate bone relationships to soft tissue.

When loaded under compression, samples generally yielded at a higher load and exhibited greater stiffness than the other loading types, which is consistent with data published by Hart et al. [6] Maximum principal strain, measured at the thinnest point of the osteotomy, was highest in bending, while torsion and compression had similar values. This suggests that samples have the highest fracture risk in bending and are strongest in compression.

Evaluating a clinical example can be useful in the context of this study; in jumping from a height of 0.65 m, peak compression forces on canine forelimbs have been measured to be 30.84 ± 3.66 N/kg [7]. Using the average canine mass in this study of 67.4 kg, this force comes out to be 2078 ± 247 N, suggesting that both compression samples would yield at lower loads than would be observed in this specific scenario. This example shows how an FE model might be used to quantify likelihood of fracture, which could aid doctors in decisions regarding radiotherapy vs stabilization.

This study had some limitations that could affect the overall accuracy and usefulness of the results. The main limitation of this procedure is the amount of manual input required to develop these models, which allows for some slight variation in properties between models, and increases the time required to test a model. These drawbacks limit this method's usefulness in clinical applications, as model creation would require trained personnel and might be expensive for patients. Another limitation is that this study utilizes simple loading conditions, whereas bones *in vivo* are subject to complex combined loading. If this model were to be used in a clinical setting, research would have to be performed regarding the type and magnitude of loading the patient's bone is most likely to endure in order for the fracture prediction to be clinically relevant.

Future studies will further validate this technique using canine radii with clinically diagnosed osteosarcoma; while the tumor was modeled as a completely empty defect in this study, real tumors will have some mechanical properties that may not follow the HU to modulus equations used for healthy bone. Additionally, various types of fixation will be tested to optimize fracture risk reduction, which will ideally be translated to use in human patients. The importance of this study is that it validated a finite element technique to predict yield, which can provide a quantitative measure of fracture risk when compared to common physiologic loads, ultimately helping doctors make treatment decisions for patients with osteosarcoma.

A NEW METHOD FOR GENERATING VIRTUAL BONE SCANS FOR THE PURPOSE OF INVESTIGATING THE EFFECTS OF CORTICAL MICROSTRUCTURE

**Zachary B. Toth (1)
Dr. Joshua Gargac (1)**

(1) Mechanical Engineering, Ohio Northern University, Ada, OH, USA

INTRODUCTION

Globally, bone fractures represent a significant public health issue, affecting 178 million individuals per year, as of 2019 [1]. According to some estimates, the United States alone spends somewhere between \$12.9 and \$16.9 billion per year on non-traumatic fractures [2,3]. Stress fractures, a type of cortical bone fracture most commonly affecting both elderly and physically active people, have a considerable rate of occurrence at approximately 5.7 fractures per 1000 people per year [4,5,6]. The significance of stress fractures lies in the form they take—small cracks in cortical bone caused by repeated mechanical stresses. Because of this, it can be seen that their formation might be influenced by factors such as the geometry and porosity of the cortical bone.

Cortical bone, while somewhat less well understood in regard to bone fragility than trabecular bone, makes up approximately 80% of the human skeleton and serves as a major load-bearing component [7]. According to Augat and Schorlemmer [8], the strength of cortical bone is not only influenced by macro-scale structural properties such as bone cortex thickness and cross-sectional area but is also largely contributed to by microstructural properties such as crystallinity, incidence of microcracks, and cortical porosity. This strength can be measured multiple ways but is primarily either found as a direct measurement through mechanical testing, or derived from Finite Element models of bone scans, such as ultrasounds or micro-Computed Tomography (μ CT) scans [9,10,11].

Evaluating the contribution of microstructure to overall bone strength is tricky since it can be difficult to control changes to pore structure. The ability to easily generate bone samples with their desired microstructural properties would make research into the effects of microstructure more precise. In this vein, designing a program that could do this is a promising solution. Given certain input parameters relating to the desired bone structure, it would generate a 3-dimensional model of micron-scale cortical bone. Ideally, these parameters could be varied to generate images with high similarity to CT scans of cortical

bone thus allowing for the simple generation of additional samples. Additionally, changing the parameters would create opportunities to isolate their specific effect on overall bone strength.

METHODS

In order to mimic cortical bone as closely as possible, previous literature about cortical bone's structure and remodeling mechanics first had to be reviewed. A MATLABTM (MathWorks, Natick, MA) program was then developed that could build an array resembling the network of canals that makes up the haversian systems characteristic of cortical bone. The program generates canals through the array, varying their size, shape, and location based on user-defined input parameters. These parameters include average pore radius, average pore circularity, pore location, and the target porosity. Each of these parameters and their input ranges are based on the current literature [12,13]. Successive canals generate, often in a network with previous canals, until the target porosity is reached. The array is then saved as a TIFF file, which can be opened and processed in other applications.

For comparison, μ CT scans of human cortical bone were acquired. The samples used were obtained from the proximal and mid-diaphysis of an 85-year-old male tissue donor. Samples were machined into cylindrical “dog-bone” specimens with a gauge length of 10 mm and a gauge diameter of 3 mm. Micro-CT scans were acquired (mCT-80, Scanco Medical AG, Brüttisellen, Switzerland) at 10 μ m resolution, 70 kVp voltage and 114 μ A current with 1000 projections at a 600 ms integration time with slices oriented perpendicular to the longitudinal axis of the specimen [14]. The μ CT scans were then processed in ImageJ (U.S. National Institutes of Health, Bethesda, MD) into binary 200 μ m cubic TIFF files.

RESULTS

The 200 μ m cubic bone cores can be opened and visualized in Seg3D (Scientific Computing and Imaging Institute, Salt Lake City,

UT). An example of a generated bone core as compared to one obtained from a CT scan is shown in Figure 1. Images in the first two rows have been inverted to show internal structure by displaying the canals rather than the solid bone. There is a remarkable degree of similarity between an actual CT scans and generated cores, indicating that early builds of the program are able to closely resemble the range of variation within living tissue. This similarity can be most directly seen in the networked nature of the model.

Figure 1: Computer-Generated Sample (Left) and Inverted CT scan of Human Cortical Bone (Right). Three views are shown: An isometric view of the bone core, (Top), a top-down view of the bone core (Center), and a non-inverted isometric view of the bone core (Bottom).

DISCUSSION

In future work, there are two main objectives. First, the program's ability to match geometric features of the μ CT scans must be evaluated and quantified. This would demonstrate the program's efficacy at mimicking real bone and might further inform future parameters for generating bone images. This step will also include identifying which input values are able to most closely approximate bones from different species and age groups. The second objective is to develop a graphical

user interface, which would make the program easier to use once it is published as an open-sourced tool.

This program could be a useful tool for investigating the mechanical effects of different porosities. For example, Schaffler and Burr [15] tested 20 bone core samples, but found that some porosity values were underrepresented due to the relatively small sample size and the variation that comes from nature. With the ability to generate additional samples within this range, less interpolation might have been necessary, potentially leading to more precise data. This program will also enable researchers to isolate the effects of specific variations in pore geometry, such as pore shape. Currently, it is difficult to find samples consisting of mostly tapered pores [16], and therefore researchers are not able to quantify the effects of this microstructural change. Using this program, the presence of these geometric features can be controlled. In practice, this could enable researchers to evaluate the mechanical effects of microstructural changes caused by new medicines [17].

ACKNOWLEDGEMENTS

The authors would like to thank Glen Niebur and Ryan Roeder at the University of Notre Dame for providing the human cortical bone μ CT scans.

DEVELOPING AND TESTING A NOVEL DEVICE FOR DETECTING PERIPHERAL ARTERY DISEASE USING RADIO FREQUENCY ENERGY

INTRODUCTION

Peripheral Artery Disease (PAD) is a condition characterized by reduced blood flow in the arteries of the arms and legs. People at high risk for PAD include those with diabetes, high cholesterol, and those who smoke. Persons with PAD have an elevated risk of cardiovascular (CV) events such as stroke and heart attack [1,2]. Generally, only people who present symptoms such as claudication and ulcers are tested for PAD. An estimated 20-50% of persons with PAD are asymptomatic, so they are unknowingly at risk for CV events [3].

Early intervention can greatly improve outcomes for persons with PAD by mitigating disease progression from asymptomatic PAD to symptomatic PAD [4,5]. This reduces the risk of claudication, ulcers, amputation, and CV events [5]. PAD disproportionately affects minority populations. In the US, African Americans are roughly twice as likely to have PAD as are non-Hispanic white Americans [6-8]. Racial Minorities also have poorer outcomes [9-12]. Among those with PAD, African Americans experience amputations at twice the rate, and Hispanics at a 50% higher rate than do whites [11]. The importance of early intervention and the racial disparities in patient outcomes presents a need for a widespread screening tool that can be used by anyone in a high-risk group.

Current methods for diagnosing PAD are limited [3,13]. The standard diagnostic tool is the Ankle-Brachial Index (ABI), a ratio of the blood pressure in the arm to the blood pressure in the ankle. ABI is administered to patients presenting with overt symptoms of PAD, meaning asymptomatic people are not tested even if they are at high risk for PAD [3]. Additionally, administering ABI tests requires special training, can be time-consuming, and the results are not always consistent with a patient's PAD status because they can vary with simple exercise such as walking [13,14]. It is not reliable in persons with arterial calcifications, such as those with diabetes, which includes many people in the high-risk categories for PAD [15,16]. This presents the

need for a screening method that can be used on anyone in a high-risk group during routine check-ups.

Infrared (IR) thermography, the process of using infrared light to obtain temperature measurements, is an emerging technology in PAD detection. Static thermal images show that reduced blood flow correlates to lower skin temperature under controlled conditions [17], but factors like skin thickness, ambient temperature, and natural body temperature can affect skin surface temperature [18]. This makes static thermographic images an unreliable method of relating body temperature and blood flow. Using similar principles, thermographic measurements can be taken over a period with a stimulus applied to observe temperature response, which removes limiting factors present in static measurements. This is known as Active Dynamic Thermography (ADT). By applying a known amount of energy to the skin and measuring the rate of skin surface temperature change, a thermal constant can be obtained and used as a normalized metric for identifying PAD.

Our lab is utilizing ADT to develop a tool for noninvasive and portable detection of PAD. This technology (REFLO) uses low-power radio frequency (RF) energy in the Ka band (26.5 – 40 GHz) to heat the skin while simultaneously measuring the surface temperature. The amount of blood flowing through the vasculature affects the temperature of the skin during and after heating, which will allow us to define 'normal' blood flow versus that of PAD [19,20].

We have tested this concept *in vivo* using rabbit pinnae, an accepted model for human skin due to its similar vascular properties [20], and *in silico* with a computer-generated flow model. We have designed an advanced prototype that is more compact and portable than previous versions. It employs a small micropatch antenna and an infrared (IR) temperature sensor, integrated in a compact transducer. A photo of the transducer is shown in Figure 1. The device is battery powered to avoid risk of shock and includes an overheat shutoff feature to avoid burning the skin. During our human subject testing in Spring

2023, measurements will be taken prior to, during, and after tourniquet-induced ischemia, using both the REFLO device and a near-infrared spectroscopy (NIRS) device. We hypothesize that the results as indicated by the REFLO device will correlate with readings from the NIRS device.

Figure 1. Device transducer.

METHODS

Our human subject experiments are being conducted under a protocol approved by the University of South Alabama Institutional Review Board. Healthy adults of both sexes between the ages of 18 and 31 are eligible to participate. During the study, the REFLO vascular assessment device will be tested and compared to NIRS, an accepted indicator of vascular function. The results will be used to assess the feasibility of using the REFLO device for future screening and diagnosis of PAD and other conditions. Ultimately, this study is designed to collect data in healthy, young adults to develop rationale for future studies within clinical populations.

A vascular occlusion test will be conducted to determine muscle oxygenation via a NIRS device. The participant will undergo 5 minutes of ischemia through a well-accepted protocol routinely used in the associated literature with no known risks other than comparable sensations to a limb “falling asleep”.

During testing of the REFLO device, a small area of skin on the lateral portion of the calf will be heated for a period of up to one minute, or until the surface temperature reaches 40°C, whichever occurs first. Skin surface temperature will be recorded continuously on a computer before, during, and after heating. To ensure safety, a failsafe mechanism in the controller will disconnect the transmitter should the skin temperature exceed 40°C during heating.

Upon the conclusion of our human subject study, thermal constants will be obtained correlating to normal, low, and high flow. We will determine if these constants are statistically significant, indicating whether our device can differentiate between normal and impaired flow.

EXPECTED RESULTS

We predict that the REFLO device will detect the highest rates of heating and cooling during tourniquet-induced ischemia and the lowest rates of heating and cooling during post-occlusive reactive hyperemia. Results will be presented showing the extent to which the rate of temperature change correlates to low, normal, and high flow, indicating the feasibility of our device accurately detecting PAD.

COMPUTATIONAL MODELING OF FLUID PERFUSION IN A BIPHASIC VOCAL FOLDS TISSUE DURING PHONATION: POTENTIAL ROLE OF PERMEABILITY

Isabella McCollum (1), Alexis Throop (1), Durwash Badr (1), Rana Zakerzadeh (1)

INTRODUCTION

During voice production, pressurized air from the lungs passes through the larynx and the vocal folds (VFs) will start to self-oscillate. This vibration is referred to as phonation and involves complex fluid-structure interactions (FSI) between the tissue of the VFs and the airflow through the larynx. VF modeling provides a prediction of VF dynamics and glottal flow which can lead to an improved understanding of these interactions. When modeling the VF, it is a common assumption to consider the tissue to be an elastic model, however, the folds behave more closely as a poroelastic tissue [1], with an 80% fluid volume fraction, which justifies the use of poroelastic models [2] and making the interactions a fluid-porous structure interaction (FPSI). Previous computational efforts that assumed a biphasic model of the VF tissue ignored the glottal aerodynamics, and the vibration was induced by applying direct load pressures [3, 4]. Combining both the porous model with aerodynamics is a computationally challenging problem but may provide a more realistic model to better help us understand VF behavior and lead to treatment and prevention of voice-related disorders such as vocal fatigue and dehydration that are commonly associated with VF permeability.

The purpose of this study is to investigate the spatiotemporal interstitial fluid dynamics of the porous VF tissue under varying permeability. Compared to previous studies, we develop a Multiphysics computational framework of the airflow through the larynx coupled with the poroelastic tissue dynamics to incorporate both aspects of the interaction. The computational model utilizes FSI methodology to simulate the biphasic behavior of the VFs during phonation as a poroelastic tissue. The effect of permeability on the fluid circulation within the VF tissue and the laryngeal aerodynamics was studied.

METHODS

A three-dimensional model of the VFs within the larynx was constructed using Autodesk Fusion 360 software and computational analysis was implemented in ANSYS Workbench software. To simulate

the dynamic FSI between the airflow and poroelastic tissue, a fully coupled Multiphysics model was created. The airflow dynamics were defined in ANSYS CFX software, while the tissue mechanics were modeled in ANSYS Mechanical.

The airflow was modeled by the unsteady, incompressible Navier-Stokes equations, while the Brinkman equation was used to govern the flow through the porous medium. The VF tissue was assumed to be a one-layer isotropic permeable material. A static inlet pressure of 1 kPa was defined at the subglottal region while the pressure at the outlet of the supraglottal region was fixed at 0 kPa with a zero normal velocity gradient condition applied across the domain. The 3D model and boundary conditions are shown in **Figure 1**. The surfaces of the VF in contact with the fluid domain are free to move with no-penetration conditions. The lateral surfaces of the VFs in contact with the outside are treated with opening conditions for fluid to circulate within the folds. All other exterior surfaces of the domains are treated with no-slip and no-penetration conditions. The FSI occurs on the superior, medial, and inferior surfaces of the VF. The material properties of the VFs and airflow used in numerical simulations were defined in **Table 1**. The permeability constant of the VFs was varied in the range of $k = 10^{-13} \text{ m}^2$ to 10^{-7} m^2 and the coupled system was solved for each case to provide a prediction of the interstitial fluid flow within the VF tissue.

Figure 1: 3D laryngeal model (VFs are shown in red, air domain is depicted in grey) and boundary conditions.

Table 1: Physical parameters and material properties.

Domain	Parameter Description	Parameter Value
Air	Density	1.185 kg/m ³
	Dynamic Viscosity	1.831x10 ⁻⁵ kg/m·s
Vocal Folds	Density	1070 kg/m ³
	Poisson Ratio	0.45
	Young's Modulus	40 kPa

The CFX and Mechanical components were joined along the FSI boundary using the System Coupling component, which solves the fluid and solid domains separately to obtain pressure loads in CFX that are applied to the VFs on the fluid-solid interface, solving for tissue dynamics in Mechanical. This process of the System Coupling algorithm in ANSYS is illustrated in **Figure 2**. The pressure loads obtained from the coupled system were then imported into the second CFX component to capture the fluid circulation within the porous tissue.

Figure 2: FPSI algorithm in ANSYS Workbench.

RESULTS

The results for the aerodynamics of the glottal flow through the larynx, particularly the pressure and velocity contours, are shown in **Figure 3**. The airflow is driven from the inlet to the outlet by a pressure drop between the subglottal and supraglottal pressures and interacts with the permeable VFs to initiate the flow-induced vibrations.

The uniform velocity streamlines at the inlet reach a maximum value between the folds at the glottis region, then recirculate before exiting the outlet. The subglottal pressure produces a pushing force in the flow direction on the VFs as well as a compressive force in the transverse direction, causing both the inferior and superior surfaces of the fold's tissue to abduct, and thus the glottis opens and closes.

Figure 3: Velocity and pressure contours of airflow in the larynx obtained at the glottal opening time instant.

As the airflow causes the folds to self-oscillate, fluid circulates within the porous tissue of the VFs. The filtration velocity streamlines from four cases with varying permeability are provided in **Figure 4**. The maximum flow velocity during phonation reaches the highest magnitude in the case where the permeability is the highest, as expected.

Figure 4: Interstitial fluid streamlines show circulation in porous VF tissue for cases with different VF permeability values.

As an indicator of fluid flow within the VF tissue, we define a measure for the volumetric average of filtration velocity over the VF domain \bar{q}_{VF} calculated by equation (1) below and the corresponding results are reported in **Figure 5** for each permeability value.

$$\bar{q}_{VF} = \frac{\int_{\Omega_{VF}} q_{VF} d\Omega_{VF}}{\int_{\Omega_{VF}} d\Omega_{VF}} \quad (1)$$

It can be observed that both the maximum filtration velocity and the volumetric average of filtration velocity vary with the permeability. The greater the permeability, the faster the flow, and thus a greater circulation of fluid within the porous tissue is observed.

Figure 5: Variation of filtration velocity in the VFs for cases with varying permeability. Bars show the peak value of q_{VF} and the line represents the change in the \bar{q}_{VF} trend.

DISCUSSION

An FPSI framework for the VF was developed to investigate the interstitial fluid dynamics within the VF tissue under varying permeability. Based on our results shown in **Figures 4-5**, we observed that the tissue permeability significantly affects the filtration velocity distribution and its maximum value. Thus, permeability plays a role in tissue perfusion during phonation.

SIGNIFICANCE OF VASA VASORUM OXYGEN SUPPLY IN THE NOURISHMENT OF THE ANEURYSMAL WALL

Manoela Neves (1), Alexis Throop (1), Rana Zakerzadeh (1)

Pittsburgh, PA, USA

INTRODUCTION

An abdominal aortic aneurysm (AAA) represents a progressive localized dilation of the central aorta that asymptotically develops over long periods of time as a result of the remodeling and weakening of the arterial wall extracellular matrix that can suddenly rupture. Most AAAs contain a layer called an intraluminal thrombus (ILT). The presence of an ILT leads to localized oxygen loss (called hypoxia) in the AAA owing to the ILT's limited diffusion, which triggers adventitial angiogenesis and aggravates inflammatory infiltration from the outer vessel layers. Hence, the loss of oxygen supply leads to inflammation, degradation, and finally weakness of the aneurysmal wall, making the aneurysm more likely to grow quickly and rupture.

Although the effects of ILT thickness on oxygen starvation in the AAA wall have been confirmed [1], features such as the adventitial vasa vasorum (VV) blood vessels have been observed to be stenotic in both small and large AAA, with the sac tissue being ischemic and hypoxic. Therefore, given the small number of VV in the abdominal aorta, their stenosis exacerbates tissue hypoxia. A parametric study can be helpful to investigate the importance of this effect, as well as to assess the contribution of VV to AAA nourishment and oxygenation.

The sensitivity of the oxygen distribution to the chosen VV value has previously been studied in idealized AAA geometries [2]; however, the effect and contribution of VV in patient-specific geometries have not been explored. Therefore, the objective of this study is to simulate and examine a patient-specific AAA model and analyze the extent to which different VV oxygen concentrations in ILT presence influence the transport of oxygen to the aortic wall. By implementing a computational model of coupled blood flow and oxygen transport, it is possible to analyze the influence of the model parameters on oxygen delivery to the AAA arterial wall.

METHODS

A patient-specific model of AAA including an ILT is considered (Figure 1). The geometry is reconstructed from computed tomographic

(CT) scans, and SimVascular software is used to segment the lumen and ILT domains. The arterial wall is extruded from the vessel wall in the image with a thickness of 2 mm. Therefore, three domains are constructed: the ILT (shown in red), the lumen, and the arterial wall (shown in grey). All three domains are meshed in the open-source software, Gmsh, using tetrahedral elements.

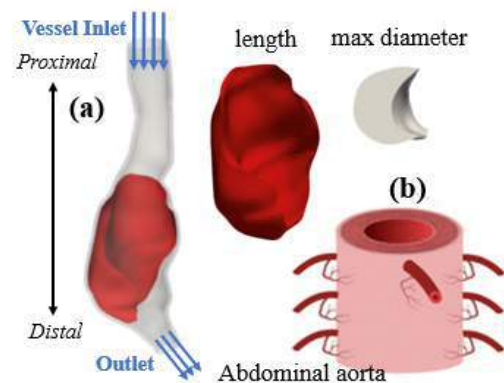

Figure 1: Patient-specific AAA geometry (a) VV vessels in the infrarenal abdominal aorta do not penetrate the medial layer (b).

The blood flow in the lumen is assumed to behave as a Newtonian, incompressible viscous fluid and is represented by the Navier-Stokes equation. The blood flow is coupled with oxygen transport in the lumen, which is governed by the convection-diffusion equation. The oxygen concentration at the inlet of the lumen is prescribed as $5.12 \times 10^{-3} \text{ kg/m}^3$. Moreover, at the lumen inlet, a uniform systolic pressure of $p_f^{in} = 130 \text{ mmHg}$ is applied as a boundary condition. A mass flow rate of 0.075 kg/s is applied at the outlet.

Both the ILT and arterial wall are assumed to be hyperelastic, homogeneous, incompressible, and isotropic materials. Moreover, the second-order Mooney-Rivlin material model is adopted for the arterial wall and ILT. In terms of oxygen transport, the ILT is assumed to be permeable to oxygen molecules through diffusion without any oxygen consumption. Thus, the oxygen transport in the ILT is modeled by the diffusion equation. The oxygen transport in the arterial wall is described by the diffusion-reaction equation, where a reaction term accounts for the metabolic consumption of oxygen. Fixed support boundary conditions are assigned at the inlet and outlet cross sections of the arterial wall. The outer AAA wall is traction-free with no external pressure on the surface.

A fully coupled multiphysics model was created in ANSYS Workbench to account for the dynamic fluid-structure interactions between the blood, ILT, and AAA wall. Hemodynamics and oxygen transport properties are defined in ANSYS CFX while arterial wall and ILT mechanics are modeled in ANSYS Static Structural component. The fluid and solid components directly interact via a single FSI boundary prescribed in the mechanical feature. The simulation is carried out using ANSYS System Coupling. Specific details of the coupled FSI-oxygen transport modeling framework are provided in [3].

In this study, the importance of the VV on oxygen flow is observed by performing numerical simulations with varying levels of oxygen concentration on the adventitia. We considered three cases ranging from neglecting VV to the physiologically normal values for the healthy artery, with oxygen concentration on the exterior wall surface (VV) of VV1 = 0 kg/m³, VV2 = 1.25 × 10⁻³ kg/m³, and VV3 = 2.56 × 10⁻³ kg/m³.

RESULTS

Using the prescribed conditions at the inlet and outlet of the AAA model, the obtained luminal velocity value matches the typical peak systolic blood velocity of 0.23 m/s (see [3] for hemodynamics results). **Figure 2** demonstrates the oxygen concentration along a cross-section on the center of the AAA bulge, which is kept consistent for all three cases. For all three cases, the highest concentration of oxygen is found within the lumen and gradually decreases inside the tissue to reach its minimum value along the arterial wall. The cross-sectional contours show a significant increase in the arterial wall oxygen concentration with increasing VV values.

Figure 2: Oxygen concentration contours along a center cross-sectional region of the AAA for three analyzed cases.

The oxygen concentration along the interior interface of the arterial wall in the portion where ILT is located, for cases with varying VV are illustrated and compared in **Figure 3**. In the regions where the ILT is not present within the AAA, the concentration remains consistent among the cases. However, with the presence of the ILT, the change in VV value influences the oxygen concentration within the region.

Similar to **Figure 2**, as the VV value increases from VV1 to VV3, the flow of oxygen to the arterial wall increases.

Figure 3: Oxygen concentration along the inner layer of the AAA wall for cases with varying VV oxygen supply.

As an indicator of oxygen transported to the AAA wall, we define a measure for the volumetric average of oxygen concentration over the aortic wall domain \bar{C}_w calculated by equation (1) below, and the corresponding results are reported and visualized in **Figure 4**. The result in **Figure 4** demonstrates an increase in volumetric oxygen concentration within the arterial wall as the adventitial oxygen increases.

$$\bar{C}_w = \frac{\int_{\Omega_w} C_w d\Omega_w}{\int_{\Omega_w} d\Omega_w} \quad (1)$$

Figure 4: Volumetric average of oxygen concentration in the AAA wall for three cases with varying VV oxygen supply.

DISCUSSION

In this study, using a patient-specific AAA model, the effect of the VV on oxygen transport was explored. The results of **Figures 2-4** indicate that hypoperfusion of adventitial VV (i.e., smaller values for VV) have critical effects on oxygen concentration inside the AAA wall and therefore can cause hypoxia. Particularly, results demonstrate that a lack of the VV blood flow supply would prevent the oxygen from reaching the arterial wall. The oxygen concentration within the AAA wall increased among the cases as the adventitial oxygen concentration increased. These observations indicate that the presence of the VV may play a significant role in AAA wall oxygenation and needs to be taken into consideration in computer simulations.

ACKNOWLEDGEMENTS

Funding for this research is provided by Samuel and Emma Winters Foundation. We would like to thank Shawn Shadden and Miguel Rodriguez for providing us with the AAA computational mesh.

INTRODUCTION

Contact is a major part of ice hockey gameplay. Body checking primarily begins at age 13 for male ice hockey players in Canada [1]. Over time, athletes are taught how to control their movements to avoid contact and prevent severe injuries. However, despite how cautious a player may be, contact is still prevalent and fundamental aspect of the game. For example, reports have shown that the median exposure for collegiate male ice hockey players is 287 head impacts per season [2].

Head injury stemming from contact is deeply engrained in the fabric of the sport. In a previous study the concussion rate in male ice hockey players was calculated to be 2.3 per 1,000 impact exposures [3]. However, while several investigations examine the severity and effects of these impacts, there has been limited research regarding the sport-specific factors influencing head impact exposure, specifically ice location, player position, and time (in-game) of when impacts occur. In doing so, “high-risk” areas and situations can be defined, improving player safety in hopes of reducing the high prevalence of head injuries seen in ice hockey. Our objective is to investigate how ice hockey gameplay factors influence head impact exposure in collegiate male ice hockey using instrumented mouthguards [4] during a single competitive season.

METHODS

Twenty-six UBC men’s ice hockey players (H21-00400) were recruited to wear Prevent Biometrics mouthguard sensors [5] for a full season of play (Figure 1). Head impact data were collected in each of the 26 regular-season and playoff games. The mouthguards contained infrared proximity sensors to detect whether the mouthguard is on-teeth during impacts [6]. Impacts that passed an individual on-teeth proximity threshold were included in the dataset. Impact kinematics were transformed to head centre-of-gravity and low-pass filtered using a 4th order Butterworth filter at 200Hz. Peak linear acceleration (PLA), peak angular acceleration (PAA), and peak angular velocity (PAV) were

recorded for each individual impact. Impact data were cross verified with the associated game video to ensure validity of head exposure events. In addition, the location of impact on the rink was estimated through video. We evaluated the effect of ice location, player position, and time in-game on head impact exposure.

RESULTS

419 head impacts were verified and analyzed. Impact kinematics are shown in Table 1. A median head impact was observed to have peak kinematic values of 9.3g for PLA, 567 rad/sec² for PAA, and 8.2 rad/sec for PAV. A 95th percentile impact recorded a PLA value of 23.2g, PAA of 1838 rad/sec², and PAV of 17.7 rad/sec. Segregating impact data by player position produced similar values. Figures 2 and 3 display location-based impact data. Impacts are seen to be clustered on the outer boundaries of the ice surface and in the offensive zone. The majority of head impacts are relatively low severity (93% of impacts below 20g, 79% of impacts below 1000 rad/sec²), and higher severity impacts do not seem to be concentrated in any particular location on ice.

Table 1: Median, 95th percentile, and 95% confidence interval (of median) are displayed for PLA, PAA, and PAV. Shading represents values from entire data set (white), defense only (light grey), and forwards only (dark grey).

	PLA (g)			PAA (rad/sec ²)			PAV (rad/sec)		
Med	9.3	9.8	9.2	567	553	567	8.2	8.3	8.2
95th %	23.2	20.9	24.0	1838	1989	1817	17.7	19.5	17.3

DISCUSSION

Previous knowledge is limited in identifying “high-risk” areas of the ice surface during gameplay. While studies have investigated what mechanism of injury is most common [8], impact exposure density based on location has not been adequately explored. Our data suggests that head impact exposure is heavily concentrated around the outer

boundaries of the ice surface, where glass boards protrude and encapsulate the area of play. This may be due to the nature of gameplay. Players with possession of the puck are susceptible to impacts in these areas; a combination of their lack of maneuverability and impaired vision in these positions. Furthermore, our results show that players are more susceptible to impacts in the offensive zone of the ice than defensive. Players can only receive contact when in possession of the hockey puck, which usually occurs in the offensive zone. However, it is worth noting that a higher impact exposure density in the offensive zone is not associated with larger kinematic values for forwards than defense, which is corroborated by previous findings [2, 7].

Our results indicate that head impact severity for median and 95th percentile impacts do not vary based on position, with forward and defense experiencing similar impact kinematics. In support, other researchers found similar magnitude of impacts among collegiate forward and defense hockey players [2]. Similarly, others reported no differences in PLA and PAA among teenage hockey player position [7]. These outcomes may likely be attributed to the lack of specificity in positional gameplay; contact tactics (such as hitting and bodychecking) do not vary by position.

The present findings reveal that head impact exposure varies by period of gameplay. Figure 3 illustrates the variation in magnitude and location of impacts between periods. Our results show that the first period tends to be the most physical of the game, with higher impact exposure density and kinematic values than the second and third periods. Correspondingly, others have found that concussions in the NHL are most common in the first period of play [9]. Hitting requires significant energy from the perpetrator; players may elect to hit less frequently in the latter stages of games, choosing to avoid contact to reduce energy expenditure and manage the onset of fatigue.

The results presented suggest that ice location and timeliness have significant influence on the degree and magnitude of impact exposure, while player position does not. In addition, the offensive area and outer boundaries of the ice can be identified as high-risk areas. Players should be particularly cognizant of potential impacts in these locations and in the early stages of games. Impact exposure data points will continue to be added, which may further reveal trends and important information of situations of “high risk” of head injury.

ACKNOWLEDGEMENTS

We would like to thank the Canadian Institutes of Health Research (CIHR) and Natural Sciences and Engineering Research Council of Canada (NSERC) for their ongoing support and funding of these studies. We would also like to thank the UBC Men’s Hockey Team players, support staff, and coaches for their continued participation in this study. Their cooperation and excitement have propelled this study forward. Finally, we would like to thank Prevent Biometrics and Susan Schmitz of UBC Dentistry for their tireless efforts in supporting our work.

INTRODUCTION

Electroencephalography (EEG) measurements have traditionally reflected brain function changes in epilepsy, neurodegeneration, and brain trauma. Recently, advances in recording hardware and quantitative data analysis methods have expanded the applications of EEG beyond clinical and laboratory settings. Mobile EEG systems and nuanced artifact removal algorithms are now being used to explore brain changes that occur in ambulatory settings. A better understanding of the normal variability of repeated EEG measurements will be important for interpreting these measurements in noisy real-world scenarios.

The literature on the test-retest reliability of common EEG metrics has demonstrated high correlations between repeated trials performed over varying time scales [1,2]. However, external factors such as alertness or physiological stress also influence cognition and may induce underlying EEG changes that can confound the anticipated results. In this study, we characterized the range of normal intra-subject variability in resting state EEG data and examined the effects of potential sources of variability.

METHODS

12 healthy adults (5 females) aged 18 to 26 years (mean age of 22.3 ± 2.6 years) participated in the study. The human participant protocol for our study was approved by the UBC Research Ethics Board (H20-02313) and informed consent was obtained from all the participants. Experiment sessions for each subject were conducted on 2 separate days to examine day-to-day variability. On each day, subjects participated in an “early” session (between 10:00 am and 12:00 pm) and a “late” session (between 3:00 pm and 5:00 pm) to examine time-of-day variability. Each session involved 3 minutes of sitting, treadmill walking (2.5-3.5 mph), and treadmill jogging (4.5-5.5 mph), each followed by 5 minutes of eyes-closed resting state EEG recording.

EEG signals were recorded through 32 Ag/AgCl active electrodes (International 10-20 arrangement) amplified using the BrainVision

LiveAmp amplifier (Brain Products GmbH, Gilching, Germany) at a sampling rate of 500 Hz. We performed all data processing in MATLAB using scripts running EEGLAB functions [3]. The raw EEG signals were first re-referenced to the common average reference, then bandpass filtered at 1-100Hz using a 4th-order forward-backward Butterworth filter. We manually removed large transient artifacts, resulting in an average loss of 5.68s per 300s recording (1.89%). We then used independent component analysis (ICA) to remove components with significant ocular or muscle artifacts.

EEG trials were separated into 2-second epochs, and the power spectrum and sample entropy were calculated for each epoch with a 1-second overlap. For power spectrum band power analysis, we defined EEG frequency bands as delta (1-4 Hz), theta (4-8 Hz), alpha (8-12 Hz), beta (12-22 Hz), and gamma (22-40 Hz). The power spectral density of each epoch was computed using Welch’s modified periodogram. Sample entropy was computed as defined in [4], with $m = 2$ and $r = 0.2$.

We constructed linear mixed-effects models to determine the within-subject effects of experiment day, time of day, activity level, and their interactions on EEG band power and sample entropy. *Post hoc* tests were conducted for all statistically significant fixed effects and interactions, using the Tukey HSD method with adjusted p -values. All statistical testing was performed in R.

RESULTS

Each subject exhibited a wide range of measurements across the 12 recording trials (Figure 1). The most consistent metrics were relative alpha power (average intra-subject mean 0.48 ± 0.03 (6.25%)) and relative beta power (0.11 ± 0.01 (9.09%)). The least consistent metrics were absolute delta power ($5.69 \pm 1.45 \mu V^2$ (25.5%)) and absolute theta power ($3.32 \pm 0.53 \mu V^2$ (16.0%)). Despite these large variations, each subject had an idiosyncratic power spectrum shape (Figure 2). Sample entropy had an average intra-subject mean of 0.58 ± 0.04 (6.90%).

Figure 1: Overall intra-subject variability in absolute delta power.

Figure 2: Individual power spectra over all trials. Each color represents the mean power spectrum for a subject and the shading indicates the standard deviation.

Activity level before resting state EEG measurement had a significant effect on relative delta power ($p = 0.027$), relative theta power ($p = 2.92 \times 10^{-6}$), absolute delta power ($p = 7.7 \times 10^{-5}$), and absolute alpha power ($p = 0.025$). *Post hoc* testing using Tukey's HSD found that relative delta power, absolute delta power, and absolute alpha power measured after jogging were higher than those measured after sitting ($p = 0.022$, $p = 0.0002$, and $p = 0.019$, respectively). Relative theta power was significantly decreased with activity in all comparisons (running < sitting, $p < 0.0001$; running < walking, $p = 0.025$; walking < sitting, $p = 0.023$). Time of day had a significant effect on relative beta ($p = 0.002$) and gamma ($p = 0.0009$) power, with the *post hoc* test revealing an increase in these metrics in the PM (Figure 3). There were no significant effects on sample entropy and no significant interactions.

Figure 3: Individual AM vs. PM relative gamma power.

Approximately half (73/144) of the sample entropy time series exhibited a systematic decay pattern over the 5-minute recording trial. These patterns had positive correlations with the high-frequency (beta and gamma) bands and negative correlations with the low-frequency (delta, theta, and alpha) bands (Figure 4). A mixed-effects logistic regression model showed no significant effects of the experimental factors on the presence/absence of decay behavior.

Figure 4: Representative time series of EEG metrics showing a settling pattern with entropy-band power correlations.

DISCUSSION

The large overall intra-subject EEG variabilities observed in this study are important for establishing clinically significant effect sizes for quantitative EEG metrics. For example, studies on Alzheimer's disease (AD) and post-concussive syndrome (PCS) patients have shown a slowing of the EEG rhythm compared to healthy controls (AD: +8.60% in absolute theta power [5]; PCS: +28.6% in absolute theta power [6]). In this case, the effect found in AD falls within our observed normal spread of intra-individual variability—the effect size may be too small to indicate altered brain function in a clinical setting.

Decreases in relative theta power associated with exercise have been reported in the literature [7]. This effect was obtained after subjects performed strenuous exercise, while the decrease in relative theta power observed in our study after a 3-minute walk demonstrates that even small amounts of physical activity can influence EEG measurements. The observed effects of exercise on theta and alpha power indicate an acceleration of the EEG rhythm after physical activity, characteristic of heightened cognitive function or alertness. The large increases in delta power after running may point to residual sweat artifacts—standard artifact removal methods (filtering and ICA) may not be completely effective in EEG applications involving physical activity.

The literature on the circadian rhythm and diurnal cycles of alertness suggests a decrease in alertness and wakefulness in the afternoon [8]. However, the increases in relative beta and gamma power in the afternoon sessions of our study reflect an increase in cognitive activity later in the day. Post-session questionnaire responses explain this unexpected result—while participants indeed reported lower alertness during afternoon sessions, they reported higher thought complexity. This may cause increased high-end spectral power despite the “post-lunch dip” in alertness.

The sample entropy and relative band power time series (Figure 4) reveal that EEG metrics can exhibit transient intra-trial variability. The absence of any significant fixed effects suggests that the observed settling pattern may be an intrinsic attribute of resting-state EEG recordings. The time required for EEG metrics to reach steady-state should be considered in future quantitative analyses of continuous EEG.

This study explored the intra-individual variability of quantitative EEG measurements over repeated trials, which can help to establish a baseline for interpreting results in clinical applications. Our findings can be made more relevant in ambulatory settings by using the same mobile EEG system outside of a controlled environment. Subsequent studies could also use a larger and more varied participant sample to account for within-subject parameters such as differing responses to exercise, diurnal/nocturnal preferences, and sex differences. Finally, the overall power spectrum shape should be further evaluated as a resting state EEG metric for its potential to have excellent test-retest consistency [9].

MODULATING THE AXIAL DISPLACEMENT OF TWO PHOTON POLYMERIZED HUMAN LAMINA CRIBROSA MODELS

Brock J. Pemberton (1), Remi J. Shittu (1), Jonathan P. Vande Geest (1,2,3)

INTRODUCTION

Primary Open Angle Glaucoma (POAG) is a leading cause of irreversible blindness and is expected to affect 110 million people by 2040 [1]. It is known that in patients with POAG, the lamina cribrosa (LC) becomes remodeled during the progression of the disease [2]. The LC is a porous disc located in the optic nerve head which supports retinal ganglion cell (RGC) axons as they exit the eye [3]. It is suspected remodeling of the LC leads to RGC death and then blindness. Elevated intraocular pressure (IOP) can be another risk factor of POAG. It is suspected that elevated IOP may play a role in LC remodeling, however there are cases of POAG without elevated IOP [4].

It would be very beneficial to model how elevated IOP may remodel the LC. If high fidelity two photon polymerized (TPP) models of the LC can be produced, their mechanics should be quantified. Ideally, the models' mechanics should match the mechanics of a real LC. The purpose of this study was to alter the stiffness of the fabricated LC and to investigate differences in anterior to posterior displacement of the fabricated LC.

METHODS

Model LCs were produced using an Olympus BX51 upright laser-scanning microscope (Insight DS+, Spectra Physics, Santa Clara, CA) controlled with a custom Python script. The laser polymerized NanoscribeTM IP-PDMS at a wavelength of 780nm. Models that were polymerized twice had the script run two times in the same area.

The models were developed for 20 min in 70% ethanol before allowing to air dry. The models measured approximately 2.5mm in diameter. They were then placed over a 2mm diameter

biopsy punched hole in a PDMS sheet. The edges were sealed with liquid PDMS and cured at 60°C for 1 h.

The mounted LCs were placed into a custom Intravital Bioreactor, where pressure was applied to the model using an ElveflowTM OB1 Microfluidic Flow Controller and DI water (Figure 1). Pressure was applied for a range of 0-67.5mmHg in increments of 11.25mmHg.

Two photon imaging was used to measure axial displacement, where the z-depth of the focal plane where the model LC appeared brightest was recorded for each pressure (Figure 2).

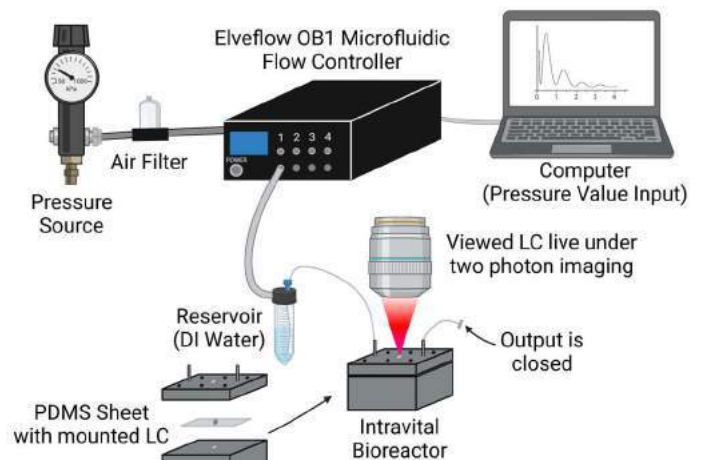

Figure 1: Experimental setup [5]

Figure 2: 3D max intensity projection of a twice polymerized LC prior to pressurization (4X, ex: 780nm, em: 620nm)

RESULTS

Preliminary results show that polymerizing a model LC an additional time before development results in a smaller posterior displacement under pressure (Table 1). Furthermore, the rate at which the displacement increases with increasing pressure for a twice polymerized LC appears to be about 0.7 times that of an LC polymerized once (Figure 3).

Table 1: Pressure and Displacement for polymerized LCs

Pressure (mmHg)	1x LC Displacement (μm)	2x LC Displacement (μm)
0.00	0.0	0.0
11.25	189.8	159.4
22.50	373.8	320.6
33.75	596.5	434.1
45.00	737.9	548.8
56.25	900.1	621.9
67.50	1017.6	714.9

Figure 3: Displacement versus pressure for a once and twice polymerized LC

DISCUSSION

The results show that repeating polymerization of a model LC decreases its axial displacement under pressure. This is consistent with expected results. A second polymerization further cures the photoresin. This increases the stiffness of the model and results in a lower displacement when put under the same pressure as a once polymerized model.

These findings complement previous work that produced models of the LC [6]. It should be noted, however, that these models were produced using subtractive manufacturing, while this study tested models produced using additive manufacturing. Prior to this study, models were similar to an LC in geometry only. These results suggest that it is possible to tune the biomechanical response of patient specific human LCs for future mechanobiological studies.

There are several limitations to this study. In the present study, only one sample for each of the degrees of polymerization were fabricated. Additional models must be created and tested to determine whether there is a statistically significant difference in axial displacement as a function of degree of polymerization. For example, models that have undergone three or more polymerizations would be interesting to compare.

In addition, there is likely some variability in the displacements due to human error. Often, it was difficult to judge at which z-depth the LC was the brightest, since there typically was a z-range where the model was visible, and its morphology changed as it deformed under increasing pressure. However, this may only have offset results by tens of microns. This variability would not have been large enough for the two LCs displacements to be the same overall.

In the future, data similar to that presented here may be used to estimate the biomechanical properties of patient specific LC models. Furthermore, these values may be compared to those derived from *in vivo* studies. Future work will continue to fine tune the biomechanical response of these surrogates for use in studies quantifying LC mechanobiology.

NINTENDO LABO FOR SERIOUS GAMING

Amanda M. Wells (1), Logan M. Suiter (1), Jacob G. Colwell (1), Joshua A. Gargac (1),

(1) Department of Mechanical Engineering, Ohio Northern University, Ada, Ohio,
USA

INTRODUCTION

Serious gaming is the practice of using video games, either commercial or specifically designed, for physical rehabilitation. Serious games have emerged in the last decade as a way to increase patient involvement in rehabilitation, increase the likelihood of patients continuing treatment after progress stalls, and generally increasing mental health during treatment [1]. However, the current literature has not kept pace with the evolution of technology and therefore the use of next-generation consoles for serious gaming is underdeveloped. The Nintendo Switch™ (Nintendo, Kyoto, Japan) console could provide new avenues for serious gaming because of the advanced sensing ability of its controllers (Joy-Cons), and the engaging ways in which the Joy-Cons can be used. Joy-Cons are equipped with acceleration sensors, gyroscopes, and infrared depth sensors, and are capable of near field communication and high-precision vibration.

Nintendo has demonstrated the capabilities of these Joy-Con with its LABO™ product. Nintendo LABO is a DIY kit that allows users to build cardboard mechanisms that house the Joy-Cons, called Toy-Cons [2]. Each LABO kit comes equipped with games that can be played by mapping physical motions of the user to the in-game controls. The goal of this research is to 1) identify candidate Toy-Cons for serious gaming, 2) track joint motion with commercially available software, and 3) biomechanically evaluate joint motion while playing the Toy-Con games. Specifically, this study primarily evaluated the fishing rod Toy-Con game from LABO Kit 01 because the game involved repetitive movements utilizing the shoulder, elbow, wrist, and hand, ideal for occupational therapy. Long-term, this data will be compared to current practices employed by occupational therapists for rehabilitation.

METHODS

A total of 5 test participants (2 male and 3 female) between 20 and 22 years of age were analyzed under IRB approval. Motion was tracked using Cortex Software (Motion Analysis Corporation, Santa Rosa, CA) [3]. Reflective markers were attached to the joints involved in the motion while using the Nintendo LABO fishing pole (Fig.1). The markers were placed on the subject's shoulder, elbow, wrist, and hand (Fig. 2). The motion capture system recorded the motion in all three planes of motion by taking position data of each reflective marker at 100 frames per second.

Figure 1: Nintendo LABO fishing pole Toy-Con and fishing interface (game).

Data was collected by utilizing six motion capture cameras located precisely around the subject. The cameras were calibrated before data collection. The subject was positioned so each joint marker was visible by at least 3 cameras. Once the recording started, the subject played the game by flexing and extending their right elbow parallel to the sagittal

plane to precisely move the in-game fishing hook up and down. Rotating the wrist allowed the participants to either reel the virtual fishing hook up (cw. rotation) or down (ccw. rotation). All of the participants were instructed to use their right arms and to hold the fishing rod in their laps relaxed. Each participant was seated in a chair placed one-foot away from the Nintendo Switch screen. The computer software collected and stored position data for each joint marker every frame. To avoid ghost markers, data was collected in dimly lit conditions with undesired reflective material hidden from the cameras. Data was cleaned using Motion Analysis' Cortex Software which allows for active joint motion tracking using the reflective markers referred to as the active marker system. The software utilizes the Ikendo Solver to make precise and accurate calculations [4]. Lost marker data was interpolated by the software utilizing the cubic join and rectify operations filling in any gaps in the recorded data.

Figure 2: Joint markers were placed at the shoulder, elbow, wrist, and hand.

The data was exported and evaluated using MS Excel (Microsoft, Redmond, WA). The shoulder points were used as the origin for relative position vector analysis. The elbow joint and wrist joint angles were calculated in the appropriate planes (Eqn. 1).

$$A \cdot B = |A||B|\cos\theta \quad (1)$$

RESULTS

The data for the fishing rod show the extremes of wrist and elbow flexion during gameplay (Fig. 3). Both the elbow and wrist angles change in a periodic fashion, and the amplitude of the angle variance changes between subjects. The motion observed can be broken down by joint into both flexion and extension. Flexion involves decreasing the angle formed by the bones of the joint, and extension is increasing the angle that is formed by the bones within the joint.

Figure 3: Joint angle variation during 15 seconds of fishing gameplay.

Across five subjects, the average min and max joint angles for both the wrist and the elbow joints were found (Tab. 1). These angles are

achieved when the elbow and wrist go through flexion and extension, and this motion is repeated during game play which is ideal for occupational therapy. On average, the participants completed 20 flexion-extension cycles for both the elbow and wrist joints during the 15 seconds of recorded gameplay.

Table 1: Minimum and maximum angles for elbow joint

	Avg. Maximum Angle (deg)	Avg. Minimum Angle (deg)
Elbow	138.0 ± 21.1	69.2 ± 20.6
Wrist	178.0 ± 32.8	120.0 ± 13.8

DISCUSSION

The primary areas of rehabilitation are the fingers, wrist, elbow, shoulder, and brain [5]. Typical ranges of motion (ROM) for effective rehabilitation of the elbow are from 0° (straight arm) to 121° of flexion for a total angle displacement of 121° [6]. The data suggests that the elbow went through both flexion and extension, between the angles of 54.25° and 163.74° for a total angle displacement of 109.49°. Overall, the motion from the fishing game accounted for 90.4% of the recommended rehabilitation ROM. For wrist flexion and extension recommended ROM is -40° of extension and 38° of flexion for a total displacement of 78° [6]. The data from the fishing game shows that the wrist went through both flexion and extension, between the angles of 89.41° and 179.97° for a total angle displacement of 90.56°. This is 116.1% of the overall recommended rehabilitation range of motion.

The data suggests that the LABO products could be useful in occupational therapy, and further study should be performed to evaluate the remaining Toy-con assemblies. A greater adoption of the Nintendo Switch could have many benefits. Commercially developed games are interactive and fun, which is important for patient retention. Additionally, Nintendo offers four LABO kits each with their own set of Toy-Cons (14 total). This opens the opportunity for different types of motions to be targeted in therapy. Additionally, the Nintendo LABO products are commercially available at a relatively low cost providing ease of access to therapy clinics. Lastly, the Nintendo Switch and LABO products could even be altered to better perform occupational therapy tasks.

ACKNOWLEDGEMENTS

OPTIMIZATION OF MOUNTING METHODS FOR TENSION-COMPRESSION TESTING OF MURINE INTERVERTEBRAL DISC JOINTS

J. Veres (1), S. Lim (2), G. D. O'Connell (2,3)

- (1) Bioengineering, University of California Berkeley, Berkeley, CA, U.S.A.

INTRODUCTION

Intervertebral discs are soft tissues found between vertebrae that give the spine flexibility, distribute mechanical load, and dissipate energy¹. Disc degeneration is a broad diagnosis, characterized by tissue damage through age-related wear-and-tear that often causes pain, limits mobility, and negatively impacts a patient's overall quality of life². Approximately 40% of adults over age 40 and 80% of adults over 80 have some degree of disc degeneration³. Since the primary function of the disc is to withstand large complex loads during daily activities, mechanical properties are a popular metric for assessing changes with degeneration.

Mice are a commonly used animal model for studying the progression or regeneration of disc disease and damage, because they can be genetically manipulated, and their discs are biochemically and mechanically similar to human discs⁵. However, due to their small size and, therefore, high sensitivity to changes in position and environment, assessing material properties of mouse discs can be challenging. In the literature, current methods of testing murine discs require expensive custom jigs or are not described well enough to replicate the methods used, making it difficult and expensive to conduct these tests. The objective of this study was to create an inexpensive, open-source method to mechanically test murine discs that was repeatable across samples and kept the disc as close to physiological alignment and tissue hydration as possible.

METHODS

Sample Preparation Lumbar columns (L1-L5) were acquired from mice through a sample sharing program at UC Berkeley. The spines were stored at -20°C until they were prepared for material testing. Preparation consisted of removing tissue from the lumbar column to expose the discs. Then cuts were made through the transverse plane of the L1/2 and L3/4 discs. Finally, the posterior bony processes were removed, leaving a L2/3 and a L4/5 bone-disc-bone motion segment.

Mechanical Testing Mechanical testing was conducted on an Instron 3400 Series Universal Testing System (Illinois Tool Works Inc., Norwood, MA) and consisted of 20 cycles of tension-compression between -1.0N and +1.0N. All samples were mounted according to one of the variable mounting techniques described below, then loaded into the Instron with the clamp ends fixed. In the final mounting protocol, samples were hydrated for 15 minutes in saline polyethylene glycol (sPEG) before testing⁶. A 17% wt/vol concentration sPEG was used to prevent the tissue from overhydrating before testing. The neutral zone (NZ), compressive, and tensile stiffnesses were measured and normalized to specimen geometry. Compressive and tensile stiffnesses were calculated by curve fitting for data between 80-100% of the maximum applied load (Figure 1A – red lines), and the NZ was determined using the double sigmoid curve-fit method⁷ (Figure 1B – blue line). Data is presented as mean±standard deviation.

Figure 1. Representative axial-tension compression curves with tensile and compressive stiffnesses and neutral zone highlighted.

Success Criteria The relative success of each mounting method was based on 6 criteria: 1) the transverse plane of the disc remained parallel to the applied load, 2) the disc was kept in a physiologically neutral position, 3) the sample was not damaged, 4) the sample remained fixed in the mount, 5) the disc stayed hydrated during testing, and 6) a tertiary load-displacement curve was observed and repeatable.

Sandpaper Mounting Methods The first sample fixation method consisted of fixing each vertebral body between two sheets of sandpaper with cyanoacrylate (n=6, Figure 2A). The second sample fixation method was identical to the first, but polymethyl methacrylate (PMMA) was used instead of cyanoacrylate (n=7, Figure 2B).

SAM Box Mounting Methods The third method introduced the first iteration of the Sample Aligning Mechanical testing Box (SAM Box). For SAM Box Version 1 (V1), the sample was potted in PMMA in 3D printed pieces that were connected with thin bridges. After the PMMA was cured, the bridges were cut, allowing for each side of the joint segment to articulate separately (Figure 2C). The 3D printed pieces were then loaded into the Instron clamps (n=7).

Figure 2. Sample mounting methods. A, B) Cyanoacrylate and PMMA sandpaper methods, C-E) SAM Box Versions 1-3 (V1-V3).

The second iteration of the SAM Box (SAM Box V2; Figure 2D) removed the alignment bridges, instead relying on clamps and the Instron to pot samples directly in their testing configuration (n=6). However, PMMA curing times in the testing configuration led to tissue dehydration prior to testing.

The third iteration of the SAM Box (SAM Box V3) added a bath around the sample, allowing for a 15-minute hydration period after PMMA curing but prior to sample testing (n=7, Figure 2E).

RESULTS

Failed Methods The sandpaper cyanoacrylate method failed 4/6 samples tested. Using this method, the sample did not remain fixed to the sandpaper during testing, parallel alignment was highly variable, and cyanoacrylate often oozed onto the disc. To address this, PMMA was used instead of cyanoacrylate, which limited oozing and created rigid fixation to the sandpaper. However, the sandpaper PMMA method also failed, with 5/7 samples failing. Using the sandpaper and PMMA, parallel alignment was difficult and highly variable.

To improve sample alignment, the SAM Box V1 was used to orient samples during potting. This retained rigid fixation and physiological alignment, but because samples were potted prior to testing, the mounting process often applied unwanted bending or torsional stresses on the joint segment. This led to failure of 7/12 samples. Next, samples were potted in place on the Instron using the SAM Box V2 method. This addressed the alignment difficulties, kept rigid fixation, and protected the disc from extraneous glue, however the added drying time led to sample failure, with 4/6 of the samples failing.

The SAM Box V3 The SAM Box V3 was the most successful prototype with the success criteria being met for all 7 samples. The added bath of the SAM Box V3 allowed for tissue rehydration prior to testing. This method was easy to use, kept samples hydrated and

aligned, and consistently produced load displacement curves that agreed well with data reported in the literature.

Axial compression-tension mechanics were measured with SAM Box V3. The normalized compressive stiffness was 4.177 ± 1.487 MPa, normalized tensile stiffness was 2.830 ± 1.271 MPa, and normalized NZ stiffness was 0.238 ± 0.138 MPa, and (Figure 3).

Figure 3. Normalized stiffnesses from SAM Box V3 pilot testing.

DISCUSSION

The SAM Box V3 is a mounting method for murine lumbar disc joints that is easy to use, inexpensive, and mimics physiological conditions. Each SAM Box V3 costs about \$1.00 in polylactic acid filament and takes about an hour to print on an Ultimaker 3.

The results presented here align well with published results. Sarver et al., reported a normalized NZ stiffness of 0.58 ± 0.45 MPa, a normalized compressive stiffness of 3.65 ± 0.98 MPa, and a normalized tensile stiffness of 2.54 ± 0.44 MPa⁸. Additionally, Choi et al. reported a normalized compressive stiffness of 5 ± 0.5 MPa⁹ using a similar test protocol. These results suggest that the SAM Box V3 method is consistent with other methods used in the field, while being cheaper and more adaptable to different fixturing methods.

Despite the consistent results presented here, there are limitations to the SAM Box V3. First, testing was performed at room temperature rather than body temperature (37°C); however, we chose to test at room temperature to better match methods used in the literature for comparison. Additionally, adding 3D printed fixtures to the load chain may result in increased in machine compliance, which needs to be accounted for when analyzing mechanical test data. However, because the applied loads are minimal (approx. 1N), it is unlikely that the 3D printed boxes will experience large deformations.

Overall, the SAM Box V3 allows for easy mounting, gripping, and testing of murine disc joint segments while maintaining hydration and alignment. It is a low-cost method that can be applied in tensile-compression mechanical tests, which is important for studying disc mechanics with degeneration, injury, or regeneration.

INTRODUCTION

As recently as the last decade, there has been an increased focus on improving efficacy of organ preservation processes for improved transplantation outcomes [1]. The most common approach to organ preservation is static cold storage (SCS), but studies have shown that this method is linked to time-dependent ischemia injury and limited preservation times [2]. More recent methods involve machine perfusion (MP), which prevent ischemia by perfusing the organ with an oxygen-rich blood substitute. Current devices on the market for MP have significant drawbacks to consider. Oftentimes they are bulky and heavy, requiring a cart for mobility purposes. In addition, they can be complicated to operate. In some instances, necessitating an additional person for procedural use. The most limiting aspect of the current devices on the market is their single organ type design, thus creating the difficulty of training personnel on proper use for each device. Our team focused on the drawbacks of the current devices on the market and attempted to solve the bulk of them.

We have designed a versatile oxygenating perfusion system (VOPS) to reduce time-related ischemia injuries and improve the likelihood of organ viability for replantation. The VOPS device was designed to preserve tissues by maintaining a homeostatic environment and allowing oxygen circulation within the tissue, those incorporating MP. It is dimensionally sized to be able to preserve a small limb, heart, kidney, pancreas and liver, and able to be carried by a single person. Some organs require different solutions to maintain organ circulation. We hypothesized that this device is capable of perfusing different levels of viscosities (1-6.5 cP) to the same standard as phosphate-buffered saline (PBS) to improve blood mimicking capabilities [3].

METHODS

Pressurized oxygen was delivered to the tubes in a pulsatile fashion that caused a cyclical effect of inflation and deflation of the tubing. As the pressurized oxygen entered the tubes, the pressure within the pump chamber increased above the hydrostatic pressure in the main organ

chamber. This caused a pressure difference that forced a bolus of oxygenated fluid from the main chamber into the pump chamber through the perfusion port[2]. During the pulsatile process, the silicone tubing experienced deflation, this dropped the pressure in the pump chamber beyond the pressure in the main organ chamber thus a bolus of oxygenated fluid was then forced back into the pump chamber; this process allowed for a pulsatile flow of oxygen throughout the device.

Figure 1: VOPS Device Design Components

VOPS is composed of four main components: the top cap (must be screwed into place onto the pump chamber), helical silicone tubing (Silastic® Laboratory Tubing, DuPont de Nemours, Inc.), pump chamber, organ chamber and base cap. Silicone tubing was placed in the most efficient formation of helical shape and was chosen because it allows oxygen to permeate through its walls[2]. The pump chamber contains the helical silicone tubing that is 6.1 m in length; the organ chamber contains fluid and vascular resistance element. The vascular resistance element is silicone tubing cut to a length that intends to mimic

the resistance a kidney would experience during normal blood flow (0.22 mmHg/mL/min) and was derived from previous research and literature[2]. The device includes six latches that secure the pump chamber to the organ chamber, and O-rings designed to ensure the device has an air-tight seal. The device was manufactured in-house at The University of Texas at San Antonio's machine shop. The top cap, pump chamber and base cap were made of 6061 Aluminum. A silicon tube holder was 3-D printed in-house (Clear Resin, Form 2, Formlabs) to ensure that helical tubing did not kink or compress. The organ chamber was made of acrylic. Use of medical-grade epoxy allowed the organ chamber to be secured in place with the base cap. The pressures that were used for testing are as follows: 27.6, 55.2, 82.7, and 110.3 kPa. Pressure transducers (PX309-030G5V, Omega Engineering, Inc.) were attached to the inlet of the vascular resistance-mimicking PVC tubing and the main organ chamber. The measured difference between the pressures at these tubes indicated the perfusion pressure. The flow rate was measured via a sensor (2PXL-TS410, Transonic Systems Inc.) attached to an exterior flow loop located outside of the device. The pressure transducers and flow sensor provided data that was recorded via a LabVIEW virtual interface (NI 9221 and NI USB-9162, LabVIEW 2019 SP1, National Instruments) and distributed to MATLAB (MATLAB R2020a, The MathWorks, Inc.) for calculation and analysis. Testing was conducted using a pneumatic switching setup with a pulse frequency of 0.25 Hz, 50% duty cycle (2000 ±100 ms open, 2000 ±100 ms closed). This approach allowed the entire system to be mechanical, without the need for batteries or electronic control. The procedure for viscosity testing started with the mixture of anhydrous calcium chloride (Flinn Scientific, Inc, Batavia, IL, USA) and deionized water, the table below describes the viscosity mixture procedure. A Cannon-Fenske Viscometer (CANNON Instrument Company, State College, PA, USA) was used to find the viscosity of the aqueous solutions with the varying mass percentage.

Table 1: Viscosity Mixing Procedure

Viscosity	Mass %	To create a 4 L solution	To create a 1 L solution
1 cP	0%	4000 mL H ₂ O, 0 g CaCl ₂	1000 mL H ₂ O, 0 g CaCl ₂
3 cP	31.53%	3204 mL H ₂ O, 1472.77 g CaCl ₂	801 mL H ₂ O, 368.2 g CaCl ₂
5 cP	37.47%	3023 mL H ₂ O, 1808.2 g CaCl ₂	756 mL H ₂ O, 452.21 g CaCl ₂
6.5 cP	39.99%	2942 mL H ₂ O, 1957.0 g CaCl ₂	736 mL H ₂ O, 489.58 g CaCl ₂

Five tests were performed at each mass percentage and the resulting viscosity data were output in centiStokes[3]. The average of these tests was obtained as the viscosity at the respective mass percentage.

RESULTS

The results of these tests required gathering data both using a baseline parameter set and a tuned set to collect peak perfusion and mean flow rates. Baseline data was accumulated using constant variables of vascular resistance and silicone tube length, however, incorporated varying oxygenation pressures (27.6 to 110.3 kPa). Table 2 shows the peak perfusion pressure (mmHg) and mean flow rate (mL/min) for each of the tested viscosities for both baseline and tuned test results.

Table 2: Viscosity Test Results

Viscosity (cP)	Peak Perfusion Pressure (mmHg)		Mean Flow Rate (mL/min)	
	[Baseline/Tuned]		[Baseline/Tuned]	
1	29.3 - 96.8	15.5 - 70.0	2.5 - 13.2	4.0 -19.4
3	17.2 - 47.5	22.4 - 83.8	5.0 - 16.0	6.4 - 28.2
5	8.6 - 49.2	11.8 - 54.5	1.5 - 12.7	5.2 -26.8
6.5	4.8 - 30.1	5.3 - 24.2	0.6 - 5.7	1.4 - 12.6

The trend that was displayed for this testing showed an inverse relationship with viscosity and peak perfusion pressures. As the viscosity increased, the peak perfusion pressures decreased, regardless of oxygen pressure rate [3]. However, this relationship did not translate to the mean flow rates. The tuned pulse frequency and duty cycle showed a trend of decreasing peak perfusion pressures and increased the mean flow rates. The use of the vascular resistance validates the VOPS device's capacity to deliver the appropriate peak perfusion pressures and mean flow rates within a targeted range gathered by data collected in porcine kidney preservation studies performed by Urbanellis et al. for each viscosity tested[4].

DISCUSSION

The VOPS device has competitive advantages over the current organ preservation devices available on the market due to its portability, versatility, and low cost. Our results indicated ideal viscosity for the current design of the VOPS device in terms of balancing oxygen supply pressures to reach appropriate perfusion parameters for the preservation of a human kidney. While the VOPS device met the perfusion parameters at more oxygen supply pressures with one tested viscosity, all viscosity solutions tested reached the flow parameters essential for kidney preservation. This provides evidence that the VOPS is highly versatile as it can potentially be used with several preservation solutions that are required for various organs.

INTRODUCTION

According to the National Council of State Boards of Nursing, 87% of nursing schools are using high-fidelity mannequin-based training in their curriculum.¹ Simulation mannequins provide an immersive learning environment by mimicking real-life clinical scenarios that healthcare workers will potentially encounter in the field. This allows nursing students to train and enhance their skills and competencies in a controlled and risk-free environment. Although today's mannequins are equipped with multiple intricate features that significantly enhances simulation experience, there is still a need for improvement of realism in several basic clinically relevant attributes. For example, the absence of blood flow in mannequins prevent nursing students from using regular pulse oximeters to measure pulse rate and SpO₂ levels.

Both SpO₂ and pulse rate are vital measurements that can indicate different life-threatening conditions (such as acute respiratory distress syndrome, pneumonia, heart failure, etc.). Hence it is important that nurses are trained to read these measurements and determine a plan of action based on the readings.

Currently, there are 2 methods that nursing instructors implement in mannequin-based simulation laboratories which allows nursing students to analyze pulse rate and SpO₂ levels. (1) In high-fidelity mannequins that have the capability to reflect physiological measurements on a monitor, the instructor sets the pulse rate and SpO₂ levels prior to the simulations. During the simulation lab, the nursing students read the measurements from the monitor and makes appropriate interventions based on their observation. (2) In mannequins that aren't equipped with these features the students during simulation use a regular pulse oximeter to mimic the action of clipping it to a finger and when completed correctly the instructor announces the measurements based on the clinical situation being simulated. Neither of these techniques are realistic. Furthermore, these options don't

respond to real-time intervention, that is if the nurses are taking an action such as injecting a drug the numbers don't automatically change in real-time based on this action.

Therefore, the aim of our project is to create a realistic (both visually and operationally) stand-alone pulse oximeter device that can be integrated into any simulation mannequin irrespective of make or model. The device should be able to reflect normal measurements and disease conditions based on the clinical situation being simulated by the instructor. Lastly, the device should be able to update its values in real-time in response to intervention from nursing students during simulation labs.

Figure 1: Sketch of the external case (done in Inventor 2020)

PRODUCT DESIGN

Design: Based on our design criteria and constraints the team proposed an app-controlled Bluetooth-based pulse oximeter device as a potential solution.

The design consists of a 3D printed finger-clip casing (Figure 1) that mimics the appearance of an alligator clip pulse oximeter and houses all the electronic components (Figure 2). The device operates via an Arduino mini-UNO microcontroller board that is connected to a wireless Bluetooth receiver, a LED light, a force transducer, and an OLED display. The Bluetooth receiver obtains pulse rate and SpO₂ values transmitted from an app designed using MIT App Inventor (Figure 3). An LED light included underneath the top surface of the case mimics the light

Figure 2: Sketch of the electronic components housed inside the case.

Instructor set-up: The app can be accessed by the instructor either from a cellphone or a computer. Prior to the simulation lab, the instructor sets the appropriate values on the app based on the clinical scenario being simulated and hits submit to transmit the data to the Bluetooth receiver.

Figure 3: Schematic of the App

Nursing student use: During simulation the nursing students will clip the device onto a simulation mannequin's finger and turn on the device using the push button switch. As the force transducer gets activated by the pressure from the finger, the values submitted by the instructor prior to the simulation is displayed.

Real-time intervention: Based on the observed SpO₂ and pulse rate measurements, if the nursing students plan and execute a course of action, the instructor can update the measurement values to reflect the effect of their action real-time via the app. The updated values will help the nursing students analyze their treatment plan and act accordingly based on improvement or deterioration in the observed measurements.

Design Analysis: There are several benefits of the design. It is easy to use for both the nursing students and instructors, as all that the students need to do is place the device on the mannequin's finger and turn it on and all that the instructor does is adjusts the values through an app. The device is interchangeable on any mannequin's finger (pediatric, adult, low-fidelity, high-fidelity, etc.) as all the device requires is a finger for the force sensor to be activated. The 3D printed casing replicates any over the counter pulse oximeter and the mechanism to operate the device mimics the same both of which

source of an actual pulse oximeter to enhance realism (Figure 1b). The force transducer placed on the inner surface of the case is activated when the device is clipped onto a finger which allows the values transmitted via the Bluetooth to be shown on the OLED display. The case contains a push button switch to turn the device on or off.

enhances realism. The device is designed to encase all electronic circuitry and the battery inside a 3D printed case for safety purposes. The device is equipped with a feedback mechanism that allows nursing students to analyze their intervention during a simulation lab.

BUDGET & MARKET ANALYSIS

According to the 2022 "Mannequin-Based Simulation-Global Market Trajectory & Analytics" report², despite the COVID-19 issue, the global market for mannequin-based simulation, which was earlier predicted to be valued at US\$1.4 billion in 2020, is now estimated to grow to US\$3.7 billion by 2027 at a compound annual growth rate (CAGR) of 14.4%. Patient simulators, one of the market segments the report looked at, is projected to develop at a CAGR of 13.9% and reach US\$2.5 billion by the conclusion of the analysis period. This shows that although the demand for simulation mannequin-based training had increased during the global pandemic (due to the limitations of on-site clinical training), the need has not subsided, and the post-pandemic market continues to grow.

Since our product is vendor independent it can be integrated into already-existing mannequins as well as newly manufactured ones which allows us to address a very large market. The parts cost to build this device is projected to be less than \$150. Given that more than 87% of nursing schools incorporated simulation-based mannequins of some form the team anticipates producing about 50,000 pulse-oximeter units each year to be incorporated both with existing and newly manufactured mannequins with a selling price of \$500 per unit. Since mass production will reduce the cost of parts, the projected income from selling one unit is estimated to be greater than \$350. This income will be used for advertisement, lab space rent, salary for engineers and employees and other related expenses. The team predicts that the device should still provide an overall profit of \$150 per device.

ACKNOWLEDGEMENTS

We would like to extend our thanks to Widener University's School of Nursing for allowing us access to their simulation lab and providing us with feedback.

INTRODUCTION

High grade serous ovarian carcinoma (HGSOC) accounts for 90% of deaths as a result of ovarian cancer [1]. Additionally, in the U.S. the median age at diagnosis is 63 and most cases are in post-menopausal women [2]. In contrast with the age of women diagnosed with HGSOC, most *in vivo* models of HGSOC use young animals. This discrepancy may add to the challenges of studying ovarian cancer, as aged animal models are expensive and require extensive care. The process of metastasis of HGSOC begins with an epithelial-to-mesenchymal transition (EMT), which promotes the migration of the cancer cells and decreases intercellular attachment [3]. The hallmarks of EMT include increased expression of alpha smooth muscle actin (α SMA) and Snail1, which promote increased cell migration and matrix remodeling. Recent work has indicated that EMT-like phenotypic shifts may be caused by mechanical forces [4]. To better understand how mechanical forces may drive changes in migration behaviors of ovarian cancer cells, we developed a microfluidic model for biomechanical studies of the tumor microenvironment. The objective of this project was to optimize a 3D microtissue model to study ovarian cancer cell migration. Additionally, we sought to use the microfluidic model to study the contribution of the senescent vasculature from aged tissues on tumor cell behavior.

METHODS

ID8 mouse ovarian surface epithelial cells with *Trp53* Δ deletion (ID8p53) are a previously established HGSOC model that allow for study of the tumor microenvironment [5]. ID8p53 cells were seeded into the center chamber of a three-chamber microfluidic device, where the tissue chambers are adjacent in series to each other [6]. Each chamber of the device is an independent microtissue connected with 20 μ m communication ports to allow cell migration and transfer of nutrients. The cells were suspended in a 9:1 fibrin-collagen matrix to mimic the natural tumor environment, with a total matrix protein concentration of 10mg/ml. The side chambers were loaded with blank, cell-free gels. The

devices were cultured for three days with a flow regime that prevented convective diffusion from occurring between adjacent regions. Before imaging, the left chambers of all devices were treated with TGF- β 1 (10 ng/ml), and an inward (left chamber to center chamber) flow was established. The right-hand chambers received control media with no exogenous TGF- β 1. The devices were imaged over either a 3hr period or an 18hr period with images taken every 5min or 30min, respectively. After treatment, cell migration was quantified using Chemotaxis and Migration Tool V2.0 [7]. After 24hr of treatment, the microtissues were fixed and stained for phalloidin and DAPI for immunofluorescence analysis to further characterize cell migration behaviors.

To measure how age associated vascular senescence differences alter ovarian cancer cell migration, we utilized human SKOV3 cells tagged with a GFP reporter in a conditioned media study. SKOV3-GFP cells were seeded into the center chamber of the device in the same conditions described above with the same 3-day period prior to introduction of conditioned media. On day 3, the left chamber of the device was treated with conditioned media from senescent human ovarian microvascular endothelial cells (HMECs) and the right chamber received conditioned media from non-senescent HMECs. The center chamber was fed with the control media. An inward flow direction was established that caused diffusion of factors in the media from side chambers towards the SKOV3-GFP in the center chamber. Images were taken at the time of initial treatment and every 24 hours for six days. The cells received fresh media every day. Migration into the side chambers was measured as percent area of fluorescence normalized to total area of the side chambers.

RESULTS

The results show that a prolonged exposure to TGF- β 1 is required to trigger a significant change in ID8p53 total migration distance (Figure 1A). For additional characterization, histograms displaying migration angles for individual cells were generated (Figure 1B, C).

Movement towards TGF- β 1 is indicated by 180°. The interquartile ranges (IQR), representing the middle 50% of the data, were determined to compare migration data trends. The immunofluorescence analysis shows that cell migrated into the left chamber with the TGF- β 1, but not into the right chamber (Figure 1D).

In conditioned media studies, our results show that over a period of 5 days, there is increased cell migration in the left chamber, towards the senescent conditioned media (Figure 2A). The differences in migration evened out on day 6. These differences in migration can also be seen in the immunofluorescence images. The left chamber of the microtissue model on day 1 of treatment shows higher levels of cell migration than the right chamber (Figure 2B). This trend is continued on day 5 (Figure 2C).

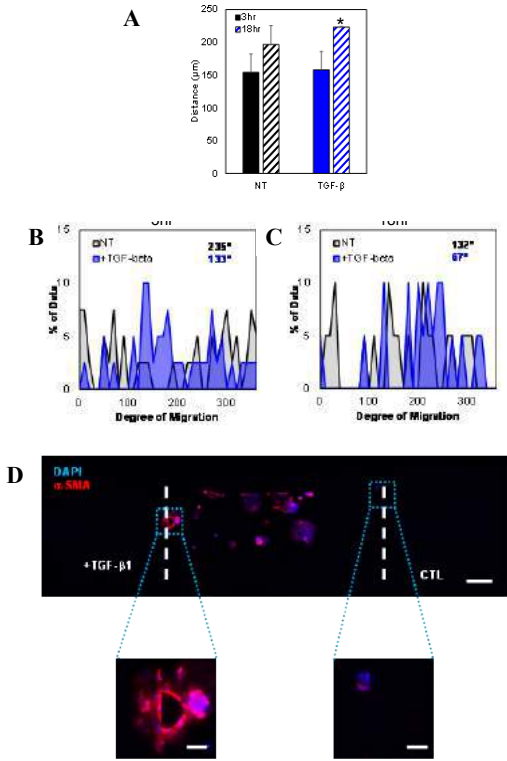

Figure 1: (A) Distance traveled by ID8p53 cells in the microtissue model. Averages \pm SEM shown. N = 2-4 devices, 20-40 cells. * $p < 0.05$ vs. 3hr NT. (B, C) Histograms showing angles of migration for cells in microtissue models. 180° represents migration towards the Left chamber, or source of TGF- β 1. Inset numbers are interquartile ranges (middle 50%) of all measured events, n=20-40 cells. (D) Representative images of microtissue model. Scale bar = 250μm. Tissue chamber borders (white dashed lines) and treatments are shown. (Below) Insets of regions near chamber interfaces. Scale bar = 50μm.

DISCUSSION

Our studies show that we can successfully track and characterize migration events for mouse and human ovarian cancer cell lines in our 3D microtissues models. We were able to control the matrix conditions, flow conditions, and the delivery of growth factors or conditioned media over multiple days while performing real-time imaging. In optimization studies with ID8p53 cells and TGF- β 1, we saw an increase in migratory behavior when exposed to TGF- β 1 over an extended period of time. Treatment with the growth factor resulted in a more directed migration,

indicated by the decreased IQR at both time points. The studies with the mouse cells allowed us to optimize the loading and fluid flow conditions, as well as the method of analysis. Moreover, our pilot studies with conditioned media from senescent endothelial cells demonstrated slight differential migration towards media from senescent cells compared to non-senescent, control cells. Our results suggest that secreted factors from senescent ovarian cancer cells may promote migratory behaviors. This could partially explain differences with ovarian cancer progression in patients of different ages. This proof-of-concept study will be used to develop future experiments to determine which factors may be responsible for the increased migration observed in senescent media-treated samples. Future work will also focus on further optimizing the microtissue model to allow for easier and less expensive study of HGSOc in an environment that closely mimics the natural tumor microenvironment.

QUANTITATIVE POLARIZED LIGHT IMAGING OF PORCINE PULMONARY VALVE LEAFLETS

Shreya Sreedhar (1), Connor Link (1), Daniel P. Pearce (1), Colleen M. Witzenburg (1)

(1) Department of Biomedical Engineering
University of Wisconsin-Madison
Madison, Wisconsin, USA

INTRODUCTION

Proper alignment of collagen fibers provides strength and support to heart valve leaflets, allowing them to effectively regulate blood flow through the heart. Aberrations in collagen alignment can cause changes in the mechanical properties of the leaflets and increase the risk of valve dysfunction and disease. Following altered loading conditions in the heart, the collagen alignment in the diseased/alterd region is known to rearrange [1]. Studying the full-field collagenous organization of a tissue can be a useful way to quantify its heterogeneous structural properties. A novel imaging technique using division-of-focal-plane polarimetry can be used to measure circularly polarized light transmitted through an unfixed tissue to rapidly quantify its collagen alignment [2]. Quantitative polarized light imaging (QPLI) is a useful tool used to study the full field collagenous organization of thin heterogenous tissues, which provides overall incident light intensity (S0), the angle of linear polarization (AoP), and the degree of linear polarization (DoLP) [3].

This method of quantification has been used previously in studying homogeneous tissues such as tendons and cartilage but has remained underutilized in structurally and mechanically heterogeneous cardiovascular tissues [2,3]. Our objective was to apply QPLI to pulmonary valve leaflets, which are thin heterogeneous cardiovascular tissues. We assessed the hypothesis that pulmonary valve leaflets would exhibit similar spatial patterns in AoP and DoLP to previously tested aortic valve leaflets [5]. We also evaluated the hypothesis that light intensity and tissue thickness are correlated, and we found a negative correlation between the two. These metrics provided by QPLI can help determine trends in the structural properties of pulmonary valve leaflets, and eventually be applied to the changes in properties in diseased states.

METHODS

Sample preparation. Pulmonary heart valves were excised from the hearts of 5–6-month old pigs obtained from a local butcher (Hoesly's Meats, New Glarus, WI). Leaflets were either frozen for later use or stored in phosphate-buffered saline (PBS) and tested within 24 hours. The leaflets were carefully placed on a black platform, ensuring to keep the sample flat. The leaflet was then scanned by the LJ-V7080 laser micrometer (Keyence) at an acquisition rate of 200 Hz to obtain a 3D thickness profile.

Fig 1: Sample leaflet

Imaging. In order to image the leaflet using QPLI, the sample was transferred to a glass platform using tweezers. The directionality of the leaflet was kept the same as on the black platform for consistency. The glass platform was placed on top of an LED light source with a circularly polarized light filter. The soft tissue was imaged with the highest intensity light setting. The image was obtained using the Polarization GUI (SpinView) at a 20 Hz acquisition frame rate and the "Polarized8" pixel format.

Data Analysis. The raw output data from the polarization GUI provides the intensity of light that passes through the soft tissue at different angles. S0, DoLP, and AoP were computed from the raw data as done previously [3,4]. S0 indicates the overall intensity of incident light. AoP

indicates the angle of linear polarization and is a measure of preferred collagen fiber angle. DoLP indicates the degree of linear polarization and is a measure of that preference, with a value of 0 showing no alignment and 1 showing total alignment. To determine trends between thickness, S0, and DoLP these values were plotted against one another for each leaflet. A Pearson's correlation coefficient (r) was calculated to quantify the correlation and a p-value was calculated to determine the significance of the correlation.

RESULTS

Fig. 2 includes a quiver plot of the AoP overlaid on the DoLP heatmap of a representative leaflet sample. The AoP vector is scaled to the amount of DoLP in that region. The belly region of the tissue exhibited low alignment, while the lower outer region of the sample exhibited high alignment. All samples showed this pattern, and these results are consistent with previously presented data on quantifying heterogeneity in aortic valve leaflets [5].

Fig. 3 includes the raw S0 and thickness values from QPLI and laser micrometry, respectively. The leaflets imaged had thicknesses ranging from 0.80 ± 0.01 mm to 1.2 ± 0.02 mm. A visual comparison suggests an inverse relationship between thickness and intensity - in regions of high thickness, there was typically lower intensity and in regions of low thickness there was typically higher intensity.

Fig. 3: S0 (left) and Unwarped Thickness (right) for a representative pulmonary valve leaflet.

In order to quantitatively compare each metric, the thickness for each leaflet was warped to fit into the border of the Intensity plot using a rotational matrix. Table 1 displays r values for comparisons between S0 and warped thickness, DoLP and warped thickness, and S0 and DoLP. Each metric was compared using pixel-to-pixel correlation. P-values for every sample were below $1e-10$. The average r value for S0 vs. thickness -0.5 ± 0.09 , indicating a negative correlation between the two metrics. This is consistent with the visual comparison between intensity and thickness. The correlations between DoLP vs. thickness and S0 vs. DoLP, remains inconclusive as there is a large standard error and no strong patterns. Fig. 4 displays the warped thickness, DoLP, and S0 for a representative leaflet.

DISCUSSION

QPLI is a useful tool that can provide full-field information about the collagenous organization of soft tissues, yet few efforts have been made to apply QPLI to structurally heterogeneous cardiovascular soft tissues. Useful metrics such as S0, AoP and DoLP were obtained for pulmonary valve leaflets. All samples showed similar regional patterns to previous studies [5]. We found that light intensity and thickness exhibited a

negative correlation, while thickness and DoLP, and S0 and DoLP were very weakly and weakly correlated, respectively. The strength of this negative correlation between S0 and thickness (-0.58), could indicate that variations in tissue density also impact S0 or that the warping of the thickness negatively affected pixel to pixel correlations. We computed the percent error of the warped thickness, and sample edges exhibited high error. This could be because the outside edges need to be warped most when expanding the tissue into the intensity border. While future work will further investigate the effects of warping there was a consistent negative correlation between thickness and intensity. DoLP of a soft tissue, however, showed weak and very weak correlations to S0 and thickness, indicating it will provide information independent to thickness and intensity on the degree of collagen alignment of a soft tissue. Future work will also include dynamic imaging of leaflets during biaxial loading. Dynamic imaging will provide more information on the collagen fiber alignment and rotation during alternative loading conditions, which can reveal more about the function of the tissue's extracellular matrix.

ANALYSIS OF THE FRICTIONAL FORCES DURING BLOOD CLOT REMOVAL IN EXPERIMENTAL MODELS OF ACUTE ISCHEMIC STROKE

Omar N. Elkhayat (1), Bryan C. Good (1)

(1) Department of Mechanical, Aerospace, and Biomedical Engineering, The University of Tennessee, Knoxville, TN, USA

INTRODUCTION

Every year in the U.S., over 800,000 people suffer from stroke, of which 90% are classified as acute ischemic stroke (AIS) [1]. AIS is defined by the obstruction of blood flow in an artery in the brain due to a lodged embolus. The “MR CLEAN” trial found that treatment of AIS was more effective with the addition of intraarterial treatment, defined as mechanical disruption of the lodged blood clot via mechanical thrombectomy (MT) [2]. Intraarterial treatment can be performed using either a stent retriever (SR) or an aspiration catheter. Although a high rate of recanalization (~85%) was found for patients treated with MT, a large rate of mortality and loss of function still occurred [3]. Currently, *in-vitro* models provide a more practical and cost-effective method of studying AIS and MT. However, Johnson *et al.* discussed the importance of characterizing vessel wall friction for the optimization of *in-vitro* modeling [4], as current experimental models do not accurately mimic the frictional and adhesive forces that occur *in-vivo*. The current gap in knowledge on AIS and MT biomechanics is the motivation for investigating the frictional interactions that occur between blood clots, materials used in *in-vitro* AIS models, nitinol materials found in SRs, and arterial walls. These findings will lead to an increased understanding of the forces involved in MTs, inspiring new surgical techniques and devices to further improve the treatment of AIS.

METHODS

For all experimental testing, custom 3-D printed attachments were made for use on a Single Column Material Testing System (Instron). Static friction testing was conducted similarly to Gunning *et al.* [5], and results were analyzed in ImageJ. Kinetic friction testing was conducted between embolus analogs (EAs) and materials commonly used in *in-vitro* models of AIS (glass, PVC, and silicone), bare nitinol material found in SRs, and carotid artery tissue samples. Additional friction experiments were also performed between a Solitare2 nitinol SR (4x40 mm) (Medtronic) and the same artificial and biomaterial surfaces.

To create EAs for static and kinetic mechanical testing, bovine blood (Lampire Biologic) was collected in CPDA-1 anticoagulated bags, centrifuged to separate red blood cells and plasma, and reconstituted to desired hematocrits (0-40%). Calcium chloride was added to promote coagulation in the blood, which then filled 3-D printed molds (20x20x10 mm) and clotted statically for 2 hours. EAs for static friction testing were formed in bare molds, while EAs for kinetic friction testing were formed in molds with one Velcro-lined wall. Velcro allowed for the fixation of one side of the clot during testing.

For kinetic testing, a modified lap-shear approach was used (**Fig. 1**). Before loading the sample onto the Instron, the initial height of the EA was recorded. The sample was then fixed onto the lower attachment and the testing material brought into contact with the EA. The compressed height of the EA between the slide and testing material was recorded. Having the initial and compressed height (strain) of the EA, the normal stress on the EA can be found using its Young's Modulus. Shearing occurred at 0.1 mm/s to minimize viscoelastic effects.

Fig. 1: A.) Instron with custom 3-D printed attachments for kinetic friction testing and B.) FBD of the testing set up.

For kinetic testing between the SR and various material surfaces, a custom 3-D printed attachment helped to translate the testing coordinate system (**Fig. 2**). The SR was unfolded on the testing material and a

weight was placed on the SR, providing a known normal force and to help keep the SR unfolded. To ensure that the coefficient of kinetic friction was accurately measured and did not change, two different loads were used during testing. The SR was pulled at approximately 2 mm/s to mimic rates used in *in-vitro* MT testing.

Fig. 2: A.) Instron with custom 3-D printed attachments for testing the Solitaire2 SR and B.) FBD of the testing set up.

RESULTS

The average coefficients of friction of EAs against various material surfaces are shown in **Table 1**. Overall, silicone experienced the highest friction between the EAs while nitinol experienced the lowest. This trend was consistent for all hematocrits in static testing as well as for the 40% EA kinetic tests. The coefficients of kinetic friction were also found to be lower than that of the static friction for all materials and EAs. An observed increase in friction corresponded with decreasing EA hematocrit. Statistical significance was found between the 0% and 40% EAs for all materials for static friction, as well as between the coefficients of static and kinetic friction for the 40% EAs.

Table 1: Average coefficients of static and kinetic friction of EAs against material surfaces, reported with a 95% CI.

EA Hematocrit	Sample Size	Coefficient of Static Friction	Coefficient of Kinetic Friction
Glass			
40%	20	0.096 ± 0.004	0.064 ± 0.010
20%	20	0.121 ± 0.010	-
0%	20	0.139 ± 0.012	-
PVC			
40%	20	0.106 ± 0.005	0.073 ± 0.015
20%	20	0.122 ± 0.006	-
0%	20	0.176 ± 0.032	-
Silicone			
40%	20	0.117 ± 0.005	0.078 ± 0.013
20%	20	0.134 ± 0.009	-
0%	20	0.223 ± 0.048	-
Nitinol			
40%	20	0.097 ± 0.003	0.031 ± 0.004
20%	20	0.115 ± 0.007	-
0%	20	0.128 ± 0.020	-

A summary of the average coefficients of kinetic friction during SR testing is shown in **Table 2**.

Table 2: Average coefficients of kinetic friction of the Solitaire2 SR against material surfaces, reported with a 95% CI.

Load	Sample Size	Coefficient of Kinetic Friction
PVC		
20 g	20	1.66 ± 0.08
30 g	20	1.73 ± 0.06
Silicone		
20g	20	4.40 ± 0.13
30g	20	4.31 ± 0.12

An example of raw SR testing data is shown in **Fig. 3**. The graph depicts a ramp-up region where there is visible stretching of the SR and a constant region in which the SR is sliding against the material. Only the constant region is used for calculations of the kinetic friction. Similar force vs. displacement graphs were observed during kinetic friction testing of EAs, with the addition of a ramp down region to a 0-force reading when EA separated from the testing material.

Fig. 3: Raw force vs. displacement data from kinetic testing of the Solitaire2 SR against silicone under a 30 g load.

The results of SR testing (**Table 2**) show no significant change in the coefficients of friction across the differing loads for the same material. Silicone had a significantly higher coefficient of kinetic friction when compared to PVC. The frictional forces obtained between the SR and materials were significantly higher when compared to the interactions between materials and EAs. Preliminary data obtained with bovine carotid arteries show coefficients of static and kinetic friction at around 0.4 and 0.2 for 40% EA hematocrit, respectively, while kinetic friction testing with SRs show significantly higher results at about 2.4.

DISCUSSION

The results of these experiments indicate that, despite EA adhesion increasing with fibrin content (i.e. lower hematocrit), the effect of this is small compared to the adhesion between the SR and the model wall. Previous findings have shown that higher EA removal forces were correlated with vascular tortuosity, which we believe may be a result of increased wall contact with the SR [6]. From this, we expect that the frictional forces between the SR and wall interface have a greater impact on MT removal forces and greater influence on EA removal than that of EA composition. However, to prove these claims, continued testing on the kinetic friction of EAs is required. Preliminary friction results between EAs and bovine carotid arteries suggest that *in-vitro* AIS models are underpredicting the *in-vivo* frictional forces by a factor of 4. Preliminary friction results between SRs and bovine carotid arteries show an underprediction of frictional forces in PVC and overprediction in silicone in *in-vitro* AIS models and needs to be considered in *in-vitro* MT models. Continued testing of vessel walls should also be conducted to confirm this, as well as to determine the efficacy of representing *in-vivo* conditions with current benchtop models. It should be noted that in both *in-vitro* and *in-vivo* environments, the presence of a lubricant (water/blood) is present and could affect the frictional forces. Future testing will be conducted to determine a more accurate representation of the adhesion of the EAs and SRs on wetted material surfaces.

INTRODUCTION

About 50% of women worldwide are affected by pelvic organ prolapse (POP), which is characterized by the descent of any or all the pelvic floor organs (i.e., cervix, uterus, bladder, and rectum) from their natural position. Age, body weight, parity, and delivery type (vaginal or cesarean births), are thought to alter the mechanical properties of the pelvic floor tissues, including the uterosacral ligaments (USLs), resulting in POP [1]. The USLs provide fundamental structural support for the uterus, cervix, and vagina by tethering the cervix to the sacrum. Pregnancy and childbirth are known to impose mechanical strain on the USLs, potentially causing damage, and increasing the possibility of developing POP [1]. Additionally, ageing plays a role in the pathogenesis of POP, but the mechanism is unknown [2].

The mechanical integrity of the USLs is derived from extracellular matrix (ECM) components like collagens, elastin, and proteoglycans. Type I collagen is the major tensile load-bearing ECM component of ligamentous tissues and therefore likely to be involved in USL failure and POP [3].

In this study, we employed a murine model to examine the effects of pregnancy and age on the biochemical composition of the USL and its susceptibility to collagen damage in response to mechanical deformation.

METHODS

Female C57BL/6J mice were obtained and euthanized according to the University of Colorado Boulder's Animal Care and Use Committee. Both mature (>17-weeks, n = 2-3) and young (10-15 weeks, n = 3-5) murine USLs were collected at three different stages of pregnancy: nulliparous (NP), late pregnant gestation day 18.5 (E18.5) and post-partum day 1 (PP1). The USLs were isolated, and a suture was tied at the cervical end. One USL was used for mechanical analysis and was left attached to the pelvis and a piece of the cervix, which were left to act as anchors, and tested while freshly harvested. The contralateral

USL was flash frozen with liquid nitrogen and kept at -80°C until later analyzed with Raman spectroscopy.

Samples used for mechanical testing were placed in a solution of Ghost Dye Red 780 (Tonbo Biosciences), which stains all free amine groups, for 2 hours at 4°C on a rocker. For the last 10 minutes, a dead cell nuclei stain, Sytox Deep Red (ThermoFisher Scientific) was added to the solution. The samples were then placed in a custom loading chamber in a 1×PBS bath connected to a 100 mN FemtoTools load cell under an upright confocal microscope (Leica STELLARIS 5). Each USL was set in a reference configuration of ~500 μN pre-load.

Collagen hybridizing peptide (CHP) was used to determine regions with significant collagen denaturation (damage) [4]. Prior to mechanical testing, the 1×PBS bath was replaced with a 10 μM solution of CHP for 15 minutes. This staining procedure was repeated after each deformation step to record the changes in collagen damage. The samples were imaged at 10× magnification (2.14 μm pixel resolution) before, during, and after deformation. Deformed configurations were prescribed by actuator displacements of 1000, 1500, 2000, and 2500 μm at 50 μm/seconds, and allowed a stress-relaxation period of 5 minutes. For each image stack, max intensity projections were created. 2D displacement fields were estimated using composite Ghost Dye and Sytox images of reference and deformed states with MATLAB's *imregdemon*s function, from which Lagrange strain fields were derived. A moving threshold was used to determine pixels with significant collagen damage,

$$\gamma_i = \mu_i + 2\sigma_1 \quad (1)$$

Where γ_i is the CHP image intensity threshold for the i th reference image, μ_i is the mean CHP intensity of the i th reference image, and σ_1 is the standard deviation in CHP intensity of the original reference image. This thresholding method is robust to increases in image intensity resulting from multiple stain times.

From the strain and damage maps, average axial (E_{11}), transverse (E_{22}), and shear (E_{12}) strains, as well as percent damaged area were

calculated for the intermediate region. A 2-way ANOVA was performed to analyze the effect of stretch state and pregnancy for each age group, with significance indicated at $p < 0.05$.

Raman spectroscopy was used to map the biochemical composition of the contralateral USLs. After thawing at room temperature, the samples were placed on a custom well and evaluated using a confocal Raman microscope system (Renishaw inVia, 785 nm laser, 1.06 μm). A grid of 100 $\mu\text{m} \times 150 \mu\text{m}$ ($\sim 3 \times 12$) spectra along the USL was obtained and heatmaps were developed in MATLAB.

Raman spectra were obtained ($n = 1\text{-}2/\text{group}$) for each sample (Fig. 4). Peaks were correlated with biochemical constituents based on *in vivo* Raman spectroscopy of the human cervix performed by [5]. Our data was normalized using the phosphatidylethanolamine peak (1769 nm). Heat maps of peak area ratios were obtained.

RESULTS

Deformation fields and collagen damage maps were inhomogeneous (Fig 1). Axial strain (E_{11}) along the direction of the collagen fibers and the number of pixels with damage (highlighted in red) increased with the applied global displacement, δ .

Figure 1: Lagrange strain fields and damage maps at four levels of global displacement, δ , in a young NP (scale bar = 500 μm).

Figure 2: A) Percent damaged area and average shear strain (E_{12}) significantly increased with global displacement and pregnancy.

The least amount of damaged area was induced in USLs from E18.5 mice from the young cohort. B) Average shear strain (E_{12}) differed significantly with pregnancy stage for both old and young cohort ($p < 0.05$).

Percent damaged area differed significantly with pregnancy stage and global displacement for the young cohort ($p < 0.05$), while for the

old age group, only global displacement was a significant factor. Following applied deformation, the damaged area was smallest in USLs from young E18.5 mice (Fig. 2A).

Average shear strain (E_{12}) was significantly different with pregnancy stage in both the young and mature cohorts, with the lowest shear strain observed in the USLs of young, pregnant mice (Fig 2B).

Raman spectra differed along the length of the USLs, with the highest intensities seen in the cervical region and the lowest in the sacral region. This trend was common to all the samples assessed. There were no significant differences in peak ratios with pregnancy stage and age.

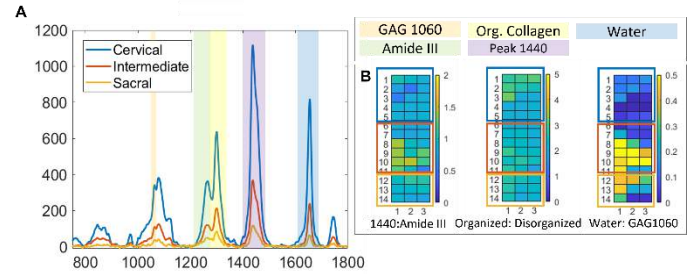

Figure 4: Raman analysis of an old NP USL. A) Representative Raman spectra and B) heat maps of peak ratios show regional (cervical, intermediate, sacral) variations in composition, but these trends were consistent across cohorts).

DISCUSSION

Our work indicates that both pregnancy and age are important factors in USL damage accumulation and mechanics. For young, but not mature mice, mechanically-induced collagen damage was significantly different across pregnancy stages for similar levels of applied strain, with less damage being accrued in USLs from pregnant mice. This suggests that the ECM in the USL remodels during pregnancy to protect it from mechanical injury, but remodeling may be less effective in older individuals. However, Raman spectroscopy did not discern any significant differences in biochemical composition with age or pregnancy stage. Thus, our preliminary results suggest that ECM remodeling during pregnancy may affect organization more than composition. The significant differences observed in average shear strain with pregnancy also point to differences in microstructural organization.

This is the first study to investigate the effects of both age and pregnancy on USL composition, mechanics, and structural damage. Our current limitations include small sample sizes, especially for identifying differences in USL composition. Nevertheless, our data suggest that both pregnancy and age affected collagen damage and mechanics in the USL, possibly due to changes in microstructural organization. Future work will aim to understand the specific microstructural changes that protect the USL from injury.

INTRODUCTION

Millions of people worldwide are blind or have reduced vision due to glaucomatous damage to the retinal ganglion cell axons that carry visual information from the retina to the brain. [1] In glaucoma, axonal damage starts at the lamina cribrosa (LC) within the optic nerve head (Figure 1a). Although the mechanisms of damage remain unclear, low levels of oxygenation within the LC are thought to be a primary contributor. [2] Direct measurement of LC oxygenation remains out of reach. Hence, the characteristics of the LC vasculature that most affect blood perfusion and oxygenation remain unknown. Using an eye-specific 3D vasculature model of the LC we recently found a strong positive relationship between vessel diameter and LC oxygenation. [3] However, eyes vary in anatomy, and it remains unclear how much these differences affect LC hemodynamics. We tested the hypothesis that despite differences between eyes, they will share general aspects of LC blood flow, oxygenation, and sensitivity to vessel diameter.

METHODS

Using methods recently described, we developed four eye-specific vasculature models based on serial histological sections of monkey optic nerve heads (Figure 1b). [3, 4] To account for differences in LC shape and boundary conditions, the region modeled was larger than the LC. LC vessels were identified by the LC collagenous beams. [3] Baseline vessel diameters were uniform. To study the effects of vessel diameter on the LC blood flow and oxygen, we uniformly varied the vessel diameter in each model as follows: 6.4, 7.2, 8.0, 8.8, and 9.6 μm .

Blood was considered as an incompressible Newtonian fluid, and its flow behavior was described by the Hagen-Poiseuille equation. [5] Pressure boundary conditions were applied to each model to estimate blood flow through the vasculature. [3] A Green's function method was then employed to calculate oxygen concentration. [6] We used the minimum (10th percentile) oxygen concentration as potentially indicative of hypoxic conditions.

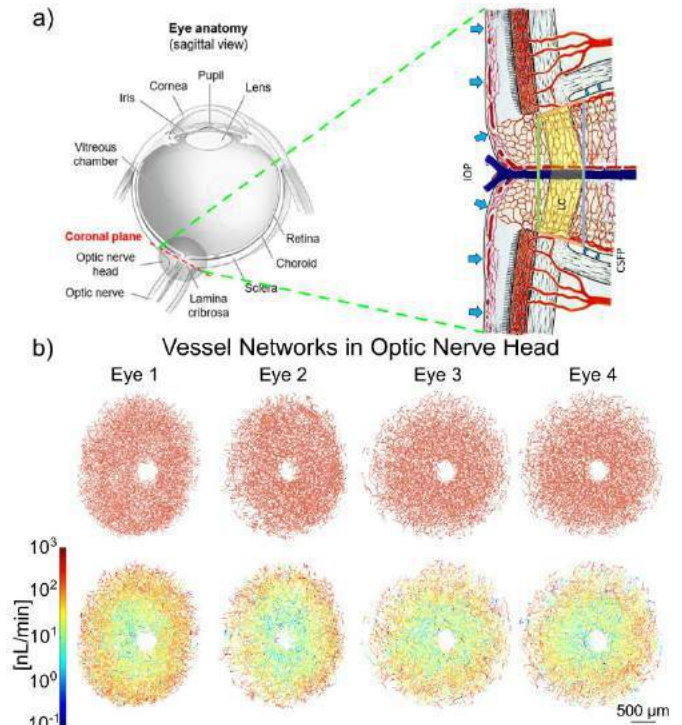

Figure 1: (a) On the left, a schematic longitudinal cross-section of an eye. On the right, optic nerve head close-up with the LC highlighted in yellow [3]. (b) Coronal front views of the four models developed in this study at the baseline vessel diameters of 8 μm . For clarity, we show them with a single color (top row) and colored by blood flow (bottom row). In general, the blood flow was higher at the periphery, decreasing towards the center.

RESULTS

All LCs exhibited variations in blood flow and oxygenation across the region, generally with higher flow and oxygen at the periphery (Figure 1b). Although eyes 1 and 4 had substantially higher minimum oxygen concentrations, all four LCs exhibited similar positive, nonlinear increases in oxygen with diameter (Figure 3).

Figure 2: Distribution of oxygen concentration in the optic nerve head neural tissues for various vessel diameters (mid-LC coronal sections). There was higher oxygenation at the periphery than the center, similar to the variations in blood flow observed in Figure 1b. Oxygen concentration increased with the vessel diameter.

Figure 3: Effects of vessel diameter on the minimum oxygen concentration in the LC. Note that there were no intermediate values between the five diameters we considered (6.4, 7.2, 8.0, 8.8, and 9.6 μm). Results are shown as lines to help discern trends. Although there were differences in minimum oxygen concentration between the eyes, the nonlinear relationships between vessel diameter and the minimum oxygen concentration were fairly consistent across the four eyes.

DISCUSSION

We tested the hypothesis that despite differences between each eye's LC anatomy, they will share general aspects of LC blood flow, oxygenation, and sensitivity to vessel diameter. Our results support the hypothesis: maps of blood flow and oxygenation were similar across the four LCs studied. Furthermore, although there were differences in overall oxygen concentration between eyes, the minimum LC oxygen concentration sensitivity to vessel diameter was fairly consistent.

The effects of vessel diameter on blood flow are reasonable: an increase in vessel diameter decreases the flow resistance, increasing the blood flow rate, and resulting in more efficient oxygen transport and higher oxygen concentration in the LC. In this work, we varied vessel diameter as part of a systematic approach to test its influence on the LC. We therefore assumed that all vessels of all LCs had the same diameters. This is unlikely to be exactly the case. Vessel diameters likely vary between eyes. They can also vary due to tissue deformations induced, for example, by changes in intraocular pressure, or changes in gaze. [7] Tissue distortions may also affect vessel tortuosity. [8] Vessel diameter may also vary due to pericyte action. In the retina, cerebellum, and cerebral cortex, pericytes were found to regulate the capillary diameter, and therefore, the blood flow in response to metabolic demand. [9-11] Although the existence of pericytes in the LC is not established, some human LC cells test positive for PDGFR β , a marker for pericytes. [12] The perfusion-labeling method we used did not allow us to simulate accurately the physiologic perfusion cycles, and therefore, the vessel diameters cannot be guaranteed to be physiologically accurate. We therefore assumed that all the vessels in a particular model had the same diameter. To the best of our knowledge, there are no studies providing detailed maps of LC vessel diameter. Further work could help provide detailed information on vessel diameters. We also assumed the oxygen consumption rate of neural tissues to be uniform throughout the LC based on literature values for other neural tissues. The oxygen consumption rate may vary with regions and/or pressure gradients in the LC. It may be advantageous to incorporate region and pressure-dependent neural tissue oxygen consumption rates in future studies.

In summary, we found that despite anatomical differences, there are important similarities in LC blood flow, oxygenation, and sensitivity to vessel diameter. Considering the strong influence of vessel diameter on LC oxygenation, situations that reduce the diameter, such as high intraocular pressure, may have a high risk of inducing hypoxia.

INTRODUCTION

While articular cartilage exhibits remarkable failure resistance, it can break down under abnormal or repetitive loading¹. Cartilage is a heterogeneous, anisotropic, poroviscoelastic (PVE) material². The solid matrix is made of collagen fibrils and proteoglycans with negatively charged glycosaminoglycans side chains that interact with dissolved solutes to swell the solid matrix². This material complexity has resulted in an incomplete understanding of cartilage failure mechanics³.

To date, there are several postulated failure mechanisms: (§1) cartilage failure is governed by the breaking of collagen fibrils⁴ and (§2) cartilage exhibits two distinct failure^{5,6} regimes based primarily on loading rate. Within rate-dependent regimes, postulated classification includes (§2.1) brittle⁶ failure at fast displacement rates (FDR) due to stress build-up at the articular surface, and shear-based ductile⁶ failure at slow displacement rates (SDR). FDR induces fracture before PVE relaxations have time to occur while SDR induces fracture after the majority of PVE relaxations have occurred⁵. An alternative theory based on crack morphology (§2.2) postulates a pressurization-fragmentation⁵ regime at SDR due to osmotic pressure build up⁷, and a strain-governed⁵ regime at FDR due to lack of fluid flow. However, it has not been resolved which failure theory is accurate.

Therefore, the objective of this study was to develop a PVE finite element (FE) model to predict the stress, strain and fluid pressure during cartilage microindentation, thereby providing insight into the mechanics driving cartilage microfracture.

METHODS

An axisymmetric FE model was analyzed using FEBio⁸. Boundary and loading conditions matched prior experiments that investigated osmolarity (hypo-osmolar, normal osmolarity, and hyper-osmolar) and displacement rate (FDR and SDR) effects⁵ (Fig. 1A). Experiments analyzed the critical displacement, defined as the point of fracture initiation, which occurred at the first drop in load.

Finite Element Model: Cartilage was modeled as a 5° wedge (Fig. 1B) with a neo-Hookean ground matrix⁴, biphasic behavior with strain-dependent permeability⁴, nonlinear fiber behavior with viscoelastic fibrils⁴, and the fluid-solid matrix interactions with Donnan equilibrium swelling. Collagen fibrils were modeled using a continuous spherical fiber distribution with power-law strain energy density⁴. Sample thickness matched the average value for the normal-osmotic condition⁵. Cartilage was discretized into hexahedral and pentahedral elements with mesh density and biasing determined via mesh convergence analysis. The indenter was modeled in SolidWorks 2022 and discretized using Gmsh 4.8.4 with triangular shell elements, and the boundary plane was modeled using a single quadrilateral shell element. Both the indenter and boundary plane were set as rigid body materials. All boundary and loading conditions were prescribed to match the experimental conditions (Fig. 1A) and models were analyzed up to experimental critical displacements.

Figure 1: (A) half-symmetry schematic of experimental set-up; (B) FE model where outputs were taken along the axis of symmetry.

Donnan equilibrium constants were fit to match measured changes in sample thickness due to varying osmolarity. Osmotic pressure (π) was

enforced through fixed charge density in the current configuration⁹:

$$\pi = R\theta(\sqrt{(c^F)^2 + (c^*)^2} - c^*) \quad (1)$$

Where R is the universal gas constant, θ is the absolute temperature, c^* is the external bath osmolarity and c^F is the fixed charge density of the solid matrix in the current configuration defined by the fixed charge density in the reference configuration⁹:

$$c^F = \frac{\phi_0^w}{J-1+\phi_0^w} c_0^F \quad (2)$$

Where c_0^F is the initial fixed charged density, ϕ_0^w is the fluid volume fraction in the reference configuration, and J is the relative volume. The initial fixed charge density of $c_0^F = -158 \text{ mM}^{10}$ best fit the relative volume change measured experimentally. Distributions of principal Cauchy stresses, max shear stress, principal solid Cauchy stresses, max solid shear stresses, principal Lagrange strains, max Lagrange shear strains, and fluid pressures at critical displacements were taken along the axis of symmetry as a function of distance from the surface (Fig. 1B). Due to space constraints, not all model outputs are reported here.

Statistical Analysis: The effects of osmolarity, rate, and their interaction were statistically evaluated at the average magnitude of each output. Normality was checked with a Shapiro-Wilk test, QQ-plot, and histogram analysis. A two-way ANOVA evaluated normally distributed outputs. A non-parametric Friedman test was used for outputs that were not normal and could not be transformed to normality. All significance was set with $p \leq 0.05$.

RESULTS

Fluid pressure, stress, and strain directly underneath the indenter tip varied in both magnitude and distribution as a function of rate (Fig. 2, 3). Third principal Lagrange strain (Fig. 2D) had a much steeper gradient at FDR compared to SDR despite reaching much higher critical displacements at SDR. Fluid pressure was also over 20 times higher under FDR compared to SDR (Fig. 3C).

Third principal solid stress showed pair-wise significance between displacement rates at each osmolarity (Fig. 2B, 3A). At FDR, there was no significant difference in the third principal solid stress by osmolarity.

Solid shear stress had pair-wise significant difference between osmolarities at FDR, which was not observed at SDR (Fig. 3B). At the hypo-osmolar case, a pair-wise difference between rate was observed.

Figure 2: Qualitative distributions of (A) most tensile and (B) most compressive solid stress; (C) most tensile and (D) most compressive strains at mean critical displacement under normal osmolarity.

DISCUSSION

In this study, dramatic differences between FDR and SDR support the existence of two distinct, rate-dependent failure modes (§2) for cartilage⁵⁻⁷ (Fig. 2). Further specifics of the outputs can be interpreted

to provide evidence for failure mechanism (§2.1), ductile-brittle failure⁶; or for (§2.2), pressurization-strain failure⁵.

The predicted mechanics are consistent with (§2.1), the ductile-brittle failure theory. Brittle failure has been shown to cause fractures of the solid matrix at the articular cartilage surface along collagen fiber orientation at FDR⁶. This study predicted no difference in third principal solid stress between osmolarities at FDR, with the maximum value occurring at the articular surface (Fig. 3A); this is consistent with brittle failure. At SDR, the solid shear stress had no significant difference between osmolarity suggesting ductile failure (Fig. 3B).

The predicted mechanics are not consistent with (§2.2), the pressurization-strain failure theory. At FDR, a significant difference between osmolarities of the third principal Lagrange strain was observed (Fig. 2D); this does not suggest a consistent failure metric at FDR. At SDR, fluid pressure had a gentle gradient descending from the cartilage surface, indicating fluid pressure dissipation, while a highly localized maximum directly under the indenter tip at FDR indicates a pressure build-up (Fig. 3C). This is not consistent with a pressurization regime at SDR since pressure is lowest at the cartilage surface where fracture occurred.

In conclusion, this study supports the concept of cartilage failure as rate-dependent with ductile-like failure under SDR and brittle-like failure under FDR.

APPLICATION OF 3D PRINTING IN SHAPE MEMORY POLYMER-BASED ENDOVASCULAR EMBOLIZATION FOR PREVENTING INTRACRANIAL ANEURYSM RUPTURE

INTRODUCTION

Intracranial aneurysms (ICAs) are present in approximately 4% of the American population [1], with the risk of aneurysm rupture scaling relative to the size of the aneurysm and the thinning of vessel wall [2]. The most devastating consequence of aneurysm rupture is subarachnoid hemorrhage (SAH) – a significant bleed within the intracranial cavity, with a 30% rate of rupture over the lifetime of the patient [3]. In addition, SAH carries a hospital mortality rate of 18% [4], along with 74% of survivors suffering lifelong complications [5].

The two most prominent treatments for ICA therapy are endovascular coil embolization and neurosurgical clipping. Coiling exhibits operative morbidity rates up to 10 times lower than clipping, which makes it the preferred method for therapy, especially for the elderly [6,7]. However, endovascular technologies suffer from limitations related to low complete and partial ICA occlusion rates, (64% and 34% of cases, respectively) [6]. Therefore, additional research efforts can be made to improve the efficacy of ICA embolization technologies, most prominently in the improvements to the rate of *complete* and *lasting* occlusion.

In this study, we proposed a patient-specific shape memory polymer (SMP)-based device, aiming to enable a higher rate of ICA occlusion for a wider breadth of aneurysm geometries, compared to the traditional coil-based methods. Further, the internal scaffolding of our porous SMP material is expected to promote thrombogenesis within the aneurysm sac that can accelerating occlusion of the aneurysm [8]. Moreover, our preliminary results and ongoing research show the great potential of our proposal method as a viable embolization technique to ameliorate complete occlusion rates of endovascular ICA therapeutics, as demonstrated by successful occlusions through *in vitro* aneurysm phantom models.

METHODS

Template Material Selection: First, we 3D printed porous polyvinyl alcohol (PVA, Form Futura Atlas Support) templates to be

used as leaching/lattice replacement agents. PVA was selected as the template material due to its great water solubility [9], biocompatibility [10], and availability as a 3D-printable filament. A thorough calibration procedure, specific to the PVA filament, was first performed to ensure consistent dimensional accuracy (i.e., line width, layer height, and structural integrity, see the Results section). This calibration procedure included optimization of the extruder temperature, volumetric flow rate, print speed, as well as several other printing parameters.

SMP Foam Fabrication: We next synthesized SMP based on our in-house protocol [11] in a molar ratio of 1:0.32:0.22, of hexamethylene isocyanate (HDI), N,N,N',N'-tetrakis (hydroxypropyl) ethylenediamine (HPED), and triethanolamine (TEA), as described previously [12]. Then, the PVA templates were coated with the liquid SMP solution and placed in a freezer (-20 °C) for 1 h, followed by a 3-step curing procedure in a vacuum oven for 3 h. at 45 °C, 1 hour at 70 °C, and 1 hour at 100 °C. Finally, the total foam construct was dissolved in a sonicator water bath at 50 °C for dissolving the PVA, leaving the porous SMP specimen (Fig. 1).

Figure 1: (a) 3D printing of PVA templates, (b) Synthesis of SMP, (c) Coating of templates, (d) Cooling of coated templates, (e) Curing of SMP, (f) Dissolution of PVA templates.

Material Characterization of SMP Porous Foams: Differential scanning calorimetry (DSC), scanning electron microscopy (SEM), Fourier-transform infrared spectroscopy (FTIR), and thermomechanical testing/characterizations were performed to evaluate the material properties of the fabricated porous SMP specimens.

Aneurysm Phantom Fabrication: Polydimethylsiloxane (PDMS) was used in conjunction with a PVA positive mold to fabricate phantoms of the aneurysm sac and surrounding arteries. This enabled testing of the SMP devices under an *in vitro* patient-specific geometry condition (Fig. 2d).

Figure 2: (a) CAD model of aneurysm and adjacent artery, (b) Top view and (c) Bottom view of patient-specific SMP device, (d) Patient-specific SMP device occlusion of *in vitro* phantom aneurysm.

RESULTS

3D Printing Resolution/Accuracy Targeted: Dimensional accuracy was evaluated via electronic calipers with a ± 0.01 mm resolution by measuring each face at the midplane point. The sample of PVA templates ($n = 40$) displayed a mean width of 10.80 ± 0.018 mm and a mean height of 9.99 ± 0.023 mm for a rectangular prism characterization model with a designed base of 10.80×10.80 mm and a height of 10.00 mm. This translated to the SMP specimens ($n = 40$) displaying a mean width of 9.85 ± 0.254 mm and a mean height of 9.99 ± 0.134 mm. The reduction in width is due to the removal of the two external wall layers, 0.4 mm each, during dissolution to expose the internal scaffold structures of the SMP material.

Microstructural Evaluation of Synthesized SMP Foams: SEM enabled the analysis of the internal scaffolds at the micro-scale and the overall geometric characteristic of the SMP specimens, as demonstrated in Figure 3.

Figure 3: (a,b) Top view and (c,d) Side view of SMP specimen

Evaluation of Glass Transition Temperature: DSC revealed a glass transition temperature (T_g) of 41 °C for the fabricated SMP material which is just above internal body temperature of ~37 °C. This ensures that the

material will not deform from its designed geometries, while the shape recover can be triggered without causing thermal damage to the arterial and aneurysm tissues during the *in vivo* endovascular procedure [13].

Uniaxial Compression – Thermomechanical Characterization: The stress-strain testing revealed cyclical stress behavior with a reduction of elastic modulus over each cycle. Along the Z- and X-axis of compression, the elastic modulus was reduced by ~50% and 15%, respectively, over 10 cycles of 80% uniaxial compression.

DISCUSSION

Current intracranial treatment methods, such as GDCs and hydrogel coils [8], utilize a uniform approach in which there is little to no adaptation for the geometric specificity of each patient's aneurysm. This results in levels of recurrence, up to 13% [6], and often necessitates additional procedures both of which increase the likelihood of debilitating complications. Our patient-specific embolization device attempts to resolve this issue by replicating the geometry of the targeted aneurysm, using additive manufacturing and shape memory technology. This is aimed at enabling more thorough occlusion and more efficient thrombosis. This device aims to reduce the post-operative recurrence rates and greatly reduce the need for follow-up procedures, reducing the risk of complications for the patient.

In addition, the SEM analysis revealed that the dissolution of the PVA templates left tunnels within the SMP internal scaffolds which further increases compressibility of the specimens. This will be vital for adequate compression of small-scale specimens, specifically those to be used in *in vivo* animal testing.

Currently, this device exhibits limitations related to the size of the target aneurysm. Our SMP and PVA template methodology has proven successful with aneurysms ranging from 10-20 mm in major diameter; however, there is still more optimization needed to expand the range of effective use to small aneurysms (<10 mm) and giant aneurysms (>20 mm). Additionally, this device requires several days of preparation to complete the previously described methodology which could limit its use case to non-emergency operations only.

Further work based on this research study will involve evaluating biocompatibility via *in vitro* testing with cell cultures which if successful will aid in the progression towards animal testing and eventual clinical trials.

INTRODUCTION

Syndactyly, one of the most common congenital malformations of the hand, is a result of a failed separation of adjacent digits [1]. These digits are common among congenital limb malformations that affect 1 out of 2,000-3,000 people at birth [2]. For any type of syndactyly, reconstructive surgery would be needed to separate the digital skin, reconstruct the web space between fingers, cover the web space, and separate digits with soft tissues [3]. Soft tissues are usually a certain shape of skin designed by doctors. The simplest design is a dorsal rectangular flap formed by connecting the metacarpal heads and a point on each digit at the midpoint of the proximal phalanx [4]. However, the area of the dorsal rectangular flap may be insufficient to cover the lateral defects at the base of the digit and even the web space [5]. The skin from another site of the body, such as the volar side of the forearm, can be used, which may lead to extended operation time as well as inconsistent skin texture and stress [5]. Other shapes of dorsal flaps were also designed to cover as much area as needed, such as rectangular, hexagonal, pentagonal, and more [5]. The result of using an improper shape and dimension of skin to cover the web commissure can lead to web creep. However, the sufficiency of the dorsal flap is still based purely on intuition and personal experiences.

Conducting a numerical study with known mechanical properties, such as Young's Modulus of the dorsal flap that varies with age, gender, and ethnicity [6], can help understand why web creep occurs and how to prevent it. To the best knowledge of authors, however, no numerical study has been conducted on the effect of the size and shape of the flap on the outcome quantitatively. This leads to analyzing the stress of the dorsal flap using a finite element analysis (FEA) that can be further investigated with 3D hand models of syndactyly digits.

This preliminary research aims to evaluate the feasibility of an autonomous low-cost solution for extracting geometric features in FEA on a dorsal flap, which can be used in optimizing their dimensions and configurations. We utilized Autodesk Recap Photo to reconstruct a 3D hand model using a series of pictures taken by an Arduino camera, the OV2640 ArduCAM model. Geometric features will be extracted from the defective and non-defected hand models to estimate the dimensions and configurations of the dorsal flap. FEA will be performed on the estimated types of dorsal flap to analyze the deformation. This potential solution would help surgeons to select the optimized dimensions and configurations of the individual's hands with precise accuracy and quantitative results and prevent the occurrence of web creep.

PRODUCT DESIGN

To extract geometric features autonomously, we aim to use Autodesk ReCap Photo software to 3D reconstruct an individual's

hand models given a series of images taken from his/her hands. The software produces a 3D model of a still object by using at least 20 in-focus pictures taken from different perspectives of it.

Tests were performed with the iPhone 11 camera and ArduCAM to find proper perspectives and resolution that provides quality pictures for 3D model reconstruction in the software while maintaining a small storage size. Various perspectives have been attempted to qualitatively find the best picture view for 3D model reconstruction. From our tests, we determined that taking pictures from an angled top-down view produced the most completed model. Figure 1(a) displays a skeleton hand model reconstructed using the pictures taken by iPhone 11 and Figure 1(b) displays a tissue box model reconstructed using the pictures taken by an OV2640 ArduCAM. We demonstrated that both an iPhone 11 camera and ArduCAM are qualified to be used. Concluding that the ArduCAM could reduce image uploading time and increase efficiency due to its lower resolution.

Figure 1(a): iPhone 11 camera Figure 1(b): OV2640 ArduCAM

A device was designed to support the functions of the camera to achieve autonomous image capturing in a more effective and efficient way. Figure 2 represents a prototype that is a proof of concept as to how the compatibility between the user and function relates. This design incorporates a movement in one degree of freedom that rotates around an axis (8) where a patient's hand will be. This simple rotation enables the camera to take hand images in the best perspectives we found. This would all be in a potential 4ftx3ft enclosed frame (2) to ensure that the device is sheltered and compact. A single appendage is attached to a stepper motor (4), held by a motor mount (3). The camera (7) would be placed at the end of the angled appendage (6) to capture images facing inwards at a minimum of 1ft away from the center axis of the armrest (1). A slip-ring (5) would be used to allow the wiring to move through the appendage without being tangled during the rotational movement. The wire would lead to a control panel (9) that is placed outside of the control space to house the Arduino UNO breadboard, TFT LCD (thin-film-transistor liquid-crystal-display) touchscreen, and battery.

Figure 2: Robotic Appendage Prototype

BUDGET & MARKET ANALYSIS

The budget for the prototype is estimated at \$2,000. To be specific, \$50 budgeting towards the ArduCAM camera and the Arduino UNO Board; \$550 towards the stepper motor that can provide a maximum of 2,124.1oz of torque to the appendage; \$500 towards a frame and mount that provides stability for our device and is aesthetically pleasing for the user; \$200 towards the armrest to provide the user with a comfortable experience during the scanning process; \$120 towards the angled appendage and maintaining wire management; and \$200 towards a control panel that allows the consumer to operate the device.

The predicted market size is around 800 in the United States. This being for hand surgeons can be benefitted from this device, along with the thousands of patients that can also be benefitted. A projected sales price would be \$2,500 per unit with a generated revenue of 2MM. Producing this product in mass with given investments towards moulding the frames, appendages, hand rests, and control panels could equvalate to prices lower than \$1,250. A profit margin of \$1,750 could generate 1.4MM, and an investment of \$500 would have a return on investment of \$2,800.

METHODS

Figure 3 shows the adoption (solid lines) and development testing method (dashed lines) of the proposed autonomous device. The images of the patient's defective hand would be taken by the camera embedded in the device and sent to Autodesk Recap Photo software to create a 3D model. Critical geometric parameters would be extracted from the model using computer vision techniques. These parameters prepare us for performing FEA on dorsal flap. Based on the FEA analysis, a dorsal flap with optimized dimensions and configuration would be recommended to doctors. As for the development testing method in this preliminary study, we plan to manually measure the geometric features, the results of which would serve as ground truth for us to compare the parameters obtained using computer vision. Since this comparison is only for this preliminary test to validate the capability of the device, it will be excluded from the actual use.

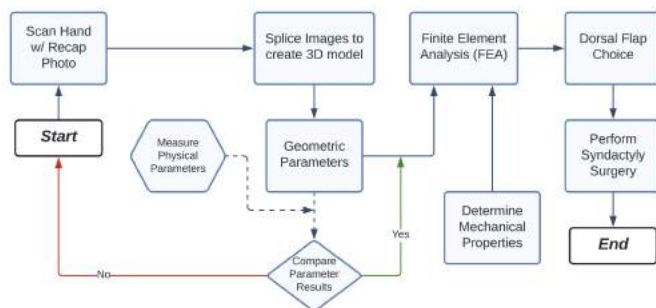

Figure 3: Flowchart of the Adoption and Testing Method

RESULTS

We adopted Autodesk ReCap Photo to create a 3D model using a series of images taken by OV2640 ArduCAM with Arduino Uno, as shown in Figure 1(b). The tissue box was used as our first testing object due to it being easily accessible. Twenty photos were taken with 800x600 quality and from the best perspective we found –

an angled top-down view/ isometric. This demonstrated that this camera module is capable of producing a model that displays significant characteristics of the object. The limitation of the outcome is that the model only rendered three out of four sides, while the fourth side was hollow. Since the current image-taking was done manually, the entire process was time-consuming. We now assume that the missing side is due to the fluctuating lighting that came from time passing. The use of the device will avoid this situation by achieving automatic image capture in a much shorter period.

DISCUSSION

To the best knowledge of authors, this is the first study of conducting FEA to optimize the dimensions and configurations of the dorsal flap to prevent web creep occurrence. The current design is based on proof of concept that can later be improved to design a more aesthetically pleasing and functioning prototype. We have demonstrated the feasibility of using a low-cost OV2640 ArduCAM in 3D model reconstruction. This prepares us for the development of a fully autonomous device, which can take images of patients' hands by enabling coding in Arduino that controls the stepper motor and the capture rate of the ArduCAM, then send the images to Autodesk ReCap Photo for 3D hand model reconstruction. The model would be used for further geometric parameter extraction for FEA analysis in future study.

ACKNOWLEDGMENTS

We want to acknowledge the College of Engineering at Ohio Northern University for contributing towards our budget.

INTRODUCTION

While much attention has been devoted to the study of the biochemical signaling processes involved in the tumor microenvironment (TME) as targets for anti-cancer therapies, there have been few studies that investigate the mechanical factors involved in supporting tumor progression. As tumors grow and expand, they require additional nutrients and oxygen which can be delivered through angiogenesis, or the process of growing blood vessels from a previously existing vasculature. [1] Recent studies demonstrate that the endothelial cells that make up our blood vessels are mechanically-sensitive, and that mechanoreceptors on these cells may play a role in guiding the growth of nascent blood vessels. Our previous work has shown that mechanical stimulation alone, without the addition of soluble factors such as VEGF, is sufficient to drive vessel growth in 3D *in vitro* models [2,3], although further work is needed to determine the precise mechanism that controls this behavior. A key component in angiogenesis is the membrane receptor vascular endothelial growth factor receptor 2 (VEGFR-2), which binds VEGF as a ligand to promote blood vessel growth. However, anti-cancer therapies that inhibit VEGFR-2 signaling have limited success in patients [4]. We believe this may be partially due to mechanosignaling through the VEGFR-2 pathway. Some studies suggest that VEGFR-2 can be phosphorylated or activated without the ligand [5]. Phosphorylation of specific tyrosine residues in VEGFR-2, Y1054/Y1059, is required to undergo angiogenic activity, while phosphorylation at Y1214 causes the activation of several other pathways, which includes many mechanotransductive transcription factors. [6] In order to identify how prolonged tensile strain alters VEGFR-2 phosphorylation and signaling in endothelial cells and if these changes correspond to differences in blood vessel growth or stability, 3-D models must be refined and utilized. These altered signaling behaviors in the endothelial cells after being strained can be defined as their "strain memory." The existence of a strain memory can be ascertained by observing pro-vasculogenic behaviors of endothelial cells following pro-longed (>24h) cyclic tensile

strain as well as measuring the phosphorylation of Y1214 and Y1054/Y1059 residues. We hypothesize that the Y1054/Y1059 residue will show an increase in phosphorylation after pro-longed cyclic tensile strain.

METHODS

Human microvascular endothelial cells (HMECs) with HMEC media (500 mL MCDDB131 media with 10ng/mL EGF, 1μg/mL hydrocortisone, 50mL HI FBS, 25mL L-Glutamine) every other day. After the cells reached confluence, they were trypsinized and seeded onto FlexCell plates with collagen I coating. In each well, 5x10⁵ cells were loaded and allowed to grow for 48h prior to strain exposure. The FlexCell (FX-6000T) system was used to treat samples with cyclic strain at 9% elongation and 0.3Hz for 24h; control cells were plated on the same FlexCell plates but did not receive mechanical stimulation. After strain treatments, cells were harvested and seeded into 24 well plate as 5x10⁴ cells per well. Once in the 24 well plate, the cells were fed with HMEC media without exogenous VEGF. After 48h, the cells were fixed and stained for pY1054/Y1059 (Invitrogen, 44-1047G, 1:500) followed by secondary (ThermoFisher, Donkey-anti-Mouse Alexa-Fluor 555 A31570, 1:500). The wells were imaged using an Olympus Microscope (IX-83). Images were processed in FIJI to determine area of positive staining to total cell area per each image; samples were run in triplicate. A second study was performed with a set of HMECs treated with strain for 72h. During the incubation prior to staining, some samples received 25ng/mL of exogenous VEGF, and the other half were given standard HMEC media. These samples were counterstained with DAPI at 1:1000. Images were processed in FIJI to determine area of positive staining to total cell area per each image; samples were run in triplicate. Statistical significance was determined using ANOVA followed by post-hoc testing or by student's t-tests assuming unequal variance.

Figure 1: (A,B) Representative immunofluorescence images of pY1054/Y1059 (red) for control no treatment (NT) or strained (ϵ) HMECs. Scale bar = 250 μ m. (C) Quantification of positive area relative to total cell area + SEM. No treatment compared with 24h strained pY1054/Y1059. * $p < 0.05$ vs. NT; $n=3$ samples.

RESULTS

The mechanical memory study performed on the FlexCell, showed a significant increase in area representing phosphorylated Y1054/Y1059 in cells that were strained versus cells that were not strained (Figure 1). Furthermore, HMECs strained for 72h demonstrated a statistical increase in pY1054/Y1059 only when exogenous VEGF was added (Figure 2.)

DISCUSSION

The objective of this project was to investigate how long-term mechanical stimulation (24h or greater) would alter phosphorylation dynamics of VEGFR-2 in HMECs. Our hypothesis was that the cells would demonstrate a strain memory and have altered levels of pY1054/Y1059 with strain treatment compared to non-strained cells. With 24h of strain treatment, the cells demonstrated significantly higher levels of pY1054/Y1059 compared to non-strained controls, suggesting that the HMECs may exhibit this type of strain memory behavior. However, strain alone for 72h did not have a significant difference in pY1054/Y1059 area compared to the non-strained cells. To further explore this, we included exogenous VEGF in the media of HMECs that had been strained for 72h to examine combinatorial effects between ligand and mechanical stimulation. However, the combination of VEGF and strain does increase overall levels of pY1054/Y1059. One possible reason for this could be how the VEGFR-2 receptor internalizes after activation and is degraded to prevent feed-forward signaling. For cells not stimulated with strain, the additional VEGF may not be sufficient to cause prolonged expression of pY1054/Y1059. On the other hand, when 25ng/mL of VEGF was added to the media with strain, there was a greater area of phosphorylation than if there was strain and no VEGF. Overall, the 72h study seems to suggest that longer periods of strain require VEGF to maintain higher levels of pY1054/Y1059. This also suggests these endothelial cells strain memory may be more potent over longer periods of time when VEGF is also involved.

Future studies will focus on taking HMECs that are treated with strain and embedding them in a 3D microtissue model [3] to determine if the strain memory affects vascularization potential of the cells. Additionally, we hope to perform similar experiments to ascertain the amount pY1214 present after different periods of strain.

THE IMPACT OF LACTATION ON PREGNANCY-INDUCED CARDIAC HYPERTROPHY DURING POSTPARTUM IN MICE

INTRODUCTION

Previous research shows that the heart grows in both mass and volume during normal pregnancy and regresses in the months following delivery in humans [1]. These adaptations help the pregnant patient accommodate the increased demand from the growing fetus while maintaining normal cardiovascular function. In some patients, however, maladaptive adaptations trigger cardiovascular dysfunction. Cardiovascular conditions account for half of all pregnancy-related mortalities in the United States. Specifically, pregnancy-associated heart failure is more likely to occur after delivery as it causes 39% of deaths between 43 days to one year postpartum [2].

Heart growth is driven by a combination of hormonal and mechanical cues. Our previous research suggests that increases in circulating progesterone (*P4*) and loading from hemodynamic changes are the primary drivers of heart growth in rat models of pregnancy [3]. However, *P4* and hemodynamic changes in the postpartum period can depend on factors such as lactation status after delivery. For example, lactating rats show elevated *P4* and cardiac output while non-lactating rats return to pre-pregnant values upon weaning [4, 5]. However, direct comparisons of heart growth between lactating and non-lactating models are lacking to date.

Therefore, the objective of this study is to assess the impact of lactation on heart growth in mice. We hypothesize that elevated hormonal levels and mechanical loading continue to drive cardiac hypertrophy after delivery, provoking additional heart growth during lactation. In contrast, we hypothesize that non-lactating mice hearts regress towards pre-pregnant size after delivery. To assess cardiac growth, we tracked changes in left ventricular (LV) size and shape throughout the entire pregnancy and postpartum period using serial cardiac ultrasound measurements. We allowed one group of mice to nurse their pups during the 21-day postpartum period and removed the pups from the other group of mice immediately following delivery. Our findings suggest that the hormonal and mechanical changes associated

with lactation prompt heart growth, while their absence allows the heart to recover to its pre-pregnant state.

METHODS

Changes in left ventricular (LV) mass, dimension, and volume were monitored throughout an average 19-day pregnancy and 21-day postpartum period in nulliparous C57Bl/6J mice using serial cardiac ultrasound measurements. Four nulliparous female mice were paired with male mice and gestational dating was performed through observation of the decidual reaction by high-frequency ultrasound (Fujifilm VisualSonics, Toronto, ON, Canada). Four-dimensional cardiac ultrasound (4DUS) was performed on days 0, 12, and 18 during pregnancy (**D0**, **D12**, **D18**) and on days 1, 7, and 21 postpartum (**PPD1**, **PPD7**, **PPD21**) using a high-frequency Vevo 3100 ultrasound system [6]. Two females were allowed to nurse their pups during the postpartum period (lactating, **L**, *n*=2) and two females had their litters removed immediately after delivery (non-lactating, **NL**, *n*=2).

A custom graphical user interface was used to segment the 4DUS scans [6]. Epicardial and endocardial boundaries were outlined at sequential time points to trace the local wall motion throughout the cardiac cycle. The 4D meshes of the epicardial and endocardial walls were used to calculate cardiac morphometry and function metrics, such as LV mass and stroke volume (SV) (Fig. 1). Researchers were blinded to the lactation status of the mice during analysis.

RESULTS

Throughout the 19-day pregnancy, LV mass increased in all four mice (Fig. 2A, Black). LV mass continued to increase during the postpartum period in the **L** group (Fig. 2A, Maroon). LV mass regressed towards pre-pregnancy values in the **NL** group, plateauing by **PPD7** in both mice (Fig. 2A, Gold).

Figure 1: Representative 4D meshes of the LV at the beginning of the study (D0), the end of pregnancy (D18), and the end of the postpartum period (PPD21) from one *L* mouse (#PP10) and one *NL* mouse (#PP09).

Similarly, SV increased in all four mice throughout pregnancy (Fig. 2B, Black). Notably, SV decreased between **D18** and **PPD1** in three out of four mice, independent of lactation status. In the postpartum period, SV remained elevated in the *L* group (Fig. 2B, Maroon), SV returned toward pre-pregnancy volumes in the *NL* group (Fig. 2B, Gold).

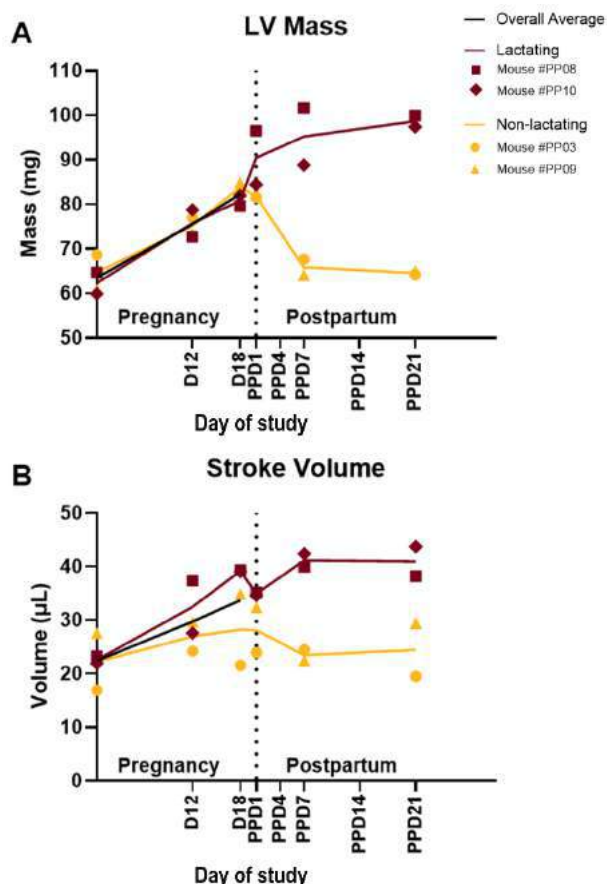

Figure 2: LV mass (A) and SV (B) estimated by ultrasound during pregnancy and the postpartum period in *L* and *NL* mice.

DISCUSSION

This study investigated the impact of lactation on pregnancy-induced cardiac hypertrophy in mice. Our results show that heart growth continued throughout the end of the study in the *L* cohort while growth reversed in their *NL* counterparts by **PPD7**, which is qualitatively

consistent with previously published trends in mice [7, 8]. Our data also demonstrates that hemodynamic metrics like SV remained elevated in the *L* group and decreased in the *NL* group, in agreement with cardiac output changes seen in rats [4]. Coupled with reported increases in serum *P4* concentrations, these findings are consistent with our hypothesis that elevated *P4* levels and cardiac outputs continue driving heart growth following pregnancy in murine models [5, 9].

The postpartum period is at least as long and just as complex as gestation, yet available literature often draws conclusions from a single postpartum measurement taken anywhere from hours to months after delivery [7, 8]. Our study illustrates the necessity of frequent and appropriately timed measurements to further our understanding of cardiac changes during the entire pregnancy and postpartum timeline. For example, SV decreased between **D18** and **PPD1** in three out of four mice, independent of lactation status. This drop in SV is likely an unloading effect from significant blood loss during delivery and subsequent decreased cardiac demand after delivery [10]. Additionally, our results show how significant cardiac changes can occur over a few days during pregnancy and the postpartum period in mice. While the **D18** scans usually occurred ~24 hours before delivery, differences in gestational periods meant that **D18** could fall a day or two before delivery [11]. For example, mouse #PP08 (Fig. 2, Maroon Boxes) gave birth two days after the **D18** scan – creating a three-day gap between **D18** and **PPD1**, during which significant growth occurred.

In conclusion, our findings suggest that *L* mice experience hormonal and mechanical changes that drive additional heart growth, whereas *NL* mice experience hormonal and mechanical changes that drive reverse growth during the postpartum period. One limitation of this work is the low animal numbers, which we are currently addressing with more scans and analysis. In the future, we will investigate how ceasing lactation after 21 days will impact heart size and shape in the *L* mice. We can also repeat this study with additional cohorts that are ovariectomized on **PPD1** to remove the influence of reproductive hormones like *P4* throughout the postpartum period [12]. Ultimately, we aim to characterize cardiac hypertrophy throughout the entire pregnancy and the postpartum timeline so that we can uncover the mechanisms behind pregnancy-induced heart growth.

INTRODUCTION

Temporomandibular Joint Dysfunction (TMJD) is a disorder where there is an anterior displacement of the articular disk with reference to the condyle. TMJD is a common disorder that affects nearly 10 million Americans [1]. The abnormal jaw mechanics causes major symptoms of discomfortability and pain. These symptoms are clicking, pain of the jaw, difficulty to chew, and severe bruxism. Bruxism is a condition where teeth grind, gnash, or clench involuntarily at any time of the day, especially during sleep time. Bruxism engages the Masseter, Temporalis, Medial Pterygoid and Lateral Pterygoid muscles to continuously be under involuntary movement which leads to the exhaustion of the muscles and jaw joints. Along with, the Temporomandibular Joint (TMJ) is nearly connected with the ear muscles where a misalignment of the articular disk can set excess pressure on the branches of the trigeminal nerve and therefore cause aching pain around the ear; exhibiting how delicate TMJD can be to the human health.

The ideal solution in the current market to treat TMJD remains unknown in the biomedical community. Within the past twenty years, treatment options to help relieve TMJD involved a series of stages and processes, like physical therapy to help alleviate TMJ pain by avoiding extreme jaw movements and using prescribed medications. One such treatment option is dental splints: plastic mouthpieces that fit on the upper and lower teeth. Although this helps with teeth alignment and reduce the effect of bruxism on the excessive wear and damage of the teeth, they do not prevent bruxism, grinding/clenching of the teeth [2]. In addition, dental guards do not alleviate pressure from the TMJ when bruxism occurs, which ultimately results in the patient continuing to experience uncomfortable symptoms. The final option would be surgical methods including arthrocentesis, arthroscopy, discectomy, and joint replacement. Although the surgical methods can help produce a

successful outcome, the process to obtain these surgical methods are lengthy and can be expensive financially. The objective of the design is to produce a dental guard that can relieve the pressure from the TMJ while it is under bruxism, preventing the patient's symptoms to augment. Therefore, the chosen design for this project is to redesign current market dental guards due to it being considerably safer and lower cost than an invasive option. Occurring concern of the lack of protection of the jaw mastication muscles will be taken into consideration.

PRODUCT DESIGN

The current prototype has two separate pieces. The upper guard covering the teeth until the premolars and the bottom guard covering the 2nd premolar and 1st molar. The bottom guard will be connected by a strap that it is still being designed. This design is still under research on how to protect the jaw mastication muscles, particularly on the Masseter considering it is the responsible muscle that elevates the mandible for jaw closure.

Figure 1: Prototype CAD model

To conduct research on a possible method to relieve TMJD symptoms, an engineering approach is needed to mechanically understand the phenomenon. The approach taken to understand TMJD is based on the fundamentals of levers. The mandible is classified as a class 3 lever [3]. The fulcrum being at the mandibular condyle. The effort is applied by the four mastication muscles, the medial pterygoid, lateral pterygoid, temporalis, and masseter. Therefore, the load is produced by the action of chewing. Positioning of the fulcrum and effort is crucial since if one of the two are out of alignment, a higher effort is required for the load resulting in a stronger tension on the mastication muscles and mandibular condyle.

A LEVER OF CLASS III

Figure 2: Mandible as a class III lever

Extensive study was concluded on various papers regarding current solutions and cause of TMJ discomfort. An occurring concern among cases is the lack of protection of the jaw mastication muscles. Dental guards can protect the teeth from grinding, excessive wear, and damage, however, there is no proven method to relieve the pressure of the jaw joints. Numerous types of current orthodontic treatments were researched before coming across the Herbst appliance. The Herbst appliance is used to correct an overbite in a patient, although, with modifications to the design, a dental guard can help relieve some of the symptoms of TMJD.

The current market dental guards do not prevent protrusion, protraction, retraction, nor lateral or medial excursion. This is a current issue as the individual is exerting forces on their jaw with the grinding movement causes the articular disk to slip. Subsequently current dental guards do not relieve the jaw muscle average bite force of 700 N on the molars and about 350 N on the incisors [4]. To counter this, the design has an upper guard custom fit with rougher under surface. The front of the upper guard will be thicker than the back portion to prevent the 1st and 2nd molars from touching. This should relieve the 700N at the back of the mouth. In addition to the top guard, there is a bottom guard made of a softer, thicker gel material. The bottom guard will only cover both premolars on both sides. This will help relieve the force on the incisors. This combination will allow for friction to be present between the dental guards under biting force preventing grinding.

BUDGET & MARKET ANALYSIS

The current market of dental guards as of 2021, is valued at 3.7 billion dollars with an average of 40 million dental guards being sold each year [5]. These dental guards come in stock, boil-and-bite, as well as custom made. Our dental guard focuses on the custom section to protect individuals with TMJD. The upper dental guard will be 3D printed with an acrylic 1.75 mm which costs \$50 per roll of 1000g. The bottom guard will be made in an elastic 50A resin with a cost of \$200 per 1020g. The average print weight for a top guard is 28 grams resulting in roughly 35 upper dental guards per acrylic roll. The bottom guard uses about 14g per print resulting in roughly 71 dental guards per elastic

50A resin. Consequently, with a cost of approximately \$300, roughly 70 customers can have a custom dental guard to help protect them from TMJD. The cost of each dental guard will be priced at 200 as current market dental guards price scale is around \$100-\$150 resulting in \$14,000 gross income per batch.

Figure 3: Manufacturing cost estimation of current design

Labor cost will come in about \$18 per hour or \$720 per week. Manufacturing time is set to be 14 hours at a \$5 rate resulting in \$70. The cost breakdown will result in an estimated profit of \$8,080. The previous prices are unofficial as it is an estimation, multiple factors will be considered with a deeper study of the market.

ASSISTIVE PADDLE MOUNTING SYSTEM FOR PARA-KAYAKING SPORTS

Betsabe Hernandez (1), Dinh L. Le (1), Weston J. Randall (1), Erin C. Ray (1)

Faculty Advisors

Victor A. Huayamave, PhD (1)
Christine D. Walck, PhD (1)

(1) Mechanical Engineering, Embry-Riddle Aeronautical University, Daytona Beach, Florida, USA

INTRODUCTION

According to the CDC, one in four adults in the U.S. suffer from a disability that affect their major life activities (1). They also report that the most common type of disability is physical, leading to mobility dysfunction (1). A major cause of physical disability is paralysis. Currently, approximately 1 in 50 Americans suffer from some form of paralysis caused by stroke or injury to the nervous system (2) due to a lack of sufficient blood flow to the brain. This poor blood flow kills brain cells in the affected area of the brain, and all neurological problems that occur are reflective of what area of the brain was affected (2). While paralysis is often permanent, the quality of life for these patients can be improved through parasports—sports designed to accommodate the limitations of the disabled— using adaptive and assistive equipment [ref].

The Oceans of Hope Foundation (OOHF) is a non-profit organization in Daytona Beach, FL, which hosts nearly 130 participants each year in adaptive kayaking events. The OOHF provides assistive equipment including the Angle Oar Gamut Hinged Mount shown in Figure 1. The Gamut Hinged Mount is an adaptive kayak mount that assists the user by self-stabilizing, thereby decreasing the stress on the user while kayaking (3). A rotating head, on the support mount, allows the user to have a large range of motion and is advertised by Angle Oar to be ideal for kayakers with rotator cuff injuries, hand, wrist and elbow stiffness, and those suffering from arthritis (3). However, the participants at OOHF have expressed their frustrations with the Gamut Hinged Mount, stating various faults with the system. Some of the most notable faults include the susceptibility to deformation, resulting in failure, when the kayakers exert a large amount of force. Such a failure inherently increases the risk of injuries by the participants in their need to compensate for the force required to paddle. Another notable problem is seen in the paddle path. Currently the path mimics a seesaw movement instead of a 'normal' stroke.

Figure 1: Angle Oar Gamut Hinged Mount

PRODUCT DESIGN

To address the frustrations of the OOHF, a team at Embry-Riddle designed a new assistive device that mimics a more natural paddling path (i.e., paddle stroke) shown in Figure 2. The paddle motion is controlled by a slotted arc allowing the

adjustable attachment to slide within it. This design allows the user a wider range of motion as opposed to the seesaw motion. To further accommodate the users, the ends of the arc are adjustable to allow the distance between the assistive device and their torso to vary.

Figure 2: Isometric View of Design's CAD Model

Results:

This design focuses on the viability of the user having the ability to mimic the wide ranges of motion.

Figure 3: CAD Model Motion Overlay

Figure 3 depicts the allowable ranges of motion the blades of the paddle would have with the assistive device shown in gray. The green and blue shapes depict the average range of motion of the paddle blades, while the pink and yellow show the range for the hands, of a 'normal' kayaker. This device is unique in that the motion of the paddle closely mimics that of a normal kayaker in contrast to similar products.

In collaboration with Embry-Riddle's Biomechanical Analyses Laboratory, the team will validate the prototype using motion capture technologies. The motion capture will aid in forward and inverse kinematics. Allowing the team to post-process the motion path of the kayak paddle when paired with the prototype. The main purpose of testing is to ensure that, not only the device follows the proper path of motion, but that the user can also follow normal and safe ranges in motion while kayaking.

BUDGET & MARKET ANALYSIS

Although a budget of \$1500 was awarded to the team for development and manufacturing, costs were saved through the collaboration with the OOFH. OOFH donated the Gamut Hinged Mount to analyze the pros and cons of the competing market design. In addition, technical papers used for this project were available through University Resources. The program used to design the prototype in a 3D space, SolidWorks, is also provided through the University Resources. Due to the minimal spending on the design process, the majority of the team's budget is going towards 3D printing the mock-up and prototype of the design shown in Figure 2. The mock-up is printed in Polylactic Acid (PLA), which has an average cost between \$15 and \$25 per kilogram, and requires multiple test-prints. With a maximum weight of 6 lbs., and a print time close to 24 hours, the mock-up has an estimated cost of \$300. The prototype is made of polypropylene, which can cost over \$100 per kilogram. To allow for any necessary re-printing the budget for the prototype print is \$600. Within the slotted arc that makes up most of the prototype, there is a ball that slides within the arc. The team needs to print this ball out of a low-friction material, such as Tribo Plus, or purchase a similar part that suits the design parameters. The cost of Tribo Plus is approximately \$200 per kg so, allowing for any necessary re-prints, the estimated cost to print the ball is \$500. The team also needs to purchase basic connectors, such as nuts and bolts which is unlikely to cost more than \$20.

Given the relatively large population of Americans with a physical disability, the potential market size is on a national scale. If just 10% of this population considers purchasing the product, the potential customers may come out to nearly 300,000 over the course of 2 years. Because this market also lacks substantial competition, the product has an even higher potential for success.

Sales predictions can be made using the competitor's sales data, and analyzing more general kayaking market data. Based upon Angle Oar's sales figures, 68% of their customer base are using adaptive kayaking equipment(6). It is likely that sales figures for the new product would be comparable to theirs. Based on the kayaking market predictions from 2020 to 2025, the share is predicted to increase to \$105.37 million, and the growth momentum will accelerate at a CAGR of 2% (7). It can be assumed that the sales of the improved product will follow this trend.

For mass-production, injection molding is the most cost-effective manufacturing option, and Acrylonitrile Butadiene Styrene (ABS) is a viable material choice due to its favorable material properties and reasonable material cost of approximately \$1.30 per pound. The cost for injection molding is dependent on several factors, including weight, complexity, and volume of order. Since the design in mind requires assembly after the injection molding, the manufacturing cost would include those additional charges. Because the part is more easily manufactured in high volumes than the current products on market, the cost of manufacturing should be notably less than the current products (8). Because the market has so little competition, and the new design offers distinct improvements over the original, the projected sales price for potential national roll out of the design is \$300, which is higher than that of the competitors without being unreasonable (3).

In order to build a company for this product, a significant investment is needed to manufacture the molds for injection molding, hire on essential administrative employees, purchase materials, and pay for distribution of the initial production.

DESIGN OF A PROPHYLACTIC KNEE BRACE TO PREVENT ACL INJURIES IN FEMALE ATHLETES

J. DiVanna (1), E. LoVerde (2), M. Taibi (3)

Faculty Advisor(s)

P. Saboori (1)

(1) Mechanical Engineering, Manhattan College, Riverdale, NY, United States

INTRODUCTION

Anterior Cruciate Ligament (ACL) tears cause an immense amount of pain in individuals and typically have a lengthy recovery time of between 6-9 months. The susceptibility and long-term consequences of such an injury are further magnified amongst female athletes - who regularly perform the intense, change-of-direction movements which are frequently associated with ACL tears and, as a result, are therefore unable to participate in the entirety of at least one athletic season.^[1-2] Additionally, females are generally 2 to 8 times more likely to tear their ACL in comparison to their male counterparts due to several anatomical and biomechanical differences between the two - most notably cited in a female's wider hips introducing a more compromising valgus force upon their knees during the landing portion of a jump.^[3] During this motion, the hip extensors are unable to control the downward acceleration resulting in the pelvis collapsing forward and causing an increased amount of strain on the knee.^[4]

With the rise in women participating in collegiate sports over the past few decades, the number of ACL injuries sustained amongst female athletes has also grown exponentially. And being that such injuries result in extensive recovery periods in addition to expensive health costs, an ACL tear can prove to be career-ending for some collegiate female athletes - eliminating the potential pathway to becoming a professional athlete and subsequently forfeiting the opportunity to stabilize their financial future with the associated generous salary rates. As such, to try and remedy the compounded effects stemming from this type of ACL issue, it is necessary to develop a knee brace that would effectively "re-train" a female athlete's muscles and landing position to reduce the stress and strain placed on the knee - reducing the risk of sustaining an ACL injury in the process. Since this is such a common injury amongst athletes, a brace would expectedly be in high demand from athletes, coaches, and physical therapists. The brace would be worn during practices to develop muscle memory within the athletes. The brace is designed to counteract the valgus motion and is strong enough to withstand strenuous movement while maintaining knee stability.

PRODUCT DESIGN

The brace was modeled and designed using NX software. The size of the brace was determined by utilizing the measurements of an "average" female adult knee. The brace's diameters are parametrically editable so that when a leg dimension is inputted, the brace automatically adjusts its shape. This allows for a range of braces to be printed depending on the test subjects used. In addition, the brace uses a four-bar mechanism for movement.

Figure 1: CAD Knee and Knee Brace Model

Once the brace was modeled, it was printed with solid ABS plastic. The ribs of the brace were designed to be in front. They were also modified to be oval-shaped so that the rib would protrude further out and allow for the brace to be positioned deeper onto the leg. The bottom rib has indents near the calf to help taper the transition from the larger-diameter thigh to the smaller-diameter calf. In terms of comfort

for the test subjects, different thicknesses of padding were also used to determine the most agreeable fit during both rest and motion.

Furthermore, the padding was added to provide cushioning for the knee and to give the knee additional support against future stresses and strains. Velcro straps were added to the back of the brace to fit better in the hitches. The Velcro straps also allowed the brace to be adjusted depending on the size of the athlete testing the brace. The thickness of the brace was increased since its original design concept to make sure the brace would be able to withstand any of the forces generated from eventual human testing. Screw countersinks were additionally cut in for a smoother movement of the brace itself and for increased comfort of the test subjects. Two screw countersinks were put into the side plates, positioned at either side of the knee, and another two were placed into the brace’s top and bottom pieces.

Figure 2: Knee Brace CAD and Prototype

This brace will be worn by athletes during their practices, requiring its design to consider the intense, change-of-direction movements commonly associated with many sports and to contain certain features that can withstand the forces generated from such motions. The prophylactic knee brace will look to “retrain” the athletes’ knee muscles to limit the compromising valgus movement that most commonly leads to ACL tears.

To determine an athlete’s pre-existing risk of sustaining an ACL injury, a screening process was also conducted before any further testing takes place. Screening the athletes included observing the degree of valgus already present in their knees during the landing portion of a series of jump squats. Using the tracking system described in Table 1, the degree of pre-existing valgus was scored for each athlete.

Single-leg squat (out of 6)	Knee tracks over inside foot.	1/6
Regular Squat (out of 6)	Knee tracks over first toe.	4/6
Jump Squat (out of 6)	Knee tracks over second and third toes.	6/6

Table 1: Example of Jump Metrics Scale

To test its effectiveness, female athletes were asked to wear the brace for six weeks through a series of leg muscle-building exercises performed twice a week. Every two weeks the athletes were rescreened to observe any changes in the magnitude of their knees’ valgus motion.

At the end of the six-week study, the risk screenings were post-processed for analysis to determine if any significant trends could be identified from the collected data. The expected results include a decreased valgus motion and an increase in knee stability. With repetition of workouts utilizing the brace along with ACL-centered exercises the results will be more apparent.

BUDGET & MARKET ANALYSIS

The prophylactic knee brace will mainly be marketed to female athletes and athletic trainers. Looking at athletes in particular, the brace would be marketed towards younger athletes ranging from 18 to 25 years of age. Since this brace represents a type of preventative care, athletic trainers could also benefit from its purchase in using it to limit their clients’ chance of ACL injury. The budget breakdown to produce the brace comes out to be about \$100/brace. This cost consists of the amount of money required to 3D print the brace, as well as the cost of Velcro, foam, and screws. The customization component adds a unique aspect to the brace which is reflected in the overall cost. The average cost of high-end braces can range between \$200 and \$400, therefore indicating that this brace would be a much more cost-effective option for consumers. However, in the future, this brace could be mass-produced and as a result allow for all its individual pieces (including the padding foam, screws, and Velcro) to become cheaper, and for its overall selling price to decrease too. With this potential for mass production, the brace would ultimately reduce in cost to about \$70/brace and, because a 3D printer will be used for production, each of the braces can be individually customized to comfortably fit each consumer.

3D PRINTED PATIENT-SPECIFIC LOWER EXTREMITY MODEL FOR ASSESSING DEVELOPMENTAL DYSPLASIA OF THE HIP

(3) Orlando Health, Orlando, Florida, USA

INTRODUCTION

Developmental Dysplasia of the Hip (DDH) is a condition that causes an infant's hip to be easily displaced from the acetabulum. An abnormally formed acetabulum is the most common case and can cause the femoral head to slip from the socket easily. Mechanically, the hip is classified as a ball and socket joint consisting of two bones, the pelvis, and the femur. The ball is defined as the femoral head and the socket is defined as the acetabulum. The joint is formed where the ball and the socket fit together and are held by cartilage and ligaments, allowing the ball to glide easily inside the socket.

Infantile hip dislocation is a common condition affecting 1 in every 1000 children born in the USA [9]. It is unknown what the exact cause of DDH is, but most cases are seen in females, breech presentations, firstborn children, those with genetic risk, and when the fetus is restricted in the womb. The most common case seen is when the acetabulum is formed incorrectly resulting in a shallow socket as shown below in Figure 1, allowing for dislocation of the infant's hip.

Figure 1: Anatomical Differences in Hip Dysplasia Patients [6]

The Barlow and Ortolani maneuvers are used to physically detect DDH by dislocating and relocating the femoral head in the acetabulum. proper training in these two tests can improve the chances of diagnosing DDH, resulting in early treatment by non-surgical methods. During the Barlow maneuver, one hand stabilizes the pelvis while the other grasps and flexes the infant's hip to 90 degrees. The hip is then adducted 10-

20 degrees and a gentle posterior force is applied to see if the femoral head dislocates from the acetabulum. During the Ortolani maneuver, the pelvis is stabilized with one hand and the hip is again flexed to 90 degrees. Then the hip is abducted, and an anterior force is simultaneously applied. The femoral head then returns to the acetabulum, resulting in a palpable clunk [8].

Current simulation trainers, including Laerdal Medical's Hippy Baby, are commonly used to teach the Barlow and Ortolani maneuvers to physicians and medical students. The Hippy Baby model presents only the lower half of the torso and limbs of a newborn and is intended for use with the Barlow and Ortolani maneuvers [7]. One issue with this trainer is the stiffness and rigidity of the model as it does not represent the same range of motion as an infant.

This study was conducted to evaluate the forces applied to the Laerdal Hippy Baby model was used by examiners while performing the Barlow and when various examiners performed measuring the force applied using a force plate. The level of force required to dislocate the femoral head from the acetabulum on the Hippy Baby is 12N, however, the average peak force applied by the examiners was 33N [4]. A medical professional could exert too much force and injure the infant while performing the maneuvers on the infant if they are practicing on the Hippy Baby because of its rigidity. Another issue with the Hippy Baby is that the internal anatomy and mechanics are not visible which hinders the student from visualizing how the femur and acetabulum are behaving while performing the maneuvers on a real infant.

In addition, a new model was developed in an attempt to minimize these limitations of current exam training simulation.

METHODS

The new model was created using the anatomy of an infant with mild hip dysplasia. This anatomy was then scaled down and mirrored, to match a 2-month-old infant with class B DDH on both sides. A transparent section will be added along the pelvic region to allow the students to observe the dislocation and reduction. A water-clear

urethane rubber was used to achieve optimum transparency. Because infant bones are not as rigid as a fully developed adult, it can be difficult to quantify their strength and flexibility. The material properties used in this project, originate from a study that performed tensile testing on cadaver infant femurs. The study consisted of a group of infant femurs ranging from 1 day old to 6 months old. Due to the two- to three-month-old age representation of the Hippy Baby, the 2-month-old subject's results were used. The cadaver bone was found to have a Young's Modulus of 803 MPa and a Poisson's Ratio of 0.30 and all analyses will use these properties [5]. 3D printed materials such as thermoplastic polyurethane (TPU) provide the required flexibility, however, it tends to buckle when put under a sizeable load.

Additionally, to compare the force required to dislocate between the new model and the Hippy Baby, a combination of load cells and force plates will be used. These results will be compared to the study mentioned above [4].

FEA analysis was performed to compare different material combinations with the infant bones. A 33N load was applied axially at a point in between the medial and lateral condyles of the femur. The femoral head was fixed within the acetabulum, to observe only the displacement in the femoral shaft. This FEA model did not allow for any movement, the femoral head was fixed in the acetabulum. Since the deflection/bending in the femur was the most important aspect for this analysis, movement in the acetabulum was negligible. Additionally, muscle activity, ligaments, and cartilage were also assumed to be negligible. All three materials were modeled as linear elastic isotropic, using tetrahedral elements.

The first model used the infant material properties mentioned above, the second uses material properties of TPU with a Young's Modulus of 27.15 MPa and a Poisson's ratio of 0.48 [1]. The final model uses the same properties of TPU along with a 3mm in diameter aluminum rod going through the center, the Young's Modulus for the rod is 68900 MPa and a Poisson's ratio of 0.33 [2].

Tensile testing will be performed on the Ultimaker 95A TPU to verify our extrapolated values for Young's Modulus.

RESULTS

A preliminary study was conducted using a Force Sensitive Resistor (FSR) to determine the force required to dislocate the Hippy Baby's femoral head from the acetabulum. The FSR was attached to the knee of the trainer. Of the 10 trials, the average applied force was 27.4N, similar to the peak force used by examiners. The actual force required to dislocate the trainer is 12N [5].

Figure 2: Hippy Baby Instrumented with a FSR

All three FEA models were tested using an applied axial load of 12N, 27.40N, and 33N. Under a 33N applied axial load, the model with the infant bone had a displacement of 0.74mm across the femur. Under the same loading conditions, the TPU model had a displacement of 22.53mm, a 2,952.85% increase from the infant bone results. With the addition of the aluminum rod, the femur displaced 0.97mm, which is within 0.30mm of the infant model.

Figure 3: Infant Model (left) with a displacement of 0.74mm and TPU with the Rod (right) with a displacement of 0.97mm under a 33N Axial Load

Amongst all three applied loads, the TPU model had significantly more deflection than the others. The large percent difference between the TPU and infant model confirms the need for an aluminum rod.

DISCUSSION

The model is limited in its anatomical representation of an infant's hip and acetabulum due to the size of the model and the time required to manufacture realistic ligaments and tendons. Even though these structures are not included, the range of motion and movement during the Barlow and Ortolani maneuvers will not be affected due to the lack of strength in the muscles of a real infant to resist these procedures.

The 3D-printed bones have been evaluated using various print orientations and infills. Ultimately, the Ultimaker 95A TPU at 100% infill would be best suited for modeling infant bones. Through FEA analysis it has been determined that an aluminum rod will be inserted into the center of the femur to reduce the flexibility of the TPU in the femoral shaft. Further materials testing will be conducted with tensile testing. A more in-depth study will be performed using load cells and a force plate to compare the applied forces on the current Hippy Baby, to the prototype during the Barlow maneuver.

The next step is to assemble the prototype and ensure the improved model accurately represents the Barlow and Ortolani maneuvers and the material properties of a real infant's bones. The prototype will also be given to the orthopedic surgeon who has been assisting in the project, for extensive feedback.

EVALUATING THE UNDERSTANDABILITY OF REAL-TIME SONIFIED BIOFEEDBACK PROTOTYPES FOR BALANCE TRAINING

Vibha R. Iyer (1,2), Mitchell A. Tillman (1), Antonia M. Zaferiou (1)

(1) Biomedical Engineering, Stevens Institute of Technology, Hoboken, NJ, USA

(2) Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, USA

INTRODUCTION

Sonified biofeedback, which conveys biological signals through sound and musical cues [1], can be harnessed to facilitate balance training. This study's purpose was to evaluate the understandability of two prototype sonified biofeedback designs during dynamic balance tasks, such as walking and turning, with young healthy adults. We asked for quantitative and qualitative feedback to inform future design iterations towards helping improve older adult balance during turns. In prior work, we found that young adults experience unstable conditions during turns by investigating two relevant balance measurements that our prototype system conveys through sound. During turns, young adults experienced larger frontal-plane whole-body angular momentum (Hf) and smaller "lateral distance" (LD), which is the horizontal distance between the body's center of mass and lateral (side-to-side) edge of the base of support (area in contact with the ground) [2].

METHODS

Five participants (two male, three female; age 20.4 ± 1.4 yrs) pursuing engineering-related undergraduate degrees provided informed consent to participate in this pilot study approved by Stevens' IRB. The study was conducted during one two-hour lab visit that began with setting up the participant with optical motion capture reflective markers. The optical motion capture system (Optitrack, Eugene, OR) monitored 3D body positions and streamed data in real-time to a second computer to compute the balance measurements using MATLAB (MathWorks, Natick, MA). The balance measurements were streamed to a third computer that used the interactive media software Max-MSP (Cycling 74, San Francisco, CA) to map biomechanical measurements to sound parameters, and generate the corresponding sound [3] (see [example video](#)). Next, within each of the two sonified biofeedback designs (Hf and LD, in randomized order) there were three sequential phases for the participant to interact with the system: (1) assessment of prior understanding of balance measurements (Hf and LD) and sound

separately, (2) familiarization period with sonification designs, and (3) assessment of understanding of sonification designs. Participant design feedback and user perceptions were quantitatively and qualitatively obtained after each step along with overall user experience at the end of each phase and the end of the entire study. During Phase 1, verbal conversation using scripted descriptions of balance metrics was used to introduce the system and establish initial familiarity with the balance measurements. The scripted descriptions were intended to be in lay terms and included: "*Larger whole body angular momentum, or larger rotation of your body around your center of mass, produce higher pitches*" and "*Smaller lateral distances, or smaller distances between your center of mass and edge of your base of support, produce faster beats*". After, participants familiarized themselves with the sonified biofeedback by performing feet-in-place weight shifting (Hf only), straight line walking, turning while walking, and free movements.

To evaluate their level of understanding, participants were asked to move their bodies to generate specific sound sequences. Sequence 1 was "high-low-high" pitch for Hf or drum beat speed for LD and Sequence 2 was "low-medium-high" pitch for Hf or drum beat speed for LD. Participants completed four trials to evaluate their understanding of each of the two designs by attempting each of the two sequences. The time series of each trial was divided into three sections based on the timing of the verbal cue to move to the next sound level and the median of each section was calculated (using LD and |Hf|). The median values were ranked relative to the previous and subsequent section; if their ranking matched the same pattern as the sound sequence (e.g., high-low-high), they were deemed successful. **Figure 1** depicts a successful Hf trial for Sequence 2 and a successful LD trial for Sequence 1. The horizontal line thresholds on **Figure 1** mark the extrema Hf and LD mapped to sound. Therefore, beyond these thresholds, the sound stayed constant. The Hf threshold was determined from prior research [2] and the LD thresholds were personalized based on the range used during straight-line gait. The rates of successful sequences are reported.

Figure 1: Example timeseries for sound generation task. (a) Hf low-medium-high pitch. (b) LD high-low-high drum speed.

Finally, participants rated their perceptions of “Ease of Use and Usability” of both designs, overall, using a 7-point Likert scale [3].

RESULTS

Overall, 65% of trials generating specific sequences for the designs were successful (Table 1). The average perceived “Ease of Use and Usability” score was 5.4 out of 7 (+/- 0.89 SD) (Table 2).

Table 1: Success of sound generation tasks by sound sequence and sonified biofeedback design.

Participant:	1	2	3	4	5	% Success
Hf Sequence 1	✓		✓	✓		60%
Hf Sequence 2	✓	✓	✓	✓	✓	100%
LD Sequence 1	✓			✓		40%
LD Sequence 2	✓	✓		✓		60%
Successes:	4/4	2/4	2/4	4/4	1/4	

Table 2: Ratings for “Ease of Use & Usability” of biofeedback technology (tech.) 7=“completely agree”, 1=“completely disagree”.

Participant:	1	2	3	4	5	Mean (SD)
“My interaction with the tech. is clear and understandable”	6	5	5	6	6	5.6 (0.5)
“Interacting with the tech. does not require a lot of mental effort”	5	3	6	5	5	4.8 (1.1)
“I find the tech. to be easy to use”	5	4	5	6	6	5.2 (0.8)
“I find it easy to get the tech. to do what I want to do”	4	5	6	6	6	5.4 (0.9)
“I find the tech. to be flexible to interact with”	5	5	6	7	7	6 (1.0)
“Learning how to perform tasks using the tech. was easy”	5	4	6	6	6	5.4 (0.9)
“The tech. has good functionality”	5	5	5	7	7	5.8 (1.1)
“I feel I have an intuitive sense of how to operate the tech.”	4	6	6	6	5	5.4 (0.9)
“I find it easy to remember how to perform tasks using the tech.”	4	5	5	6	5	5 (0.7)
Mean (SD)	4.8 (.7)	4.7 (.9)	5.6 (.5)	6.1 (.6)	5.9 (.8)	

DISCUSSION

Participants performed better with the Hf system, passing 80% of trials, in contrast to only passing 50% of LD trials. All participants

achieved a successful Sequence 2 (low-medium-high) for Hf. In contrast, only two participants achieved a successful sequence 1 (high-low-high) for LD. Some of these results could be because LD was designed to be used during walking and requires the participant walking forward while modulating LD, whereas, the Hf design allows simpler feet-in-place body movements, like tilting the torso side-to-side. Additionally, some participants out-performed others. Participants 1 and 4 successfully completed all four sequences, in comparison to Participant 5, who only succeeded in sequence 2 for Hf.

As for perceived Ease of Use and Usability, the lowest average rating for a question (4.8 / 7) was given in response to “*Interacting with the technology does not require a lot of mental effort*”, which relates to our current research about cognitive load during sonified biofeedback. The best average rating (6 / 7) was given in response to “*I find the technology flexible to interact with*”, which may be a helpful design feature as we seek to use the system for multifaceted balance training.

This was a preliminary evaluation of the level of understanding of complex biomechanical measurements conveyed through musical cues in near real-time. Therefore, the sample size is small and limited to collegiate engineering students and students of related disciplines. The fact that participants may have learned about angular momentum or biomechanics in coursework could bias the results and *re-emphasizes viewing this study as a first step towards a multifaceted user-centered design process* that we are using to develop the system for older adults. Surprisingly, this small cohort still yielded a variety of responses and results in assessments, which may relate to the need to personalize these systems and familiarization protocols in future designs.

Results indicate that there is generally positive perceptions of the ease of use and usability of the systems, but room to improve the understandability of the sonified biofeedback systems. We are currently using the results of this study to improve the overall sonified biofeedback design, descriptions of the balance measurements and the sounds, familiarization tasks. Further, we are also incorporating design feedback from older adults, and physical therapists from focus groups and “think-aloud” user sessions.

NUMERICAL MODELING FOR INFANTS WITH DUCTAL-DEPENDENT PULMONARY FLOW

S. Mulla (1), M.H. Alzaeim (1), W.S. Basha (1), K.B. Kose (1)

(1) Biomedical Engineering Department, Istanbul Medipol University, Istanbul,Turkiye

INTRODUCTION

The treatment of pulmonary atresia (PA) and Patent Ductus Arteriosus (PDA) requires a comprehensive approach owing to their highly variable morphological features [1]. The decision-making process can be complex, leading to excessive resource and time consumption in both cardiology and cardiac surgery [2]–[4]. It is a very sensitive process to decide whether the treatment will be surgical or catheterization and, in these cases, whether the PDA will remain open or closed.

This study focused on investigating whether utilizing numerical simulations to predict the optimal approach for ductus-dependent congenital circulation has significant consequences. A comparative blood flow simulation study was performed with medical image data and clinical data of selected newborns.

METHODS

Three patients with PA and PDA agreed to participate in this study, and computed tomography image datasets constituted the initial input of the study. The image-based three-dimensional (3D) model was obtained by image processing toolkits [5].

The virtual models were created with open-source computer-aided design tools [6]. The finite element method has been used to simulate patient-specific blood flow[7]. The blood was defined as a Newtonian fluid, with a kinematic viscosity of 0.004 m²/s and a density of 1060 kg/m³ (Eq.1,2).

$$\nabla \cdot \mathbf{u} = 0 \quad (\text{Eq.1})$$

$$\rho \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla p + \nabla \cdot [\mu(\nabla \mathbf{u} + (\nabla \mathbf{u})^T)] \quad (\text{Eq.2})$$

The pulsatile velocity profile of the patient is created on MATLAB and, was defined as the boundary condition (Figure.1) [8].

Figure 1: Patient-specific Virtual 3D models anterior (left) and posterior (right) views. RPA: Right pulmonary artery.

RESULTS

For three newborn patients, a hemodynamic visualization was made based on the digital twin model and two virtual 3D models obtained from the pre-operative DICOM image. Virtual repair methods, which did not highlight one of them, gave different results for each patient, as we predicted. Pressure drop

in a congenital artery is typically considered acceptable if it is between 10 mm Hg and 50 mm Hg [9]. In the first patient, the PDA-removed flow visualization results indicated a large pressure drop. It was found to be within the acceptable range in the second patient without aortic coarctation. Velocity streamlines depicted a better result than the pre-operation models in all simulations, it was observed that vortices were found in patients with coarctation, and it was seen that it would affect the decision according to the segment in which it was located. Evaluations for wall shear stress (WSS) provided the most useful findings for clinical decision-making. While the surgical repair was planned for the first patient, the hemodynamic analysis showed that closure of the PDA could provide a more risk-free flow as a result of the numerical simulation (Figure.2).

Figure 2: The WSS distribution of the virtual shunt (left) and removed PDA (right) models of the first patient.

DISCUSSION

This hemodynamic methodology has guided our ability to evaluate flow patterns in shunted configurations and the associated unmeasurable but calculable mechanical consequences [10]. The WSS distribution, which was confirmed as the cause of endothelial remodeling, was visualized and compared with actual postoperative findings. It was seen that the evaluation of the dimensions and materials of the shunt configurations on their digital twins for three patients could provide significant contributions to pre-operative planning. In the future steps of this study, it is planned to increase the number of patients and to include anastomosis angles in the evaluation as well as optimal shunt diameter and sizes.

ACKNOWLEDGEMENTS

INTRODUCTION

Aortic stenosis (AS) is the most common valvular condition in the developed world, manifesting in 1.3% to 4% of adults between the ages of 65 and 85.[1] It is characterized by a narrowed orifice area between the leaflets of the aortic valve, often caused by calcification or other factors, such as a congenital bicuspid valve.[2] AS causes obstruction of left ventricular (LV) outflow, increasing the pressure required to drive cardiac output.[3] These changes can lead to heart failure and death.[4] The gold standard for treating AS is (surgical) aortic valve replacement (AVR), comprising of the resection of the diseased leaflets followed by the implantation of a mechanical or bioprosthetic valve.[5]

Patient-prosthesis mismatch (PPM) is a frequent outcome of AVR, wherein the implanted valve is too small to accommodate for the cardiac output required by the patient. PPM is defined as an indexed effective orifice area (i.e. the valvular orifice size standardized to body surface area) of $<0.65 \text{ cm}^2/\text{m}^2$ (severe) or $<0.85 \text{ cm}^2/\text{m}^2$ (moderate).[6] It represents 54% to 65% of cases, and it can cause compensatory remodeling and hypertrophy of the left ventricle.[7, 8] To prevent PPM, aortic root enlargement (ARE) was proposed to be performed in tandem with AVR to increase the aortic annulus size by up to 10 mm.[9, 10] It has been noted that ARE is associated with LV regression and a significant reduction in transvalvular pressure gradient, both of which indicate a trend toward cardiac competency.[9, 11] However, an increase in annular diameter reduces outflow velocity and may cause hemostasis which can increase the risk of thrombosis.[10]

In this study, we utilized computational fluid dynamics (CFD) simulations to model hemodynamics in the aortic root following AVR and AVR+ARE. In doing so, we non-invasively estimate pressure, velocity, and residence time. Using these values, we work to evaluate the risk of thrombosis after aortic root enlargement *in silico*, providing a basis for future longitudinal clinical studies.

METHODS

To evaluate the hemodynamic impact of ARE, CT scans of three AVR patients (Patients 1, 3, & 5) and three patients who underwent AVR+ARE (Patients 2, 4, & 6) were collected, wherein Patients 1 and 2, 3 and 4, and 5 and 6 were paired. These patient pairs were matched on age, sex, ejection

fraction, and native annulus size. As a secondary control, a “virtual” AVR (vAVR) model without an ARE was generated for each AVR+ARE patient using preoperative anatomy and annulus dimensions. Transvalvular pressure, peak velocity, and blood residence time (time to exit the model from a given starting location) over six cardiac cycles were computed at a temporal resolution of 0.02 seconds.

Pre- and post-operative computed tomography (CT) images were acquired for each patient, and 3D models of the ascending aorta and aortic root were segmented using 3DSlicer. Segmented models were imported into SimModeler for smoothing, tetrahedral mesh generation (using boundary layer refinement). Hemodynamic parameters, including heart rate (70 bpm) and stroke volume (73.5 mL/beat), were standardized for all patients to isolate the effects of root anatomy. Meshes were coupled with a closed-loop 0D model that represents the remaining cardiovascular system.[12] CFD simulations were performed on the finite-element multiphysics solver CHeart.[13]

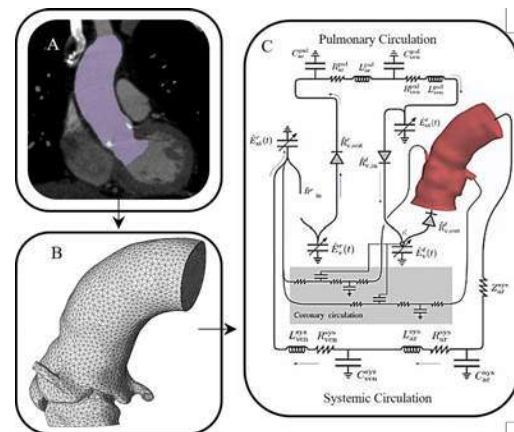

Figure 1: Aortic Root Modeling Pipeline. (A) Pre- and post-operative CT images are segmented to create 3D models of the aortic root blood volume. (B) Tetrahedral volume meshes are generated in SimModeler. (C) Meshes are coupled with a closed-loop 0D model.

Due to poor image resolution, valve leaflets could not be segmented from the CT images. Instead, the aortic valve was modeled in SimModeler as a 2D plane. The location and orientation were based on landmarks in the patient images. The anatomic valvular orifice area (AVOA) was defined on the plane and was based on the patient's implanted valve. This area is used to control flow in the simulations, mimicking the opening and closing of the aortic valve throughout the cardiac cycle.

RESULTS

AVR+ARE increased the annulus diameter by 2 valve sizes in Patient 2 (21 → 29mm), and by 3 sizes in Patients 4 and 6 (23 → 29mm and 21 → 27mm, respectively). CFD simulations demonstrated an expected decrease in mean and peak pressure gradients in AVR+ARE cases compared to AVR (42.9% and 69.8% decrease, respectively) and vAVR (41.3% and 66.4% decrease, respectively). Peak velocity was also reduced after root enlargement by an average of 37.9% and 40.0% relative to AVR and vAVR. Finally, residence time decreased by 0.11% on average ($\sigma = 2.61$) in AVR+ARE models compared to AVR, wherein Patients 2 and 4 had a slight increase and Patient 6 had a slight decrease.

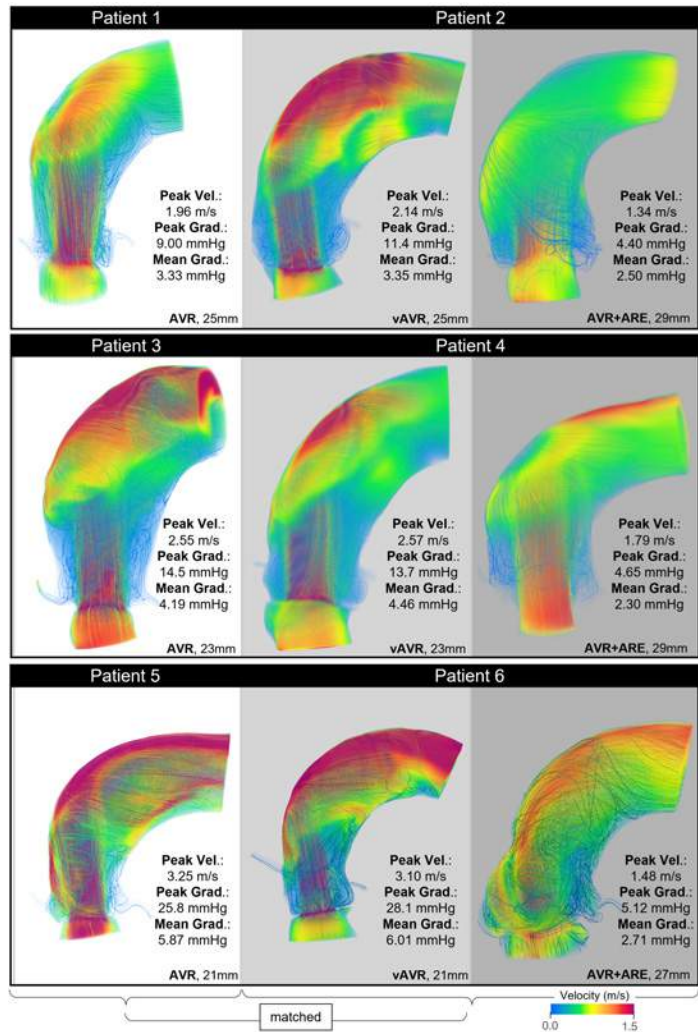

Figure 2: Velocity fields at peak systole are shown for AVR, AVR+ARE, and vAVR. Abbreviations: Vel. = velocity, and Grad. = transvalvular pressure gradient.

DISCUSSION

In this work, we modeled blood flow in AVR and AVR+ARE patients to study how an ARE changes the risk of thrombosis and local hemodynamics. We observed a global decrease in transvalvular peak velocities and pressure gradients following post-ARE in comparison with AVR-only models. This is in line with the results of earlier studies.[11]. We also demonstrate a minimal change in residence time and blood stasis in the si-

nuses following root enlargement. This suggests a limited added risk of thrombosis.

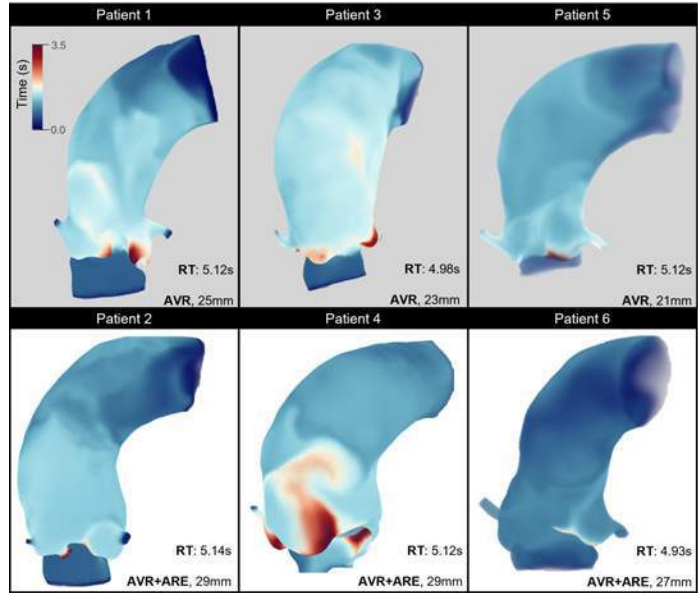

Figure 3: Residence time fields are shown for AVR and AVR+ARE. Abbreviations: RT = residence time.

We observed that patient 6 (AVR+ARE) had a lower residence time than its matched patient, patient 5 (AVR only). This suggests that there are other factors, including possibly the way that a new valve is implanted, that have a competing influence on the occurrence of hemostasis following valve replacement. This might further explain the lack of consensus regarding the longitudinal effects of ARE.[11, 14]

In future work, we plan on examining velocity, pressure, and residence time in models that include dynamic valve leaflets, which more closely matches physiological conditions. In doing so, we hope to further elucidate the longitudinal effects of ARE, as patient-prosthesis mismatch becomes an increasingly debated topic.

INTRODUCTION

According to the U.S. Fire Administration (USFA), there are 11 million deaf or hard of hearing Americans who are unable to rely on the life-saving warning sounds of a smoke alarm [3]. This deficit extends to all life-saving emergency warning devices that utilize auditory alerting. Currently available solutions are expensive and require special installation - limiting such technology to the homes of individuals that can afford them. Examples include bed-vibrating fire alarms and specialized strobe-light systems. Outside of the personal residence, the hearing impaired must rely on cues from their surroundings to interpret nearby emergency alerting. These cues can be difficult to interpret, particularly when the individual is preoccupied with other tasks. Our team designed an affordable, wearable, haptic-rich solution that best addresses this problem.

PRODUCT DESIGN

Emergency Listening, Emergency Responsive, Technology (ELERT) is a wearable device that responds to auditory input via haptic user-interfacing. The current prototype is in the form of a device that can be worn as one would wear a wristwatch. The 3D printed mechanical housing is shown in Figure 1.

Figure 1: ELERT mechanical housing for the haptic system.

Creating a compact, but feature-rich, device was challenging. The microcontroller, microphone, haptic motors, haptic motor driver, and battery all had to be organized within a compact, ergonomic case. Since the unit would also be vibrating against the user's body, there also had to be careful consideration taken for haptic motor placement, and isolation (mechanical and electrical) of the vibratory motor from other sensitive electronic elements. Figure 2 provides an internal view of the wristwatch case design, with recessed space for components to be seated.

Figure 2: Internal housing depicting integrated electrical cutouts.

The vibrational motor is press-fit into a circular cutout, minimizing the distance between the motor and skin, improving the magnitude of vibratory stimulus transmitted to the user's wrist. When the top and bottom of the case are mated together, there is a circular hole allowing for projection of the microphone sensor, vastly improving auditory signal detection. The case is held together with a snap-fit joint that interfaces with the main mechanical housing, keeping the device together and protected. A hook-and-loop fastener is currently being utilized as the strap, allowing for easy donning, doffing, and adjustability.

The microphone is a KY-037, which is used to sample audio signals at a frequency of 11,000 Hz. The haptic motor is driven by a haptic driver (DRV2605L), vibrating at a frequency of 166 Hz and magnitude of 0.4 G - more than adequate to stimulate the mechanoreceptors located within the skin of the wrist [4]. All of these components are controlled via an Arduino Micro and powered by a coin-cell battery. Figure 3 shows the assembled device.

Figure 3: Assembled device and electronics.

The device was coded using a combination of Arduino and C. The audio signal from the KY-037 microphone was processed using the arduinoFFT data-processing library. This allowed for the extrapolation of the input audio signal’s frequency content, which was then stored and assessed according to a rolling-average of the frequency data. A rolling-average threshold of 2200 Hz was specified for our prototype. When this threshold was met, the device began actuating the haptic motor, alerting the user. The threshold of 2200 Hz was specified in accordance with NFPA 72, the National Fire Alarm and Signaling Code, which requires that emergency alarm systems use a temporal-three sound, produced at a high frequency of about 3,150 Hz [1]. Using a rolling-average accounts for background noises and other frequencies that may be sampled during the pauses of the temporal-three sound.

BUDGET & MARKET ANALYSIS

Our team’s budget for the prototype was \$240.00, provided through a KEEN Engineering Unleashed Fellowship Award. Table 1 depicts the cost-breakdown of the final prototype and anticipated production costs.

Table 1: ELERT prototype and production budget breakdown.

Item Name	Quantity	USD/Unit	Production USD/Unit
KY-037 Microphone	1	\$1.92	\$0.37
Arduino Micro	1	\$24.20	\$0.75
Haptic Motor	1	\$1.95	\$1.56
DRV2605L Haptic Driver	1	\$9.50	\$0.95
Coin Cell Holder	1	\$4.84	\$0.48
Hook & Loop Strap	1	\$5.99	\$0.18
Misc*	-	\$20.00	\$2.00
TOTAL	-	\$68.40	\$6.29

* Cost estimate for plastics, wires, etc.

As seen in Table 1, purchasing components in bulk would reduce the cost of a production model significantly. Costs could also be significantly reduced by choosing a cheaper microcontroller. All of these factors, in combination with mass production methods, brings the cost of a production model to an estimated 6.29 USD. With production overhead, and other costs in mind, we estimate an MSRP of around 15.00 USD. We anticipate that this device would be considered a General Wellness Product and would not be subject to regulation by the FDA [2].

This low cost is highly favorable in the current market. Table 2 provides details on the costs of our product’s market peers, clearly demonstrating that our device has a competitive advantage when it comes to offering an economical alerting device. The ELERT poses as a viable solution to fill a significant gap in the market for the hearing impaired.

Table 2: Cost of ELERT compared to market peers.

Assistive Solution	Description	Cost
First Alert [5]	A fire alarm designed for the hearing impaired with a built-in strobe light	\$100
Safe Awake [6]	Smoke detector with built in bed shaker	\$250
ELERT	Portable, haptic alerting aid	\$~15

DISCUSSION

Currently, the device can alert the wearer to the standard high-frequency temporal-three sound for smoke alarms and the standard high-frequency temporal-three sound for fire alarms. Once these alarms are stopped, the device continues to haptically alert the user for a few seconds. While our device currently targets fire-related emergency alerting, it has the potential to offer users alerts to a wide range of auditory stimulus. This could allow for the user to customize their device to respond to particular auditory signals, such as classroom bells, an infant crying, dog barking, or work-related alert-sounds. We would also like to explore alternative designs for the device, allowing users to wear the device in more intuitive and comfortable ways. This could take the form of a haptic necklace or other wearables. Our device has proven its viability to compete with current market solutions and has the potential to become a customizable wearable solution, supporting the hearing impaired in their everyday life.

DEVELOPMENT OF A NOVEL ANIMAL MODEL FOR OSTEOCHONDritis DISSECANS: A RADIOFREQUENCY ABLATION APPROACH

Kosisochukwu Ogonna-ukuku (1), Boyuan Liu (2),
Kristine Fischenich (3), Virginia L. Ferguson (1,2)

INTRODUCTION

Osteochondritis dissecans (OCD) is an acquired focal knee disorder that occurs in the secondary physis and adjacent subchondral bone in distal femur. The resulting tissue necrosis ultimately can result in partial joint destruction and early degenerative arthritis [1]. Imaging techniques have improved clinical diagnosis of OCD, but a lack of animal models that adequately replicate OCD makes further advances challenging. Existing models frequently involve acute damage to the articular cartilage rather than the underlying bone. These models mimic a focal cartilage defect and do not capture the unique presentation of OCD, which includes cartilage and underlying bone necrosis. Here, we propose to use radiofrequency ablation (RFA) (Fig. 1A) of subchondral trabecular bone, thereby generating a highly controlled tissue necrosis that can precede articular cartilage damage. We propose that this novel approach will enable a translational animal model of OCD to evaluate pathogenesis along with modalities for early detection and treatment.

understand the thermal necrosis during RFA in the knee joint, we seek to develop an ex-vivo RFA experiment, in which by defining power and time inputs we can generate a controlled volume of thermally damaged subchondral bone tissue to guide the development of a novel animal model of OCD. Using these experiments, we aim to demonstrate the efficacy of RFA to generate focal tissue necrosis in subchondral trabecular bone to, later, demonstrate OCD-like outcomes in a live, large animals.

METHODS

For this study, we selected swine models due to the suitable size of the pig's knee joint for conducting RFA and the similarity of the bone, cartilage, and vascular architecture of the distal femur to juvenile human subjects [2]. We designed an ex-vivo ablation experiment in porcine condyle tissue with a commercial RF generator (Medtronic plc) (Fig. 1B). Briefly, fresh cadaveric porcine distal femurs were collected from a local abattoir. An RFA probe (17-gauge, 5 mm active tip) was inserted from the non-loading region of the femoral medial condyle through a hole (slowly drilled by a 1/16-inch drill bit to avoid thermal damage from friction) to a depth that is determined by a computed tomography image of each joint and which is guided by our computational finite element model described below. The probe was connected to the RF generator and applies the RF signal to induce resistive heat thus creating ablation. An in-house fabricated grounding pad (10 mm x 10 mm) was placed on the side of the condyle close to the probe. This custom-designed grounding pad included aluminum foil at the outer layer to connect to the RF generator by wire and a piece of gauze pad at the inner layer that connected the grounding pad contact to the curved condyle surface. An electrode gel (Parker Laboratories, Inc.) applied to gauze pad: 1) adhered the aluminum foil-gauze pad and the gauze pad-condyle connections and 2) enabled electric conduction between the sample and the grounding pad.

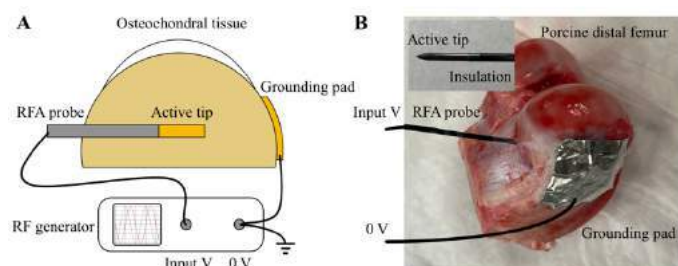

Figure 1: A) Schematic of a radiofrequency ablation system. B) Ex-vivo RFA experimental setup of a porcine condyle tissue.

RFA is commonly used to treat a range of conditions affecting soft tissues. The available protocols and guidelines of clinical RFA apply to human tissue that lacks the structural complexity of bone. Thus, to

RESULTS

To date, we established an experimental setup that will enable us to ablate a controlled region of bone and marrow, with minimal damage to the overlying articular cartilage. We aim to use this experimental setup to optimize experimental parameters and demonstrate proof-of-concept for a novel large animal model of OCD.

In our ongoing studies, we will first conduct experiments that verify our experimental setup and compare results to those in our established computational model. A small RF signal will be sent from the generator to detect the resistance of the whole circuit. We will vary the size and the location of the grounding pad and record the changes in the measured resistance. In our previous simulations, we observed that the grounding configuration have a significant influence on the ablation region. Thus, our experiments will measure the voltage differences between the probe and the different locations of the grounding pad. This process will enable us to determine if the grounding design is sufficient to dissipate the electric current across the whole region and prevent unwanted burning on the condyle surface.

We will next conduct a series of ex-vivo RFA experiments by varying the input voltage to induce different regions of thermal necrosis in the distal femoral condyles from porcine knees. The temperature spread of the tissue will be monitored by thermal probes inserted at different locations of the condyle. Assuming subchondral bone thermal necrosis when temperatures exceed 50 °C [3], we will estimate the necrotic lesion size from the measurements. After the experiments, the tissue will undergo formalin fixation for 14 days. We will employ histology to assess cell death and tissue degradation and compare the size of damaged regions with computational models using the same parameters.

Additional to the experiments, our team has created a computational finite element model based on actual tissue geometry from an X-ray microscope scan of porcine subchondral bone (Fig. 2A). The model simulated heat dissipation during RFA in one-half of the femoral medial condyle (i.e., to reduce computational cost), where articular cartilage, subchondral bone plate, and subchondral cancellous bone were separated and subchondral cancellous bone and marrow were homogenized. A cylindric electrode tip model used in the experiment (17-gauge probe, 5 mm active tip) was included to apply RFA input and a 10 mm x 10 mm pad was placed on the side of the condyle to apply zero voltage grounding boundary condition (Fig. 2B).

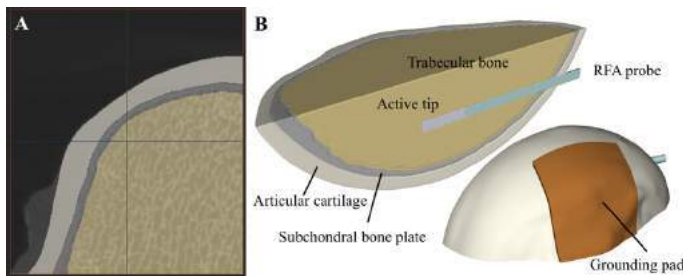

Figure 2: Simulation of RFA in porcine subchondral bone. A) X-ray microscope scan of a porcine femoral medial condyle. B) Reconstructed model of the scanned volume that includes the RFA probe and grounding pad.

Temperature contours of the tissue were plotted to evaluate for thermal necrosis. These initial model inputs will guide selection of optimized inputs (voltage and time) for experiments. Initial simulations were performed with different input voltages were run (10 V, 15 V, and 20 V; 10 mins of heating) to evaluate thermal spread from RF ablation resistive heating using coupled thermal-electrical analysis. An

additional simulation with 15 V input for 20 mins was run to evaluate temperature stability during RFA. Proper material properties and other boundary conditions including body temperature (37°C) were set. Varying the input voltage showed that RF ablation generated maximum internal tissue temperatures of 48.3, 61.8, and 81.1 °C. We observed that the 15 and 20 V inputs generated necrotic lesions with radii of 8 and 15 mm, respectively (Fig. 3A), with the size of thermal necrosis induced by 15 V close to the size of necrosis found in pigs with OCD [4].

With a 15 V input, the peak temperature near the RFA tip was identical (61.8 °C) at 10 min and 20 min time points (Fig. 3B) of the simulation. We believe it is sufficient to run the simulation and future RFA experiments for 10 mins with 15 V input to trigger OCD-like necrosis.

Figure 3: RFA simulation results. A) 15 V and 20 V inputs generated necrotic lesions with radii of 8 mm and 15 mm at the end of the ablation (10 mins). B) Peak temperature near the RFA tip remains the same after 10 mins of ablation.

DISCUSSION

Simulation of a porcine femoral medial condyle model was used to predict thermal spread in subchondral tissue, including trabecular bone and marrow, during RFA. Our results showed that by varying power and time, we can generate a controlled volume of thermally damaged tissue that compares with the volume of necrotic tissue in OCD. Our ex-vivo experiments are ongoing. We are collecting temperature data *in situ* to estimate the thermal necrotic lesion sizes. We will analyze cell death and tissue degradation. These experimental results will help us to 1) validate the simulation model and 2) determine if we can induce the unique presentation of OCD tissue damage using this novel RFA approach.

Using the simulation results, we selected the input voltage and run time for our proposed experiments. Combining these two parameters, our approach will allow us to develop a novel, thermal injury model of OCD to allow for the eventual study of disease progression and evaluation of novel therapeutic approaches. Further, our study can provide guidance to other RF ablation procedures such as removal of tumors in the musculoskeletal system.

ACKNOWLEDGEMENTS

We are grateful for the funding support provided for this research by CCTSI TM-Pilot FY18.220.012, which is supported by NIH/NCATS Colorado CTS Grant Number UL1 TR002535. We thank Robert Behnke and Medtronic Surgical team for loan of the RFA system.

INTRODUCTION

Extracorporeal membrane oxygenation (ECMO) machines are artificial lung devices used to support patients with significant lung damage, who cannot be kept alive with conventional lung ventilators in an intensive care setting [1]. In the aftermath of COVID-19, the need for such artificial lung mechanisms has been emphasized. ECMO is often a vital treatment for patients suffering from acute respiratory distress, hypothermia, cardiac arrest, and other life-threatening conditions. Recent studies have shown that ECMO improves patient outcomes drastically (36%) for patients that experience a cardiac arrest when it is applied within 15 minutes of the cardiac arrest [2]. Current ECMO machines are expensive and complex to operate, so adoption is mostly limited to larger hospitals, keeping them inaccessible for large portions of the population.

The creation of a portable artificial lung would allow for first responders needing to transport patients to begin blood oxygenation with ECMO immediately. This year, the Queen's Biomedical Innovation Team (QBiT) has undertaken the task to develop the Ultraportable ECMO machine, which will be more affordable, robust, and suited for use in a wide range of conditions. Design aims were assessed for use in hospitals and clinics that do not possess the infrastructure for traditional ECMO, or with pre-hospital critical care teams in the field.

The current ECMO machine market is worth \$740.85 million globally and is expected to grow at a 5.74% compound annual growth rate [3]. QBiT's design is anticipated to sell for approximately \$4,140.50, far lower than market alternatives. Demand for inexpensive, compact ECMO remains high, especially in underserved healthcare settings.

PRODUCT DESIGN

In ECMO, the interconnectedness between the blood and oxygen streams allows for passive diffusion of oxygen (O₂) and carbon dioxide (CO₂). The O₂ gradient will flow from the pure O₂ gaseous stream into the desaturated blood stream, while the CO₂ gradient will flow from the

blood stream into the gaseous stream. The design of the gas transfer system will maximize gas exchange. Sweep gas of 100% O₂ will be supplied through the membrane oxygenator. At a minimum, the sweep gas flow rate should be equal to the blood flow rate. Increasing the sweep gas flow rate will increase CO₂ elimination if necessary. The device will use custom triply periodic minimal (TPM) surfaces, which minimize the spanning area between boundaries and have a continuous shape. They function as a membrane through the laminar mixing and subsequent recombination of the fluid. Compared to a hollow fiber design membrane, TPM surfaces increase the O₂ transfer capabilities by up to 69.8% [1]. This significant increase is possible because TPM surfaces disrupt the laminar boundary layer, the main source of diffusional resistance in hollow fiber membrane oxygenators. The membrane is printed using VeroClear resin and coated in silicone to increase biocompatibility and provide a smooth outer coating. The TPM surface divides the 3D structure into two separated, interconnected channels. These channels possess a high surface area to volume ratio, allowing two flows to pass through simultaneously [1].

The design of the case and internal components of the ECMO device are crucial to the ability of the device to perform as needed, as it must be lightweight, impact and weather resistant and portable. The case and internal components must also not impede the life-saving functions of the device and allow for its operation in any conditions. QBiT has opted to use a wheeled PelicanTM hard case to contain the components such as the dissolved oxygen (DO) and pH sensors, along with semi-rigid foam to cushion any impact, as seen in Figure 1.

Figure 1: Ultraportable ECMO casing and components.

3D-printed mounting brackets and supports are used to maintain the position of each component in the case, and medical grade tubing is used to ensure proper blood flow through the device.

The electronic components within the Ultraportable ECMO machine perform three main tasks: control blood flow, blood temperature and gas pressure. These tasks facilitate the oxygenator by maintaining O₂ pressure while passing blood through the membrane at the correct temperature and rate for safe human use. The electrical sub team is responsible for designing, implementing, and testing all the included electronics. This includes sourcing appropriate parts, creating a power grid and programming control functionality.

The implementation of the electronics for the Ultraportable ECMO machine is far smaller and less expensive than currently available ECMO machines. Microcontrollers are organized in a two-tiered hub and spoke network, where the lowest level nodes represent sensors and actuators. An Arduino Nano was chosen as the central microcontroller and handles two-way communication between the nodes and the user interface using the I2C protocol. Once the user input has been gathered by the interface and communicated to the nodes, the node controller autonomously uses live sensor data to adjust its actuator output to achieve the target input. Each node runs on its own power rail, generated by a 120 AC-DC converter, and a total of 400 Watts is provided to the system. Shunt regulators are used as they only require three parts, making them small, cost effective, and easy to design in-house.

Blood flow is monitored with an in-line flow sensor. As the fluid flows past a turbine, the speed at which the turbine spins is proportional to the flow rate. The flow is controlled using a Genedey 12V ½ inch brushless centrifugal pump. The pump possesses a 5 m static head and can exceed the optimal blood flow rate for oxygenation, which was determined to be 0.2-5 L/m. Blood temperature is monitored with a non-invasive infrared sensor and temperature can be increased with heating pads, which are fitted to a heat-conducting pipe. The heating element follows an actuator model, through which temperature increases result from increases in the microcontroller duty cycle. The O₂ concentration in the blood is measured with a galvanized steel probe, while the CO₂ concentration is calculated from pH, as measured with a pH probe. The pressure of the gas inside the oxygenator can then be adjusted with a solenoid gas valve. The duty cycle and valve opening size are directly proportional, so as the microcontroller duty cycle increases, the valve will open, with gas influx from the compressed O₂ tank increasing the pressure within the system. Python is used to create a display monitor to organize data collected by an Arduino Nano, as seen in Figure 2.

Figure 2: Monitor displaying the collected ECMO data.

The display includes the output temperature [°C], blood flow rate [L/min], blood oxygen saturation [%], and CO₂ concentration [%] displayed to three significant digits. The display allows for real-time monitoring of the sensor data and efficient analysis of a patient's vitals.

BUDGET & MARKET ANALYSIS

The total design budget for the Ultraportable ECMO machine is \$3,185. The cost of materials for the prototype is \$2,475, including all parts necessary for assembly. Additionally, a cost of \$400 is associated with the building of the prototype, and the remaining \$310 is budgeted for testing. The current markup on medical devices is very high, reaching up to 50%. QBiT estimates that the Ultraportable ECMO machine could sell at a 30% markup, or \$4,140.50 [4].

The Covid-19 pandemic has highlighted both the value and scarcity of respiration devices for treating respiratory illnesses in medical emergencies [1]. The target market for the Ultraportable ECMO machine are use in EMS vehicles or remote locations. Studies highlight the benefit of ambulatory respiratory assistance via ECMO machines, with a study from Columbia University Medical Center finding that 80% of patients who received a successful lung transplant were supported by an ECMO machine during ambulatory transport [5]. It is clear that access to ECMO machines is crucial to positive clinical outcomes. The ECMO market is expected to be dominated in North America, with a potential market size projected to grow significantly from 2023 to 2028, reaching multimillion USD by the end of the forecasted period [6].

ACKNOWLEDGEMENTS

We thank the members of the QBiT for their work on this project and review of this abstract. We thank SparQ Queen's for permitting use of their manufacturing equipment, Dr. Ramiro Arellano for his medical expertise, and Dr. Claire Davies for her technical expertise and support as QBiT's faculty advisor. We are grateful for funding from Dean Kevin Deluzio, the Sci'73 foundation, and Makers Making Change to support QBiT's design efforts.

THE EFFECTS OF PROGERIA ON CENTRAL VASCULAR TISSUE, BLOOD FLOW, AND BLOOD PRESSURE

L. Roukoz (1), T. Hopper (1), S. Murtada (2), J. Humphrey (2), C.A. Figueroa (1)

(1) Biomedical Engineering, University of Michigan, Ann Arbor, Michigan, United States

INTRODUCTION

Progeria shows an advanced aging phenotype from a young age. It can affect the central vasculature in different ways, inducing changes in thickness, cardiac output, pressure, and stiffnesses compared to healthy controls. These alterations can increase risk of cardiovascular disease, including stroke and heart failure [1]. In this project, we use a mouse model of progeria [2], biomechanical phenotyping to characterize aortic tissue, microCT imaging, flow and pressure data, and computational modeling techniques to study cardiovascular alteration in three progeria mice compared to three wild type controls.

METHODS

Mice were anesthetized to measure flow and characterize aortic anatomy. Doppler ultrasound measurements were taken at the carotid arteries, iliac arteries, and ascending aorta. Mice were placed supine in a microCT scanner to image the aorta and main branches. Pressure was assessed via tail-cuff, while mice were awake. Mice were then sacrificed, and biaxial tissue testing was performed [3] to measure vascular thickness and anisotropic (circumferential and axial) stiffness at the following locations: ascending thoracic aorta (ATA), proximal and distal descending thoracic aorta (pDTA and dDTA), supra-renal abdominal aorta (SAA), and infrarenal abdominal aorta (IAA).

A 3D model was built of the aorta and main branches by generating centerline paths and 2D contours to represent the luminal diameter. Aortic diameter was extracted from these models at the previous 5 locations to linearize in vivo stiffness and thickness values [4]. Values at these 5 locations were then linearly interpolated over the entire aorta and branches.

For the hemodynamic fluid-structure interaction (FSI) analysis, aortic inflow waveforms were prescribed from the ultrasound data. Three-element Windkessel models, consisting of a proximal resistance, a distal resistance, and a compliance, were prescribed at each vessel outlet to represent the distal vasculature. Resistance and compliance

values were iteratively adjusted until computed tail cuff pressure values matched experimental values. Given that flow and anatomy were assessed under anesthetized conditions, but cuff pressure under awake conditions, anesthetized values of pressure were estimated by scaling measured systolic and diastolic pressure by 0.76 and 0.89, respectively. These values were obtained by studying the impact of isoflurane on pressure in wild type mice (ongoing study). Fluid structure interaction (FSI) analyses in progeria and wild type specimens were performed using the open-source software CRIMSON [5].

RESULTS

Vessels in progeria mice are thicker than those in wild type controls, while also having a different pattern of thickness. In wild type mice, the thickness across the entire aorta is relatively constant, while progeria mice have a larger thickness in the ATA, and then relatively constant thickness throughout the rest of the aorta (Fig 1). Circumferential material stiffness is smaller throughout the aorta in the progeria mice, except for the ATA, where it is comparable to the wild type (Fig 2).

Subject-specific flow waveforms were prescribed at the ATA from the available Doppler ultrasound data for progeria and control mice. Values of three-element Windkessel models for each outflow branch were iteratively adjusted until a good match (e.g., discrepancies smaller than 10%) was achieved between simulation and data. Specifically, between pressure computed at the tail and cuff measurements, as well as computed and measured mean iliac flows (Fig 3).

In the distal vasculature, progeria mice have larger resistances and compliances than wild type mice.

Wild type and progeria mice have similar flows in the ATA and DTA. However, due to the smaller caliber of the DTA in the progeria mouse, blood velocities are noticeably larger (Fig 4).

Figure 2: Aortic circumferential stiffness (MPa) for progeria (Orange) and wild type mice (grey).

Figure 3: Validation of computational results against available experimental data. Left: pressure cuff data. Right: Mean iliac flow data. Pressure and flow values to indicate validity of the progeria mouse model

Figure 4: Volume render of blood velocity from a progeria mouse (left) compared to a wild type of mouse(right). Insert shows aortic inflow waveforms for each specimen.

Discussion

Aging is known to affect the stiffness of heart and blood vessels. Over time, elastin fibers degrade and are slowly replaced by collagen, leading to an overall increase in stiffness.[6] Progeria has an extreme ageing phenotype which shows different symptoms than those of simple aging. To quantify some aspects of the exacerbated aging in progeria, we used a rich amount of data on anatomy, flow, pressure, and tissue stiffness, together with the hemodynamics modeling software CRIMSON.

The results show that progeria mice tend to have thicker walls on their central vasculature. This replicates the thickening known to occur with aging in wild type mice [8]. Patterns of stiffness, however, show a different distribution compared to aging mice. Circumferential stiffness, except for the ATA, were all smaller than in wild type mice [2].

Computational modeling, informed by experimental data, can shed light into disease patterns, as well as quantify markers of disease progression that are not attainable through experiments alone. Computational modeling may also facilitate using data acquired under certain physiological conditions, and to combine it with data acquired under different physiological conditions (e.g., anesthetized versus awake).

Some limitations of this study involve accurate delineation of the aortic geometry from the microCT data. Furthermore, parameter estimation is a time-consuming process, requiring many iterations on the Windkessel values to match the available data on flow and pressure.

Progeria shows an advanced ageing phenotype, while also presenting differences compared to normal ageing, especially in central vascular stiffness. While stiffness increases with age in wild type mice, progeria mice show decreased values of material stiffness in most regions of the aorta, except for the ATA. This study is the first step towards understanding alterations in progeria relative to both aged-match wild type as well as normal aging subjects. Future work will extend into studying differences in heart function in these mouse models of progeria.

INTRODUCTION

Postoperative pulmonary complications (ie. pneumonia, respiratory failure, etc.) occur in ~5% of the 20M inpatient surgeries in the United States and cost the healthcare system over \$3.42 billion annually.^{1,2} The current standard of care (SOC) to prevent postoperative pulmonary complications (PPCs) includes incentive spirometry, which involves patients performing breathing exercises with an incentive spirometer (IS) for 5 minutes every 1-2 hours post-operation under the guidance of a nurse. Incentive spirometry has been shown to reduce the risk of PPCs and healthcare costs, with studies reporting shorter hospital stays, decreased time on ventilators, and lower healthcare costs (by over 500\$ in certain subgroups), in patients that used an IS.^{3,4}

Still, there exist multiple shortcomings of the current ISs used in hospitals. Current devices do not enable providers to accurately and efficiently collect patient-use data. Nurses and physicians are unable to reliably track patient progress and adherence, resulting in ballpark discharge decisions and extra time spent sitting with patients as they complete their IS exercises to ensure adherence and proper use. This creates a significant time burden for nurses keeping them from performing other crucial tasks.⁵ Furthermore, the lack of data collection and low adherence has prevented research on the clinical benefit of incentive spirometry and its impact on patient recovery trajectories.⁶

With more than 19 million ISs prescribed annually in the United States, there exists a need for a device that can 1) accurately collect patient data, 2) improve patient adherence, 3) reduce nurse time burden, and 4) is scalable to personalized treatment applications.⁷

PRODUCT DESIGN

We have designed the inSPIRE digital incentive spirometer with an integrated mobile app to increase adherence to IS exercises, reduce the time burden for nurses, and provide clinicians with more, higher quality patient recovery data (Figure 1). The inSPIRE device utilizes a digital sensor to measure airflow in the device, which enables the collection of patient use data (Figure 1a). A microcontroller with

Bluetooth capability then continuously sends user data to the integrated app accessible to both patients and nurses (Figure 1b). The physical device is made up of 2 components: (1) a detachable and disposable mouth-piece and (2) the connected housing that contains the airflow tube and the electronic components of the device (rechargeable battery, microcontroller, and digital sensor).

To validate our design for measuring airflow, we created a prototype of our airflow chamber with our digital sensor and connected a large syringe to the opening where a patient would be inhaling from. By adding varying weights to pull down on the syringe plunger with constant velocity, we created known and constant airflows in the chamber that our sensor could measure. After using our sensor to measure various airflows, we performed a linear regression on the air flow rates our sensor measured versus the actual airflows. This yielded a slope of 0.999 and an R^2 of 0.989, suggesting that our design accurately measures air flow (Figure 1c).

inSPIRE was designed with incentivizing features and to be easy-to-use for patients. With inSPIRE, patients perform breathing exercises as they would with current ISs while exercise data is automatically stored and displayed on the integrated mobile app. Training modules and real-time visual cues on the app allow patients to easily complete exercises correctly. Patients can track the completion of their daily prescribed exercises with stored data, and a reminder system will notify patients of upcoming and missed exercises for the day. We also gamify the completion of exercises through different games in the app to make completing exercises easier (Figure 1b.). The compact handheld design will also make handling the device easy, with all of these features ultimately improving adherence and thus reducing the risk of PPCs.

Clinicians will benefit from features aimed at streamlining hospital workflows. The app will make patient-use data available to clinicians such that nurses can monitor the adherence of all their patients on one remote system. This will significantly reduce the time nurses spend monitoring patients and ensuring exercise completion. Clinicians will also be able to access quantitative patient lung recovery data based on

exercise performance through the app, enabling informed decisions regarding hospital discharge, ventilation, and other interventions.

Looking forward, inSPIRE’s applications may extend beyond post-surgery settings to include asthma, COPD, Covid, and other chronic respiratory conditions. By leveraging data collection and analysis applied to these indications, inSPIRE will create additional services and value, improving the standard of care in the pulmonary rehabilitation space. In the post-op setting, analyzing the recovery and exercise data collected from our device may enable development of patient-specific training regimens that minimize PPC risk or reveal trends that can be used to detect PPC onset early. This approach could lend itself well to elucidating trends in long-covid recovery and other indications as well.

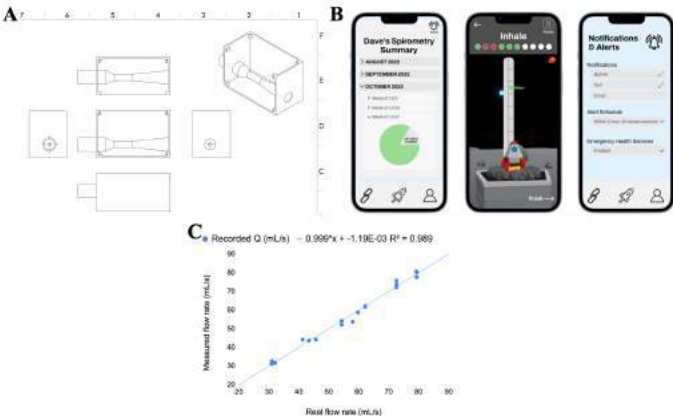

Figure 1: A) Prototype CAD design B) Mockups of mobile app tracking, gamification and reminder features C. Data from validation setup shows a strong correlation between real and measured flow rates.

Digital spirometers currently on the market measure peak expiratory flow as a measure of lung health, and some companies have developed digital breathing trainers, similar to incentive spirometers, for non-clinical use that range from \$100-\$300 (Airofit Pro, MIR Smart One, ViQure Opump). Our device is novel in that its core technology reliably measures airflow and it is catered to in-hospital incentive spirometry applications through our cost-effective, easy-to-use design.

BUDGET & MARKET ANALYSIS

Table 1: Design budget for building prototype

Item	COST PER UNIT (\$)	NUMBER OF UNITS	TOTAL COST PER ITEM (\$)
3D printing elastic material (TPE or TPU)	39	1	39
3D printing non-elastic material (PLA, clear)	24	1	24
Liquid rubber sealant	16	1	16
Screw set	9	1	9
Arduino MKR wifi 1010	39	2	78
Battery	12	2	24
Pressure Sensor	15	2	30
TFT LCD screen	20	2	40
			TOTAL COST: 260

Our revenue model will initially consist of one-time sales of the reusable main body of the inSPIRE device and recurring revenue generated from sales of the disposable mouthpieces. Current single-use incentive spirometers sold to hospitals cost on average \$4.50 per unit. We plan to sell the main body of our device for \$100 and our

mouthpieces for \$1 per patient. As the mouthpiece would be a simple injection-molded part and the main device body would be an injection molded part with a microcontroller and other basic electronics, we believe we can manufacture the components for \$0.20 and \$20 respectively. Assuming an average patient stay of five days post-surgery, there will be a turnover of approximately 73 patients per bed annually. This means that current ISs would cost hospitals \$328.5, whereas implementing our device would cost \$173 per bed annually. With this business model, inSPIRE would undercut the overall cost of current incentive spirometry programs at hospitals and reduce hospital waste.

In addition to saving on implementation costs, inSPIRE may also deliver savings to hospitals through reducing nurse monitoring time and the rate of PPCs. As incentive spirometry instruction is not a billable event for hospitals, our product which will have integrated training, set up, and monitoring of patients will save hospitals costs in nurse hours. As data analysis is used to produce predictive metrics for preventative treatment or other services, our revenue model may adapt to include a subscription to these software elements. This data could also lead to a billable event for hospitals, encouraging them to adopt our device.

The Hospital of the University of Pennsylvania (HUP) and other research hospitals that perform many inpatient surgeries will serve as our beachhead market. With a case study on HUP, which has 988 beds and an average ~70% capacity, we can achieve \$115K ARR if we fully serve the hospital with 660 devices and 48,000 mouthpieces purchased annually. Our beachhead market consists of 55 hospitals of similar size or larger than HUP (>800 beds), totalling to roughly a \$6.5MM annual market. Considering the total postoperative space in the United States and the 19 million patients currently prescribed an IS in the US, we will address a market of ~\$45MM annually, consisting of potentially 260,000 devices and 19 million mouthpieces that could be sold each year. Beyond postoperative use cases, we plan to expand to additional indications needing long term respiratory rehabilitation.

We estimate further physical device development costs to be \$25k and app development costs to be \$100k. Injection molding tooling costs for a simple piece like our mouthpiece should fall around \$15k, while tooling for the main device will be more complex and may cost \$100k. In all, we anticipate development and manufacturing preparation to cost ~\$240k. Despite costs, we hope to generate significant ROI. If by year 2 we capture 10% of our beachhead market, we will be generating \$650k in revenue with gross profits of \$520k. If by year 4 we then capture 15% of the total market, we will be generating \$7MM in revenue with gross profits of \$5.6 MM.

ACKNOWLEDGEMENTS

We are proud to have developed our technology in the Stephenson Foundation Educational Library and Bio-MakerSpace at UPenn. We feel fortunate to have access to the Penn Medicine network, as it was in collaboration with nurses and clinicians at HUP that the unmet needs in respiratory rehabilitation were identified. Our solution was developed and iterated on with feedback from stakeholders and faculty with diverse backgrounds spanning UPenn’s Engineering School, Wharton, Penn Medicine, and the Penn Center for Innovation.

AUTOMATING COLLAGEN GEL IMAGE SEGMENTATION USING DETECTRON2: AN APPLICATION OF MODERN COMPUTER VISION TECHNIQUES

Michael I. Cafiero (1), Spencer P. Lake (2), Michael A. David (3)

- (1) Computer Science, Washington University in St. Louis, St. Louis, MO, USA

INTRODUCTION

The collagen gel model system can be used to study cell contraction and the impact of drug treatments [1]. Quantifying gel area change (i.e., degree of contraction) often requires manual segmentation, which is a lengthy process and prone to human-to-human variability. One possible solution to this is machine learning (ML): a predictive modeling approach that uses previous data to perform automated decisions and tasks.

An open-source ML tool that has demonstrated success for object detection and image segmentation resource is Detectron2 (Meta) [2]. Detectron2 is a next-generation computer vision platform that allows for easy training and application of modern models, such as Mask-RCNN, TensorMask, and others. A Mask-RCNN model is designed to generate instance-level segmentation, which allows for more precise identification of individual objects/instances in an image. In this study, we aimed to develop a ML model with the Mask-RCNN framework to automatically segment collagen gels and wells. (Figure 1).

Figure 1: Gel Setup and Images (Adapted from [1]) and Automation Flowchart

METHODS

For this study, a previous database of collagen gel images was used [1]. The Detectron2 underwent training on a set of 50 randomly selected images, which were randomly selected from a total image population of ~8000 images, using an automated API script. This dataset was annotated to facilitate training using COCO (Common Objects In Context) format, a common object identification method for neural network training. Before using the COCO format, the laboratory employed binary image masking, a well-established approach for data analysis. A data pipeline (Figure 2) was constructed to obtain COCO annotations that converted binary image masks into COCO annotations via the identification of the mask perimeter, providing a scalable and efficient solution for image masks of varying shapes.

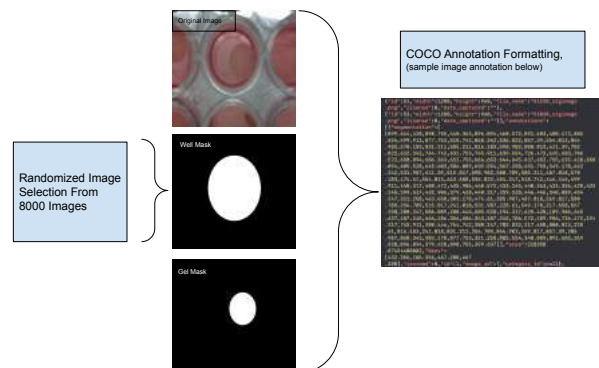

Figure 2: Preprocessing Pipeline Diagram.

For ML applications, a model requires a training dataset, and a testing dataset to validate the model on separate data that the model has not yet been exposed to. The testing dataset was also selected at random from the ~8000 image population and did not contain any images from the training data. The data pipeline facilitated the random selection, annotation, and grouping of images for both training and testing purposes.

To evaluate the model's output, we compared the human-generated mask with the computer-generated mask to calculate the Dice score, which quantifies the similarity between the two masks. We also judged the success of the training process using total loss and accuracy. Total loss is a metric for error that quantifies the performance of the model at each level of optimization. The other key training metric, accuracy, measures the percentage of correctly identified images.

The training procedure was executed for 1000 iterations, with a learning rate of 0.00025 as recommended by the Detectron2 documentation. The standard Detectron2 framework was used for training, with the majority of the initial hyperparameters employed. A Google Colab environment was used for computation with an NVIDIA V100 GPU.

RESULTS

Training of the model took approximately 7 minutes and 30 seconds, without evidence of overfitting. Total loss conformed to a negative logarithmic curve, which is standard for neural networks (Figure 3). Additionally, the accuracy of the Mask RCNN steadily increased during training, until it reached a plateau towards 1000 iterations.

Figure 3: Total loss and accuracy graphs of model training

Results were evaluated on a separate testing dataset containing 100 images randomly selected from the same population as the training dataset (~8000 images). For the well segmentation process, the model yielded a Dice score of 0.989 across the 100 images. Visually, the model produced an accurate trace of the well, which can be seen in purple in the image (Figure 4). Detectron2 provides an easy visualization method, which plots the mask against the original image with a randomized color, as well as the bounding box.

Figure 4: Sample result of well segmentation.

The gel recognition model also performed well, with an average dice score of 0.987 across 100 images. The model precisely identified and segmented the collagen gels within each of the wells, which is a more challenging task to perform visually (Figure 5).

Figure 5: Examples of uncontracted (top) and contracted (bottom) gels and resulting ML gel segmentation.

DISCUSSION

Our results show that Detectron2 can achieve high accuracy and precision in segmenting culture plastic wells and collagen gels, making it a valuable tool for researchers. This technique can be used for future lab automation, and will enable efficient analysis for thousands of gels and their response to different treatments using this *in vitro* model system.

Additionally, the model can be optimized to accurately segment uncontracted collagen gels, which can be difficult to identify by human eye as opposed to contracted gels. Detectron2 also supports multi-object detection, which can be used on images containing several object types, making it a scalable solution for more complex segmentation needs.

To increase practicality, the data preprocessing pipeline can be further developed to support conversion from other annotation types and prevent annotation by hand where possible. Additionally, the model should be further tested to determine its practicality for non-circular object types and robustness. To conclude, this study demonstrates the feasibility of Detectron2 computer vision to automate common lab tracing and segmentation techniques and highlights its ease of use and customizability.

TRACKING OF PEDICLE SCREWS USING EXTENDERS AND LENTICULAR ARRAYS

INTRODUCTION

Spinal correction surgeries require precise placement of pedicle screws in that connect metal bars to vertebrae. Tracking these screws is critical for the efficient and accurate completion of these surgeries, and is essential for inserting patient-specific rods that connect between pedicle screws and determine the patient's final spine disposition. However, this is challenging because the screws lie out of plain sight of the surgeon, and because their orientations are difficult to track. Our goal was therefore to create a simple, user friendly system which obviates tracking issues caused by occlusion of pedicle screws, streamlines the rod-shaping process for surgeons, lowers the total amount of time spent operating, and facilitates better patient outcomes.

We propose to achieve this using removable extenders to pedicle screws that enable the surgeon and the operating room imaging system to identify the positions of the screw ends, and lenticular arrays attached to the ends of these extenders to enable a single camera to identify the three-dimensional (3D) orientation of these extenders.

BACKGROUND

Lenticular Arrays Lenticular arrays reflect different colors when viewed from different directions in a relationship known as the hue response function (HRF). Using the observed color of a given lenticular array, along with its HRF, it is possible to determine its orientation about its major axis[1]. By creating a fiducial marker with two planar lenticular arrays with perpendicular major axes, we propose to determine the orientation and position of the marker in space using complementary information from each of the arrays.

Camera Calibration To identify the camera pose from the lenticular markers, a fully defined system can be solved by calculating the rotation and translation matrix of the lenticular markers according to the five pose constraints outlined in [2]:

$$\mathbf{R}\vec{n}_{hue1} \cdot \vec{r}_1 = 0 \quad (1)$$

$$\mathbf{R}\vec{n}_{hue2} \cdot \vec{r}_2 = 0 \quad (2)$$

$$\mathbf{R}(C_2 - C_1) \cdot (\vec{r}_1 \times \vec{r}_2) = 0 \quad (3)$$

$$(\mathbf{R}C_1 + \mathbf{T}) \times \vec{r}_1 = \vec{0} \quad (4)$$

$$(\mathbf{R}C_2 + \mathbf{T}) \times \vec{r}_2 = \vec{0} \quad (5)$$

where rays \vec{r}_1 and \vec{r}_2 are the rays from the camera to the lenticular marker, \vec{n}_{hue1} and \vec{n}_{hue2} define the unique planes corresponding to the observed hue of the lenticular markers, \mathbf{R} is the rotation matrix, \mathbf{T} is the translation matrix, and C_1 and C_2 are the locations of the markers in world coordinates.

METHODS

Markers and Practical HRF To generate a proof-of-concept HRF, a 1.1 by 1.1 cm lenticular marker was constructed from two lenticular array segments with perpendicular major axes, each measuring 1.1 by 0.55 cm. Photographs of the marker were taken using an iPhone 7 mounted on a 108 cm diameter semicircular track. Photographs were taken at 2.5° intervals ranging from 45° to 135°. Lighting consisted of ambient light from ceiling lights and the camera flash from the iPhone camera. After taking all photographs for the first array of interest, the marker was rotated 90° to obtain photographs for the second array. The average hue of the lenticular marker was mapped to a hue dictionary for each array, and the HRF was found by fitting average hue vs. orientation by a 2-term Fourier series using MATLAB (Natick, The Mathworks). To test the accuracy of the HRF, photographs of the entire marker were taken at 1.25° increments (over 65° – 71.25° along the camera track under the same lighting conditions, and data were used to validate the HRF.

Extenders PLA plastic prototypes of pedicle screw extenders were 3D printed. The initial design focused on driveability of the screw through the extender, integration with existing technology and proprietary threadings, creation of large surface area for markers, and monoaxial constraint of

polyaxial screws. This design (Fig. 1A) consists of a lofted marker attachment and a driving pin coaxially inserted into the loft. The lofted attachment possesses threads matching proprietary threading from the relevant screw tulip brand and size; the screw used in this study was a two-times scale, 3D print modeled after the Stryker EVEREST Screw (Kalamazoo, Stryker). The driving pin integrates with the EVEREST Screw tulip to set into the shank drive, thereby constraining the tulip to monoaxial movement and interlacing any rotation of the driving pin with that of the shank.

To provide rotational freedom, the final design, shown in Figs. 1B, 1C, leverages the pedicle screw tulip's rotational degree of freedom by using a cylinder to interface with the shank drive, thereby retaining the monoaxial configuration of the screw while still allowing independent rotation of the tulip and extender. The second degree of rotational freedom is enabled by the hinge between the marker arm and extender base (Fig. 1C). Locking pegs on the outside of the marker arm interlock with counterpart holes in the extender base on a circular track, allowing the user to rotate the arm in increments of 30°. As a precaution against obstruction by walls of muscle, fat, or tissue, the marker arm can be attached to the extender base before or after it is threaded into the tulip. Two entry slots at 0° and 90° polar angles ensure simple attachment of the marker arm (Fig. 1C).

Figure 1: Initial prototype, final design, and section view.

BENCHTOP PROTOTPYE TESTS

The measured HRF for the lenticular arrays was periodic, with some hues were repeated at different angles. This was problematic because the lenticular calibration method requires a unique hue to determine a unique orientation. To address this issue during testing, only angles ranging from 50° to 105° were considered because this range exhibited an approximately affine relationship between hue and orientation. Raw data for angles 45°–135°, raw data for the one-to-one regions ranging for 50°–105°, and the Fourier fits are shown in Figure 2.

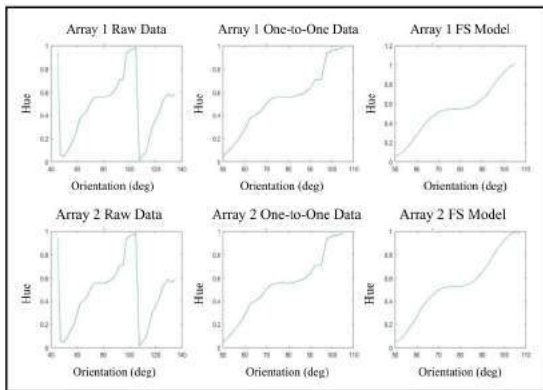

Figure 2: Lenticular calibration model.

Once the HRF fit was generated, photographs were taken every 1.25° from 65° to 71.25° relative to the major axis, beginning from the plane of the marker. The results of the back calculation of camera angle relative to the marker for each photograph are shown in Table 1.

Table 1: Results of lenticular orientation estimation using proof-of-concept HRF.

Measured Angle (deg)	Calculated Angle (deg)	Error (deg)
65	69.35	4.35
66.25	69.90	3.65
67.5	70.99	3.49
68.75	71.50	2.75
70	71.91	1.91
71.25	74.82	3.03

Error Analysis All of the observed errors were within 5°, which is promising considering the technological limitations of the experimental setup. However, it is important to note that much more research is needed. During future research, it will be important to take several hue measurements at each angle in order to establish a variance and to use more precise instruments to measure the camera angle.

DISCUSSION

Camera Calibration In addition to further benchtop testing, goals for future development include investing in a motorized camera track with a fixed speed to take a video of the lenticular array and relate frame to orientation for a more accurate angle measurement. A camera mount to hold the camera perfectly tangential to the arc will also greatly improve accuracy of angle measurements. Finally, designing and printing a perfectly linear hue gradient, to place behind the lenticular array will more practically address the issue of generating a one-to-one HRF. Translational error was not tested in this study, however for a full analysis of the tracking quality of the lenticular arrays, these errors should be collected and compared against those measured in [1].

Extenders As the system stands, the polar angle is chosen within a set of defined values and locked in place by the surgeon in the corresponding peg hole. Although this simplifies communication of the polar angle between the surgical team and computer system, it also limits the closeness with which the plane of the marker can match the image plane. This could be remedied by a more continuous and friction-locking mechanism for choosing polar angle. One solution for this is to make both the extender and its associated screw driveable, which could be accomplished by introducing successive, detachable sheaths. By introducing a sheath which solely interfaces with the tulip threading while remaining coaxial with but rotationally independent from an internal sheath, a stable monoaxial configuration can be achieved for the screw.

Market analysis The spine market of \$13B/year provides ample grounding for a device that can increase the speed of surgery. We anticipate that using these devices can save the surgeon 10-45 minutes per procedure by accelerating the process of bending and inserting a fixation rod. With these surgeries billing at \$10K-\$45K per hour, the price point of \$1K per set is easily justified, with a 1% market share yielding a profit of \$10M per year, including a 50% overhead to the sales and distribution force. The patent space for pedicle screw tracking is dense, but no use of a lenticular array has yet been patented. Our patent application is now under review.

INTRODUCTION

The dentin-enamel junction (DEJ) separates the two mechanically dissimilar tissues in teeth: dentin and enamel, Fig 1. Biological interfaces such as the DEJ are frequently the site of stress concentrations which makes them prone to failure [1]. Despite appearing as an abrupt interface, the DEJ is highly resistant to fracture [2]. This high toughness may be the result of multiscale gradients present at the DEJ. Previous work has shown that gradients in composition and mechanics exist; however, there is no unanimous consensus on the true width of the junction with values being reported from less than 5 microns to as large as 100 microns [1, 3]. Looking at compositional and structural gradients will move the current understanding of the DEJ forward. For this reason, we start by looking at long-range density gradients using high-resolution micro-computed tomography (μ CT). These results will help elucidate the structural features responsible for dissipating stress concentrators at the DEJ.

Figure 1: Micrograph of the murine DEJ showing the seemingly abrupt interface between enamel and dentin.

tissue, wrapped in gauze, soaked in a phosphate-buffered saline solution, and placed in a -20° C freezer for storage.

METHODS Tooth

acquisition: 4-5 month old CD-1 mice (Charles River, CT) were sacrificed via CO₂ asphyxiation. Lower right (LR) murine incisors were extracted, cleaned of any remaining soft

Micro-Computed Tomography: Five lower right incisors were thawed and analyzed for structural changes using a Scanco 50 microCT system. Whole teeth were placed in the system and the midsection of each tooth spanning 7.3 mm was imaged at a resolution of 3.4 μ m. μ CT data was reconstructed to obtain cross-sectional data for each region of interest. This data was analyzed to obtain information about the volumetric contribution of each tissue present as well as the density gradient width across the DEJ.

Volumetric analysis: Cross-sectional microCT images were loaded into the CTAnalysis software (CTAn, Bruker), Fig 3. The threshold for pulp, dentin and enamel were separately established by an experienced user to isolate each of the tissues of interest. On a 255 bit density scale the enamel threshold was set between 240-255, dentin between 120-240, and the pulp between 10-120. 3D analyses were then performed to obtain volumes of each tissue for the scanned region. Relative values were calculated as percentages.

Gradient width collection: Three regions of interest were selected in the tooth located several mm from the apical tip, several mm from the coronal tip, and one in the mid-section. For each location 5 sections were analyzed to ensure experimental robustness. For each section, five lines were drawn perpendicular to the DEJ starting from the pulp cavity and extending across the DEJ interface eventually reaching the edge of the enamel boundary, Fig 2. The attenuation coefficients, which are correlated to material density, were collected along each of these lines. This set of 375 lines of density information was then analyzed to determine DEJ gradient widths as well as develop a library of density data.

Gradient width analysis: Gradient widths were calculated using the attenuation coefficient data. The linear outputs were fit using custom MATLAB programs which performed a linear fit on the

Figure 2: Visualizing pixel intensity changes through the transition from dentin to enamel.

gradient region by minimizing R^2 values across the region of interest. The maximum intensity was divided by the gradient slope to calculate the gradient widths.

Once all gradient widths were determined, a one-way ANOVA test was run for each tooth as well as Tukey's range test to determine if the gradient width changed as a function of location both within a specific tooth and between different teeth.

RESULTS

Volumetric results: On average, dentin makes up the bulk of the tooth composing 81.33% of the total volume. This is followed by enamel at 13.75% and the pulp with 5.02%.

Figure 3: Percent tooth volume of the three main tooth regions.

Gradient results: There is significant variability in gradient width within individual incisor specimens at different locations along the length of a tooth. However, when comparing the average density gradient width of the three locations (C, M, and A) between the five teeth samples, it can be seen that there is no significant difference in the average gradient length. Comparing the different teeth, the mean gradient width of the coronal section was 22.33 μm , which is very similar to that of the middle section (22.89 μm), and the apical section (24.404 μm) as well, Fig 4. Consequently, the total average density gradient width was measured as $23.12 \pm 2.48 \mu\text{m}$.

Figure 4: Average density gradient width does not vary with tooth location.

DISCUSSION

Murine incisors grow continuously throughout the animal's life due to the presence of a stem cell niche located at the apical part of the tooth [4]. While variations in density gradient width occurred within individual teeth, ANOVA testing showed that there is no significant difference in gradient width between different tooth samples. In addition to this, no discernable pattern was noted for gradient width discrepancies within individual teeth. For these reasons, it can be seen that the density gradient is ostensibly not a function of tooth location or tooth maturity. While the stages of tooth development are highly conserved across toothed vertebrate species, variations in gradient width were most likely due to the natural inconsistencies associated with the murine DEJ and the formation of surrounding tissues [4].

The literature is very sparse with respect to the DEJ when utilizing μCT to characterize this unique interface. Stock et. al. used synchrotron μCT to differentiate the mineral content present in bulk dentin, enamel, and the region separating the two tissues in one of the only studies involving this technique. Through their investigation utilizing bovine incisors, a region of punctate contrast with diminished mineral deposition was determined to be mantle dentin [5]. Although these tissues can be highly variable when comparing different samples and even more so across species, similarities can be shown as the data presented also depicts a gradient of increasing attenuation coefficient (density) when transitioning from the dentin to the more mineralized enamel, Fig 2.

Using μCT , it has been proposed that the width of the DEJ is approximately 23 μm which is curiously similar to those values suggested by nanoindentation studies [6]. Further studies using Raman spectroscopy to look at compositional gradients, proposed a functional width for the DEJ as small as 4 μm . It is possible that the larger size calculated for the DEJ's width when analyzing the interface with μCT , in addition to the difference in resolution of the technique (3.4 μm for μCT and 0.65 μm for Raman), may be due to the fact that the measurements are taking into account the mantle dentin region which extends beyond the composite interface. Similarly, there may be mechanical and density gradients that exist at a larger scale than any compositional gradients.

It is clear that there are many factors influencing the current understanding of the DEJ's functional width. Higher resolution methods consistently express smaller functional width measurements according to the literature. Moreover, how the junction is defined can also play a large role in how it is measured. Rather than view the structure as a sharp transition between two dissimilar tissues, some investigators propose the DEJ as a relatively broad structural transition zone including the mantle dentin and the inner aprismatic enamel [5]. Our results support this concept and add to the idea that multiple gradients are present at varying length scales.

DEVELOPMENT AND ASSESSMENT OF A NEW WEB APPLICATION TO MEASURE THE ORIENTATION AND ALIGNMENT OF FIBROUS TISSUE

Katherine J. Fors (1), Kyle Shannon (3), Kate J. Benfield (2), Trevor J. Lujan (1)

- (1) Department of Mechanical & Biomedical Engineering, Boise State University, Boise, ID, USA

INTRODUCTION

Fibrillar networks in soft and hard tissue govern the macro and micro-scale mechanical behavior and are critical to cell function.¹ It is therefore important to accurately quantify structural characteristics of fiber networks to advance a mechanistic understanding of healthy, damaged, healing, and repaired tissue, and to serve as a diagnostic tool for disorders and treatments. To support this need, a number of research groups have developed free software applications to extract descriptive structural parameters from two-dimensional images of fiber networks including mean fiber orientation and fiber alignment (dispersion). Together, these two parameters define material anisotropy and can be directly inserted into material models for computational simulations. Software applications that measure these two parameters include: OrientationJ (ImageJ)², Directionality (Fiji)², CurveAlign³, CytoSpectre,⁴ as well as FiberFit⁵, which was developed by our lab in 2016. These applications have been increasingly used in the biomedical community for a broad range of research projects that include mechanobiology, tissue engineering, and cell biology. However, there are two notable limitations that have hindered their reliable and widespread adoption.

The first notable limitation is the reliability of the values calculated by the software tools. At this time, no study has directly compared the accuracy of different software applications in measuring mean fiber orientation and fiber alignment. Although one recent study did report correlations between the parameters computed by different software, they did not report errors.⁶ Researchers are therefore unable to make informed decisions about what software tool to use, and consequently, reported data may be inaccurate. The second notable limitation is accessibility. Although the previously listed software applications are free to use, they do require the user to download and run an executable that may not be compatible with their operating systems. An attractive alternative is to create web-based applications that allow instant access to anyone with an internet connection.

The first objective of this study was to convert FiberFit software into a web-based application. The second objective was to compare the accuracy of FiberFit with other free software applications that similarly quantify mean fiber orientation and fiber alignment from two-dimensional images.

METHODS

Web Application Development. The portable FiberFit software application⁵ was converted from Python script to a web application (**Fig. 1**). The original Python code (available on GitHub) was installed on a server and a web interface was written in standard HTML, JavaScript, and CSS. The server processes data files in parallel, writing the output

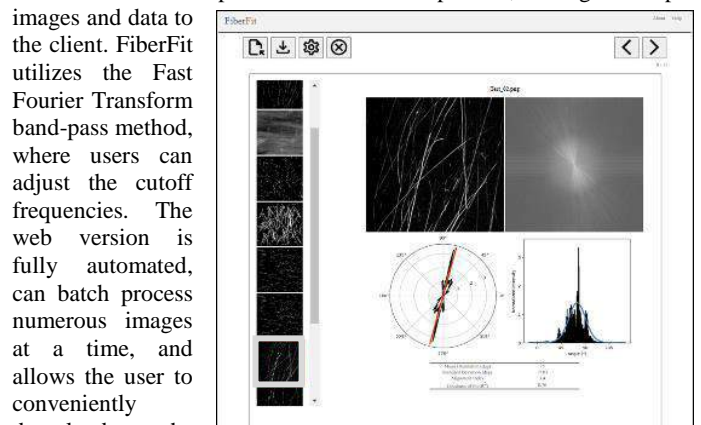

Figure 1: FiberFit web application

images and data to the client. FiberFit utilizes the Fast Fourier Transform band-pass method, where users can adjust the cutoff frequencies. The web version is fully automated, can batch process numerous images at a time, and allows the user to conveniently download the results through generated reports, summary tables, and histogram data. Users can view all uploaded images in a scroll bar to the left, and view the results of any selected image on the right (**Fig. 1**). This web application is now available online at <https://ntm.boisestate.edu/fiber-fit/>.

Accuracy Measurement. A set of 52 unique images of known fiber orientation and alignment were generated using a custom Matlab program (**Fig. 2**). A binary image was populated with straight lines based on a semicircular von Mises probability density function for specified values of alignment k (dispersion) and mean orientation μ . These manufactured images were then input into the five previously mentioned software applications. The programs were run under their default settings according to their manuals with the exception of OrientationJ where a gaussian gradient filter was applied according to our previous work.⁵ The fiber angle distribution histogram generated by each program was then extracted. This data was input into a custom Matlab program that calculates μ and k by curve fitting the data's histograms to a von Mises distribution. The error between the known and measured values of μ and k were calculated (actual – predicted) (**Fig. 2**). Images were broken into two categories: disordered fiber networks ($k \leq 1$) and aligned fiber networks ($k \geq 2$).

Statistics A repeated measures ANOVA was run to determine the effect of each software program (within-subject) on μ and k errors. One-way ANOVAs were run to determine the effect of alignment type (disordered vs aligned) on μ and k error.

RESULTS

FiberFit and CytoSpectre had significantly lower mean orientation and alignment errors than the other three software applications (**Fig. 3A-B**). CurveAlign, Directionality, and OrientationJ had higher errors when calculating mean orientation in disordered fiber networks (**Fig. 3C**). With the exception of FiberFit, all software applications had significantly larger errors when quantifying the fiber alignment (dispersion) in images with highly aligned fiber networks (**Fig. 3D**), with CurveAlign having errors 8-40x greater than other software.

DISCUSSION

This study found that FiberFit and CytoSpectre were the most accurate programs for calculating mean orientation and alignment of fiber networks from manufactured images. While all programs were able to accurately measure the mean fiber orientation in images with highly aligned fiber networks, FiberFit showed the best results in measuring mean orientation in disordered fiber networks (**Fig. 2C**). CurveAlign was unique in having very high errors when measuring fiber alignment in images with highly aligned networks. Based on our findings, we would 1) not recommend CurveAlign for calculating the two tested parameters, and 2) FiberFit or CytoSpectre would be preferred when analyzing images with disordered fiber networks. Differences in error may be related to the underlying algorithms used to generate the fiber angle histogram. FiberFit, CytoSpectre, and

Directionality use Fourier Transforms, while OrientationJ (structure tensor), and CurveAlign (CT-FIRE/CFR) use other algorithms.

To the best of our knowledge, this is the first time the accuracy of these programs has been directly compared. An innovation of this study was to use a standardized process to analyze the fiber distribution histograms generated by each software. By using the same Matlab code to calculate μ and k from downloaded histograms (**Fig. 2**), we were able to quantify differences in accuracy. Importantly, the Matlab code gave mean orientation results very close to the mean orientation calculated by each individual program (average difference of 1.2 degrees), which gives us confidence in the relative errors reported in this study.

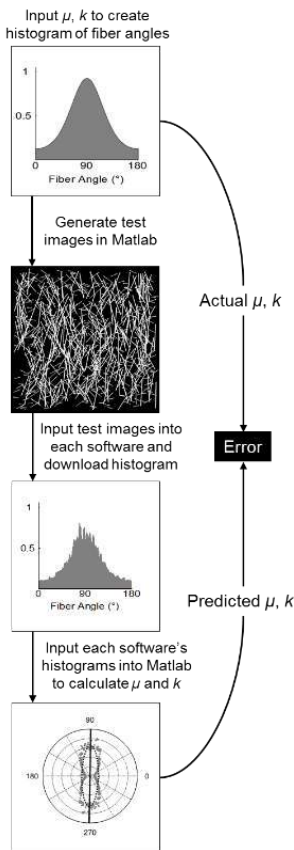

Figure 2: Method to calculate software error.

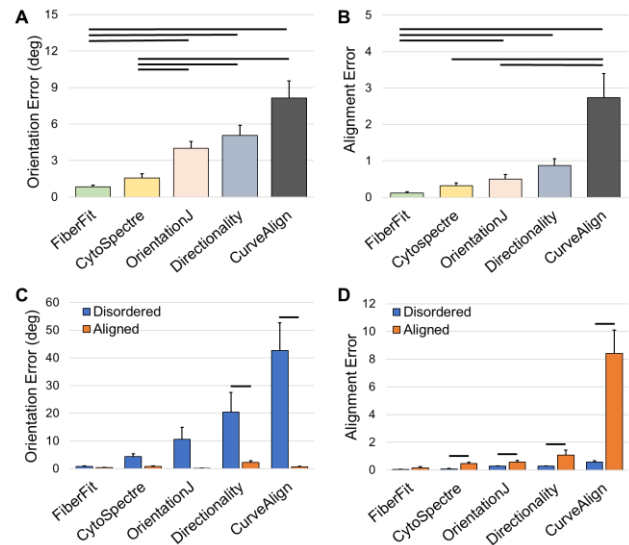

Figure 2: Software comparison. Orientation and alignment error were determined for (A-B) all images and (C-D) aligned or disordered networks. Lines = sig. difference ($p < 0.05$)

There are notable benefits of certain software applications apart from their accuracy in characterizing fiber images. Both FiberFit and CytoSpectre are capable of handling multiple images at a time and are very user-friendly with a short learning curve. Other programs such as CurveAlign, Directionality, and OrientationJ have additional features that may be better suited for specific applications (e.g. collagen interactions with epithelial cells).

In conclusion, this study has developed an accurate web application that can quantify material symmetry in 2-D images. The conversion of FiberFit into a web application will provide on-demand access to a scalable software tool (<https://ntm.boisestate.edu/fiber-fit/>). This will eliminate barriers related to downloading and installation. This study has also provided perspective on differences that exist between available software tools. Future work will expand this assessment by examining software accuracy when using confocal images of soft tissue. The development and adoption of reliable computational tools can help advance a mechanistic understanding of biological materials.

INTRODUCTION

Because of their wide attachments, ligaments undergo non-uniform loading that differs with joint angle. Measuring these regional loads is important for characterizing ligament biomechanics and executing surgical procedures such as total knee arthroplasty (TKA). Outcomes after TKA depend, in part, on the proper tensioning of the collateral ligaments [2]. However, existing methods to assess ligament tension are subjective, indirect, and/or invasive [3]; and are unable to capture the non-uniform loads on wide ligaments such as the medial collateral ligament (MCL). Therefore, a method to quantitatively, directly, and non-invasively evaluate non-uniform ligament tension could improve surgical outcomes, streamline the TKA workflow, and enhance our understanding of complex ligament biomechanics.

Our research group has developed a handheld sensor called a shear wave tensiometer to measure ligament tension directly and non-invasively. This technique uses the linear relationship between squared shear wave speed and axial stress to measure tension in load-bearing tissues such as ligaments [4]. This method has been validated in uniformly loaded tissues [5], and a preliminary study in a finite element model recently suggested that shear wave speed varies regionally in non-uniformly loaded tissues [6]. However, it is unknown how tensiometer measurements are affected by non-uniform loading experimentally.

Accordingly, *the aims of this study* were to 1) determine how accurately the tensiometer can measure the total tension in a non-uniformly loaded specimen, and 2) determine the effect of load gradient and tensiometer tip position on measured shear wave speeds. We hypothesized that 1) a tensiometer with a tip width that spans the width of the specimen will measure total tension under varying gradients, and 2) shear wave speeds measured with a smaller tip width will be sensitive to both tip position and the degree of the load gradient.

METHODS

Mechanical Model: We used a mechanical knee model to simulate loading of a phantom collateral ligament during a varus-valgus laxity assessment (**Figure 1**). Our phantom ligament has mechanical properties comparable to those of biological ligaments [7] and dimensions similar to those of the MCL [8]. The phantom wraps around 3D-printed bone contours to mimic MCL wrapping around the femur and tibia. The clamp representing the femoral attachment includes a slotted connection that allows for rotation about its centerline to introduce non-uniform loading (**Figure 1**). The phantom is tensioned by applying a valgus torque to the simulated tibial shaft. We incorporated in-line load cells on the anterior and posterior borders of the phantom ligament (**Figure 1**) to confirm that we created a non-uniform gradient in the phantom.

Figure 1: Mechanical knee model with phantom ligament showing positioning of load cell tips to measure regional shear wave speed.

Shear Wave Tensiometer: We measured shear wave speeds using our handheld tensiometer. The tensiometer consists of a voice coil tapper, which excites shear waves, and a downstream piezoelectric load cell, which tracks shear wave propagation along the length of the tissue. We computed the time delay between wave arrivals at the tapper and load cell. Shear wave speed was computed by dividing the distance between the tips by the time delay. For this study, we fabricated two different tensiometer tip widths, including one that spanned the entire width of the phantom and another that spanned a third of the width of the phantom ligament (**Figure 1**).

Experimental Design: We first oriented the femoral clamp such that the load cells displayed equal tensions indicating a uniform load across the phantom. We then positioned the tensiometer on the phantom over the joint space and applied a ramped valgus torque to the model to tension the phantom (**Figure 1**). For the full tip width, we measured shear wave speeds with the tensiometer centered over the phantom. For the third tip width, we measured shear wave speeds with the tensiometer placed over the anterior, central, and posterior portions of the phantom (**Figure 1**). We repeated this measurement process with two different non-uniform tension gradients that were achieved by rotating the clamp counterclockwise by 10 and 15 degrees to increase the tension in the anterior portion of the ligament.

Statistical Analysis: To determine errors between tensiometer-measured tension and total tension in a non-uniformly loaded specimen (Aim 1), we first fit a linear regression between shear wave speed (independent variable) and total tension (dependent variable) for the trials with a uniformly loaded phantom and a centrally positioned tensiometer with a full tip width. We then used this regression to compute tensiometer-measured tension for each non-uniform gradient with a centrally positioned, full-tip-width tensiometer. Errors were computed between the tensiometer-measured tension and the gold-standard total tension, which computed as the sum of the in-line load cell measurements (**Figure 1**).

To determine the effects of tip position and the degree of load gradient on shear wave speeds measured with the third tip width (Aim 2), we performed a two-way ANOVA test with an interaction term. We also performed post hoc pairwise comparisons (Tukey's tests) to identify which tip positions, gradient levels, and tip position-gradient level interactions had significantly different shear wave speeds.

RESULTS

The error analysis revealed that tensiometer-measured tension were greater on average than the gold-standard total tension. The root-mean-square error increased by 22% as the gradient increased from a 10-degree clamp rotation to a 15-degree clamp rotation (**Table 1**).

Table 1: Bias and precision errors between tensiometer-measured tension and gold-standard total tension.

	Bias Error [N]	Precision Error [N]
10-degree gradient	28.4	33.1
15-degree gradient	25.3	49.8

The two-way ANOVA test found a statistically significant difference in measured shear wave speeds with varying tip position and load gradient ($p<0.001$). Pairwise comparisons for tip position revealed that shear wave speeds at the posterior position were significantly different than those at the anterior and center locations ($p<0.001$). Pairwise comparisons for the interaction between tip position and load gradient revealed several interesting differences (**Figure 2**). For example, with the 15-degree gradient, shear wave speeds were significantly higher in the anterior and central regions compared to those in the posterior region ($p<0.001$).

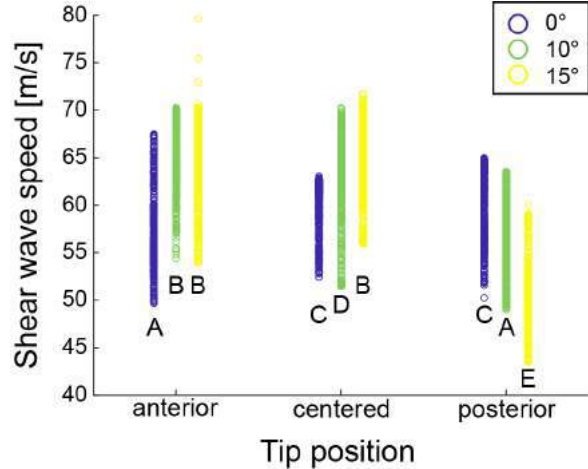

Figure 2: Plot depicts the effect of tip position and gradient on measured shear wave speeds. Data sets labeled with the same letter do not have statistically different shear wave speeds.

DISCUSSION

The errors in total tension (**Table 1**) indicate that a tensiometer with a tip width that spans the entire width of the specimen may over-predict the total tension in the structure when it is calibrated using measurements in a uniformly loaded structure. Thus, measured shear wave speeds may be more sensitive to high-load regions than low-load regions. Tensiometer users should take this over-prediction into account when performing measurements in non-uniformly loaded structures. Despite these errors, our findings indicate that tensiometer measurements still provide information about relative changes in total tension in non-uniformly loaded tissues, which is important for clinical applications such as ligament balancing in TKA.

The ANOVA test indicated that shear wave speed measurements are sensitive to tip position and load gradient. In general, the effect of tip position on shear wave speeds is dependent on the degree of the gradient. There was evidence among non-uniform gradients that measured shear wave speeds increased as tip position moved anteriorly. This is consistent with greater regional tension anteriorly due to our 10- and 15-degree gradients and suggests that the tensiometer captures regional differences in shear wave speed. Our ongoing work includes supplementing these experimental findings with a dynamic finite element model that enables us to perform probabilistic simulations of a wider range of loading gradients, tip widths, and tip positions.

In conclusion, we determined that tensiometers tend to over-predict the total tension in a non-uniformly loaded structure. We also found evidence that tensiometers can capture non-uniform loading across the width of a specimen, as well as the degree of non-uniform loading. Together, our findings demonstrate that our handheld tensiometer is a promising device to quantitatively, directly, and non-invasively measure tension in both uniformly and non-uniformly loaded tissues.

INTRODUCTION

The recent increase in popularity of running on off-road trails has resulted in numerous serious fall-related injuries [1]. The terrain and environmental factors are subject to unforeseen variation, with fluctuations in altitude, unstable surfaces, and rock falls representing major obstacles to participants [1], [2]. Despite the possibility for severe head injuries on unmaintained trails, many runners do not use helmets. Traditional helmets are often considered too bulky, conspicuous, or expensive, such as the “Vapor Helmet” offered by Track N Trail [3]. A product must be developed that maximizes cranial safety, while being appealing and comfortable for the user.

The Queen's Biomedical Innovation Team (QBiT) is developing the CogniGuard, an inflatable helmet geared toward trail runners and other individuals at risk of fall-based head injuries. The product will detect falls prior to their occurrence using onboard software and sensors and protect the user's head with an embedded inflation system.

This device is being developed to minimize fall-based injuries for trail running, with additional applications including usage by patients with a fall risk, such as individuals recovering from an injury, the elderly or patients with epilepsy and other neurological conditions. The device will detect and protect individuals in case of a fall, and with an aesthetically pleasing design, it will provide an appealing improvement to users over pre-existing helmets.

PRODUCT DESIGN

The user will be able to wear this device like a normal hat. If the sensors incorporated into the helmet detect a fall, the airbag will expand around the user's head, protecting vital areas, including the temples and back of the head. The dark blue patches, as seen in Figure 1, are composed of Nylon 6.6, and will absorb an impact and prevent inflation system rupture in the case of rough or abrasive terrain. The inflation system airbag is composed of two materials, Nylon 6.6 and polyethylene. The dual-material system allows for inconspicuous airbag storage within the helmet and providing a protective external coating.

The primary airbag material chosen, Nylon 6.6, is advantageous due to its high safety factor and lower density than contemporary materials [4]. Polyethylene was used as the secondary material due to its ability to easily fold inside the hat and inflate quickly. Figure 1 below shows a schematic of the helmet with the airbag expanded, connected to the microcontroller armband via wiring.

Figure 1: CogniGuard after airbag inflation.

The casing for the microcontroller and battery will be stored within an armband to reduce helmet weight and potential damage to components. Soft PLA was used as 3D-printer filament for the armband casing due to its durability and vibration-dampening properties [5].

The polyethylene airbag was sewn onto the hat fabric through a multi-directional stitching method, using heat-bonding and silicone as a sealant. This bonding method, also used for car airbags, maximizes airbag integrity [6].

The inflation system integrates a compressed air source and airtight container design to seamlessly transfer gas. Its low weight of approximately 0.45 kg allows for installation within the helmet. A 12-

gram CO₂ cartridge is used for inflation and is installed in a custom 3D-printed holster within the helmet. A ¼" bolt is threaded into the holster and tightened to secure the cartridge. When activated, a microprocessor-controlled, onboard 12-volt push-pull solenoid electromagnet will puncture the seal of the CO₂ canister, inflating the airbag.

Ease of manufacturing was considered for all parts. The main body of the inflation system is 3D-printed so it can easily be produced using the accessible PLA material. PLA was chosen due to its high tensile strength of 50 MPA [7]. The push pull electromagnets can be implemented by hand [8]. The Uxcell electromagnets were chosen because they can be used with only 12 volts of electricity which will be electrically feasible [8]. The 12-gram crosman CO₂ cartridge was chosen because it has a high pressure of 850 psi allowing the size of the canister to be small, only 8.4 cm long [9]. The pressure of an average airbag is 30 psi, so utilizing Equation 1, the volume for the inflated airbag was determined to be 0.674 L.

$$\text{Equation 1: } P_1V_1 = P_2V_2$$

The electrical system of the CogniGuard, contained within the armband casing, consists of sensors for fall detection and a connection from the microcontroller to the inflation system. The electrical system consists of a ESP 32 microcontroller, a GY 521 sensor module, a TIP 120 transistor, 1N4001 diode, and various resistors and batteries. The GY 521 module is comprised of a MPU 6050 tri-axial accelerometer and tri-axial gyroscope, allowing for six degrees of freedom. The GY 521 module connects to the board with I2C protocol for a maximum data transfer rate of 400kHz [10]. The accelerometer and gyroscope values range from ± 2 to $\pm 16^\circ/\text{s}^2$ and ± 250 to $\pm 2000 \text{ dps}$ respectively, allowing for motion capture. The input data is fed into a MATLAB Machine Learning (ML) model that will determine if a fall has occurred. To ensure that the model is universally applicable, over 50 hours of training data will be sourced from different team members. The module includes an on-board voltage regulator to regulate input voltage to 3.3V, allowing it to receive voltages from 2.5-5V and preventing damage from fluctuating output voltages [10]. The solenoid used in the inflation system requires 12V of power, which is not possible to be obtained directly from the ESP 32 microcontroller. As a result, the system uses a TIP 120 transistor to switch to an 18V power source once a fall detection signal is generated to activate the solenoid. The system is also connected to a 1N4001 diode to prevent the reverse voltage spike from solenoid activation from damaging the other electrical components [11]. In addition to the system's accuracy and providing a high data collection rate, the combination of the GY 521 sensor with the ESP 32 controller is a highly accessible and affordable option. The TIP 120 transistor has a low base-emitter voltage of 5V, making it ideal for being controlled by the ESP 32 and it is rated for 60V, which is more than enough to remain operational when connected to the 18V power supply [12].

The software sub-team focused on the embedded system of the inflatable helmet, which would detect a fall and trigger the inflation system. As previously described, accelerometer data would be fed into a ML model to determine if the falling condition is met, so an Arduino-based microcontroller will be utilized to trigger the inflation system, as the embedded system's microcontroller. This is a safety critical system, where reliability is key to maintaining proper function of the device. Therefore, no wireless or internet of things technology was used in the device. These technologies would reduce the reliability of the device as wireless technology is prone to failure, and the conditions in which this device would be used might not have access to the internet.

BUDGET & MARKET ANALYSIS

In the US, in 2017, it was recorded that 9.15 million people trail run, so a large potential market exists for the product [13]. The prototyping budget for one CogniGuard was \$1,609.12 for materials and

\$1,853.20 for manufacturing, and \$1,525.50 for testing, resulting in a total cost of \$4,987.82. The team estimates that production scaling will drop the cost per unit to \$320. Currently, there is a single alternative on the market, the Hövding 3, a Swedish inflatable biking helmet, selling for \$505.07 [14]. Selling the CogniGuard for \$448 will ensure it has a 40% return on investment while being a cheaper and therefore more appealing alternative in the market. The CogniGuard will be a considerable addition to a diverse market of users including trail runners, cyclists, the elderly, and patients with neurological diseases.

ACKNOWLEDGEMENTS

We thank the members of the QBiT for their work on this project and review of this abstract. We thank SparQ Queen's for permitting use of their manufacturing equipment, as well as Dr. Claire Davies for her technical expertise and support as QBiT's faculty advisor. We are grateful for funding from Dean Kevin Deluzio, the Sci'73 foundation, and Makers Making Change for their financial support for QBiT's operations and design efforts.

INVESTIGATING ANTHROPOMORPHIC HAND MOVEMENT PATTERNS TO SIGN AMERICAN SIGN LANGUAGE (ASL) ACCURATELY AND REPEATEDLY

Lillie Bukzin (1), Sophi Schneider (1), Julia Zelevinsky (2), Ethan Danahy (2), Samantha Johnson (3)

INTRODUCTION

A primary mode of communication for the DeafBlind community is tactile American Sign Language (ASL). Tactile ASL, which follows a similar structure to ASL, involves an individual receiving signs by placing a hand on their signing partner. Research by Johnson *et al.* investigated the potential of an anthropomorphic robot hand that signs tactile ASL in an effort to make an independent communication tool for those with deafblindness [1]. To do this effectively, the focus was placed on accurately and repeatedly recreating ASL handshapes (Fig. 1), the core of all ASL signs. This focus highlighted the need to specifically understand how the hand moves between handshapes to avoid collision and confusion.

Understanding how the human hand moves between handshapes lend itself to faster, more concise, and more fluid signing that eliminates unneeded movements and delays. Fluid hand movements are also essential to forming comprehensible signs and decreasing miscommunication events. Additionally, the community of those who sign is widespread, creating a range of dialects and regional signs. This, as well as individual differences and preferences, leads to specific signs being produced in several different ways [2]. However, since all signs are made up of a finite number of handshapes, by developing transitions for these handshapes, we can ensure fluidity of signing variation.

The complexity of hand anatomy allows for many unique forms of movement and individual degrees of freedom (DoF). The 30 muscles in the hand support movement, allowing for flexion/extension and abduction/adduction around three phalangeal joints [3]. Due to the nuance of human hand motion, as well as ASL signing, a research gap exists surrounding how the hand smoothly transitions between complex handshapes. Our research objectives focus on understanding the movement between handshapes and finding patterns in the varying handshape movements to support efforts of signing phonology and robotics. Specifically, our findings will be tested on an 18-DoF robotic hand to determine accuracy and repeatability.

METHODS

To determine how the human hand moves between handshapes, each motion was analyzed by joint.

Numbering Joint Transitions for Each Handshape. All DoF were assigned a number between one and 18, and documentation was created for every handshape transition (e.g. A \rightarrow Open A, A \rightarrow B, A \rightarrow Open B, etc.). Using previous recordings and background in ASL handshape formation, joints were labeled in an order of movement that enabled a fluid transition from the starting handshape to the ending handshape. Labeling joint transitions in this manner allowed for an easier transfer of knowledge from the document to the robotic hand code. Notably, specific joint angles were not needed at this point; instead, angles were later implemented through joint mapping.

Handshapes Consistency Key (HCK). As the numbering of joint movements between handshapes continued, observations and similarities between various transitions were recorded. To keep transitions consistent between handshapes, a HKC was created. In this key, rules were listed that defined the order that joints should move when multiple are changed within the same transition (e.g. beginning joint movement at the index finger and moving medially). Additionally, this key determined when handshape transitions occurred in two parts to avoid collision during movement in opposing planes. This key provided a resource to produce all future handshape transitions and confirmed the accuracy of existing transitions.

MediaPipe Validation. To validate these handshape transitions, motion capture analysis was completed using MediaPipe, specifically, to confirm two-part handshape transitions and hand timing. For each of the starting handshape transitions, a human hand was recorded completing the specified transition. Using the mapped DoF points, the position of the TIP joints in the X, Y, and Z direction on each finger were mapped across 80 ms frames. Depending on the axis of movement, the change in position (speed) was graphed relative to the frames to display peaks for significant joint movement for each. To only capture relevant information and avoid interference, frames were removed at the

start and end to sanitize the data set. These graphs consequently allowed for the most significant starting frame for each hand to be determined to confirm hand timing.

RESULTS

The proposed HKC was applied to all letter transitions, as seen in Figure 1, to provide reliability and develop patterns. Each joint was assigned a number, name, and place within the movement order. Coloration was assigned to each number in the movement order to aid in pattern identification (coloration remained consistent between all handshake transitions).

Figure 1: A Sample Transition (A → B) with hand detailing the location of each joint number seen in the first column.

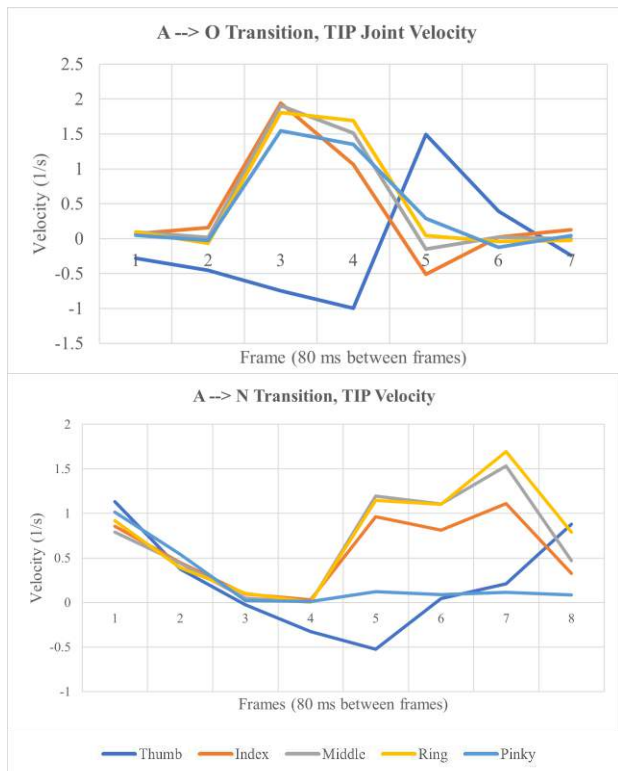

Figure 2: Motion capture validation of A → O and A → N Transitions using velocity of the TIP joints

The HKC contains 25 rules, for example, when the fingers are extending, move all Metacarpal Interphalangeal (MCP) joints before Distal Interphalangeal (DIP) joints. Key HKC rules were analyzed for their use within coded hand transitions. The transition from every

handshape to 'B' (an open handshape) was used to analyze fingers extending and determined that 97.06% of these transitions followed this rule.

Importantly to using the HCK, timing and inherent delays of the transitions were introduced and confirmed using MediaPipe. For example, in Figure 2, the recorded data from the transition from 'A' to 'O' indicate that all non-thumb fingers move first in frame 3, followed by the thumb in frame 5 to complete the transition. The transition from 'A' to 'N' displays the distinct peaks across the frames that denote two parts are needed for the joint sequences to successfully complete the transition without collision. At frame 5, the thumb moves out in the away from the rest of the hand while the non-thumb fingers move upwards. Between the two peaks at frame 5 and 7, the thumb moves into place while the non-thumb fingers stall. This indicates the delay in the movement of the non-thumb fingers to allow the thumb to move to its final position successfully. The lack of movement by the pinky indicates its lack of prevalence in the overall transition. This motion capture result thus portrays how the fingers' movements are timed in ways to prevent collision relative to if the joints were to move immediately to their final positions on the robot.

Testing the proposed transitions with the ASL signing robotic hand, the team was able to determine the functional accuracy of their design. In trials with DeafBlind users (N=5), we saw a recognition rate of 90% of fingerspelled words, confirming the HKC's success. DeafBlind users remarked at the 'fluidity of the signing' and said the transitions made the fingerspelling much 'smoother.'

DISCUSSION

The numbering of the joints with the HKC allowed for a repeatable and concise understanding of overall hand movement. All transition decisions were made to prevent collisions and interference between finger movements. This research takes advantage of what is known anatomically of hand movements to better understand how those movements can be applied in ASL, specifically in relation to natural movements from one handshape to another.

The consistency key enabled the formation of patterns and forced reevaluation of inconsistencies. Validation using the signing robot also provided a secondary measure to confirm the strength of the data. User testimonials demonstrated the practical successes of the transitions to have improved the robot's functionality.

This motion capture validation allowed for the recognition of patterns and confirmed the necessity of two-part transitions. Further, the graphical representation of the hand movement allows for critical analysis of how the hand moves and what role each joint plays in the overall transition and how they interact at the same time frames.

As our next steps, critically, we will compare the motion capture results on the human hand with that of the robot hand and ensure that the proposed transitions are accurately mapping human movements. This extended motion capture analysis will further enhance the ability for pattern recognition and minute differences between various handshape transitions.

Through this research, the team recorded and analyzed realistic anthropomorphic hand movements, highlighting key hand anatomy and the specific application in robotics.

ACKNOWLEDGEMENTS

We would like to thank Tatum Robotics for proposing this project and supporting ongoing research and improvements. Also, we thank Tufts University for its commitment to accessibility projects.

INTRODUCTION

Instability of the shoulder leads to a range of debilitating pathologies [1]. At the extremes of athletic performance, human shoulder joints must support loads across a range of angles of up to 140° [2] (Fig. 1). Injuries are frequent in these regimes, and the tendon tears that can result are difficult to repair [3]. Identifying mechanisms that enable shoulder stability at the extremes of motion is important for guiding surgical repairs.

Bats provide an interesting model for this. Although bats have evolved high-force overhead motions (Fig. 1), they do not seem to injure their shoulders as frequently as humans [4]. Our objective was therefore to model the ways that shoulder stability is maintained in bats, and to compare this to mice, similarly sized animals in which overhead motion is not observed.

A range of computational models exists to describe the motion of the shoulder and the resulting strains of tendons that connect to the shoulder [5]. Although these models provide exceptional anatomical accuracy and are predictive of shoulder kinematics, they are not well suited to closed form analysis and parametric study across species. We therefore developed a simplified model of shoulder stability and applied it to enable cross-species study. We hypothesized that the anatomy of bats provides advantages over that of mice to promote shoulder stability.

METHODS

Mathematical model: Based upon CT scans of the bat and mouse glenohumeral joints (not shown), we developed a simplified model of the energy barrier to shoulder instability as a function of the glenoid and insertion angle between tendons and the humeral head. Depicted in **Fig. 2(a)**, The two-dimensional model considered the glenoid as an arc with radius r_{gle} and angle α . The humeral head of radius r_{hum} rests at the bottom of the glenoid with a section of bone with width w . The total length from the bottom of the humeral head to the other end of the bone is H . Distanced a from the edge of the bone, two linear elastic tendons

with gauge (unstretched) length L_0 and initial length L were inserted to both sides of the bone at an angle θ . The other ends of the tendon were fixed. Both tendons were linear elastic with stiffness k .

Figure 1: (a) A bat, a mouse, and a butterfly swimmer (photo credits in Acknowledgments). (b) Model of the glenohumeral joint in its initial condition and (c) loaded condition.

To model response to destabilizing forces, a concentrated force F was applied quasistatically as shown in **Fig.1(b)**. Force was ramped linearly until the humeral head became unstable, and the force required to displace it further in the glenoid decreased. To calculate the resistance of the system to instability, the work U done by F up to the point of instability was calculated: $U = \int \vec{F} \cdot d\vec{r}$, where $d\vec{r}$ is the increment of

path length followed by the point of application of the force. Using the Matlab (Natick, The Mathworks) environment, force-displacement curves and U were calculated for different combinations of glenoid arc angles α and tendon insertion angles θ . In all simulations, the following baseline parameters were used: $L_0 = r_{gle} = 7.5$ cm; $r_{hum} = w = 5$ cm; $H = L = 15$ cm; $a = 3$ cm; and $k = 2500$ N/m.

RESULTS

Simulations revealed that the force-displacement relations varied with insertion angle (Fig. 2, for the case of $\alpha = 180^\circ$) and glenoid angle (not shown). Force rose nonlinearly as the humeral head reoriented during its traversal of the glenoid arc. As tendon insertion angle increased, the structural stiffness of the system increased, suggesting that a larger tendon insertion angle leads to stiffer humerus-glenoid assemblies. The peak force needed for instability was highest at intermediate tendon insertion angles, while the maximum displacement of the humerus prior to instability was highest for lower insertion angles.

Figure 2: Tendon angles affect the relationship between force and humerus displacement. Here, force was normalized by the kL_0 , and displacement was normalized by the glenoid radius, r_{gle} .

The elastic energy barrier that must be overcome for instability is a function of the stiffness, peak force, and peak displacement, of the tendon-humeral head assembly, as well as of the depth of the glenoid. To evaluate how this energy barrier for instability changes with tendon insertion angles and the depth of the glenoid, a phase diagram was drawn (Fig. 3). In this phase diagram, darker shades of red correspond to higher energy barriers that must be overcome for instability to occur. The plot shows that small tendon insertion angles (ranging from 0° to $\sim 30^\circ$) lead to relatively small energy barriers regardless of glenoid arc angle. On the other hand, for certain tendon insertion angles greater than 30° , the energy barrier increases with glenoid arc angle up to a threshold. The maximum energy barrier occurs for tendon insertion angles in the range of 50° – 60° , although the rise to this is nonmonotonic. The energy barrier is relatively insensitive to the glenoid angle beyond an instability threshold that is associated with full dislocation of the humeral head from the glenoid; thereafter, the instability is associated with a bifurcation in humeral head position within the glenoid, and the energy barrier for this does not vary with the spatial extent of the glenoid.

The range of glenoid angles observed in mice is $42^\circ \pm 10^\circ$, and that of the bat is $73^\circ \pm 10^\circ$ [6]; the insertion angles for both species are more difficult to estimate, but appear to be greater than 45° . In the context of the phase diagram, this places bats in a range that can accommodate a greater range of stable tendon insertion angle than the mouse.

DISCUSSION

The impact of this study lies in understanding the factors that may lead to instability in human shoulders. Comparing mice, which have limited shoulder mobility, to bats, which can perform diverse flying maneuvers

with both mobility and stability [3], is instructive. While the simplified mathematical model certainly does not capture all of the complexity of shoulder motion, it does allow certain comparisons to be made. First, the deep glenoid and larger arc angle of the bat promote stability over a much broader range of tendon insertion angles than does that of the mouse.

Figure 3: Phase diagram representing the energy barrier that must be overcome for instability of the model shoulder to occur.

Second, in Figure 3 the state of the mouse shoulder lies close to the diagonal line separating regions of low energy barrier to regions of high energy barrier for insertion angles less than 45° . Stability in this region may be enabled by the anatomy of the mouse, which prevents overhead motion [2].

Third, the bat anatomy encompasses the range over which the maximum energy barrier is found (insertion angle of $\sim 60^\circ$ and glenoid arc angle $\sim 60^\circ$), indicating that a larger disturbance is required to dislocate the humeral head from the glenohumeral joint. Beyond about $2\alpha = 75^\circ$, the model predicts that no additional benefit would be found by further increasing the glenoid angle. This suggests that the bat anatomy is well optimized to maximize the energy barrier associated with dislocation, and is significant because it provides a target for human glenoid reconstruction surgeries [7].

We note that the model is idealized. Although the human shoulder can be studied using this model, future studies should add additional detail. Rather than concentrated force, tendons exert distributed force over an enthesis footprint area. Future studies could account for this, as well as the more complex geometries of glenohumeral joints across species. However, even with these limitations, the model provides evidence to support the hypothesis that the anatomy of bats provides advantages over that of mice to promote shoulder stability, and provides insight into targets for surgical reconstruction of the glenoid.

INTRODUCTION

Despite technological advancements over the past four decades, the mortality rates of cervical cancer, the third most frequent malignancy, have remained about the same [1]. Cervical cancer is often successfully treatable if identified early through routine screening and various stage specific treatment procedures. Currently, treatment options include chemotherapy, radiation therapy, and surgical intervention. Cervical cancer poses a global burden due to the therapeutic challenges low- and middle-income countries face as they are both inaccessible and unaffordable [2].

Biodegradable polymers have enabled many novel approaches to drug delivery. For an effective drug delivery system, it is crucial to deliver medicine to the right place at the right time. Implantable drug delivery systems were developed to overcome problems associated with oral and injectable administration approaches of bioavailability, patient adherence, and first pass metabolism, among others. Polymeric drug delivery systems are versatile and have shown promise to overcome these issues.

The solution proposed is the Multistage Polymer Delivery System (MPDS), which is a biodegradable polymer able to control administration of drugs over 2 to 3 weeks through geometry and composite structures. This study's objective is to demonstrate our MPDS demonstrates a biphasic linear controlled release profile, which we believe would indicate potential as an effective treatment vehicle for cervical malignancies.

METHODS

PCL (Polycaprolactone) was chosen for this study due to its hydrophobicity and slow degradation rate, which were hoped could be leveraged into an effective treatment vehicle to deliver hydrophilic drugs including cisplatin, tetracycline, and carboplatin, which are traditionally used to treat cervical cancer [4]. PLA (Polylactic acid)

was also selected due to its versatility as a biopolymer, ability to exhibit thermoplastic behavior; and previously demonstrated utility in various applications including drug carriers, cancer therapy, and medical tools [5]. Rhodamine B was selected as a model for hydrophilic drugs, due to its similar hydrodynamic radii to those mentioned, water solubility, and ease of detectability [6]. Once submerged in PBS (Phosphate buffered solution), the release of Rhodamine B within the device was tracked through UV-Vis Spectrophotometry.

To batch manufacture polymer devices and ensure minimal error, a two-sided metal injection mold was designed to create twelve 0.100 cm spherical devices. Two g of PCL and 0.002 g of Rhodamine B were weighed out to create twelve devices. A hotplate was used to bring the polymer to 60 °C, the melting point of PCL, so Rhodamine B could be evenly distributed. The polymer mixture was then placed into the metal injection mold and pressed to form equal-sized spheres. These steps were repeated to create the PLA devices.

The purpose of the first experiment was to evaluate the release rate of Rhodamine B over an extended period and determine the replicability of the results. The experiment included 250 mL beakers with 100 mL of PBS. Magnetic rods were placed in each beaker to ensure the solution remained well-mixed. At the start of each experiment (Day 0), the device was submerged into the beaker with PBS and stored at 37°C for 21 days. Each day, 2.5 mL was extracted and replaced with fresh PBS.

The second experiment's purpose was to determine the release rate at different points in the device. PCL and PLA devices were both split into four pieces. The experiment involved submersion of each piece in a separate 50 mL volume of PBS that was maintained by a stir bar. The experiment was conducted at 37°C for 12 days using the same method for daily sampling.

RESULTS

Figure one exhibits the results of the Rhodamine B release experiment: the release rate of PCL and PLA over a 21-day period. The PCL devices exhibited a biphasic linear controlled release profile. However, the PLA devices did not release any Rhodamine B over the 21-day period.

Figure 1. The release rate Rhodamine B in PCL and PLA devices for an extended period

Figure 2. The release rate Rhodamine B in PCL devices when cut in four pieces

Figure 3. The release rate Rhodamine B in PCL devices when cut in four pieces

Figures two and three exhibit the results for experiment two: the release rate of PCL and PLA devices for a 12-day period when cut into four equal pieces. The variety of mass of each sub-divided piece was normalized for comparison. The PCL devices displayed comparable results to experiment one. Again, figure three exhibits that PLA did not exhibit any release over the 12-day period when cut into four equal pieces.

DISCUSSION

After evaluating the data collected from the two experiments, all the devices display comparable results, which indicate the repeatability of the fabrication process. Experiment one displays a linear biphasic release of Rhodamine B within the PCL device over an extended period. Experiment two displays a comparable release rate which conveys the objective of ensuring each device exhibits similar release. Furthermore, it displays the direct relationship between surface area and release rate.

The biphasic linear behavior of PCL release follows a loading and maintenance dosage administration schedule. The release data from the PCL device fulfilled the biphasic linear profile objective. While PLA did not exhibit release in either of the experiments, it displayed the possibility of creating a polymer composite that could be leveraged to control aqueous access to drug-loaded PCL. The data in this study provides a foundation for future development of this polymeric drug release regulation approach for treating cervical cancer [7].

INTRODUCTION

Bioprinted scaffolds provide a promising alternative to the current standard of care for orthopedic injuries (ie. autografts, allograft, synthetic implants) in their biomimetics and enhanced functionality [1]. However, the efficacy of these constructs depends on their cellular differentiation and successful integration into the native tissue—a challenge that has yet to be addressed. Previous work has shown that a combination of mechanical and graded biochemical cues can stimulate mesenchymal stem cell (MSC) differentiation into osteoblasts and tenoblasts [2]. This study aims to determine whether such mechanically-stimulated differentiation can be achieved in cell-laden scaffolds by designing a bioreactor that simulates the native tissue environment and generates a stress field of tension-compression forces akin to those endured by musculoskeletal cells around many bony pulleys along the tissue construct. The initial bioreactor was manufactured using acrylic and polyethylene terephthalate glycol (PETG), and a second generation model is being developed with anodic aluminum oxide for increased durability and stability. The stress field due to the cyclic tension induced by the bioreactor was determined via Finite Element Analysis (FEA) and will be correlated to the cell morphologies that arise in tension versus compression regions of the scaffold following sample testing in future studies. If variable differentiation and cell morphology is achieved across the stress gradient, that would inform how bioprinted constructs might react and develop when implanted into musculoskeletal tissue.

METHODS

Ring-shaped scaffold samples consisting of a polycaprolactone (PCL) backbone and gelatin-fibrin hydrogel were synthesized as 7 cm x 1 cm matrices [Fig. 1], and MSC-bearing droplets were deposited within the construct via Acoustic Droplet Ejection (ADE).

Figure 1: Linear scaffold sample consisting of a PCL backbone

and MSC-laden gelatin fibrin bioink. Two 1 cm PCL end strips were sutured together to form a 7 cm-long, ring-shaped scaffold. (1 cm scale bar)

In order to generate a stress field mimicking what the sample would undergo *in vivo*, a bioreactor that subjected the cells to a grade of tension to compression forces was manufactured. The device's loading configuration resulted in a cyclic stress when the bioreactor was in operation [Fig. 2].

Figure 2: Each ring sample was wrapped around two reciprocating loading rods in a symmetric manner as a representation of a wrap-around tendon on a bony pulley. Linear actuation subjected the rods to cyclic bidirectional movement, resulting in the ring stretching and compressing with a sinusoidally-described displacement and maximum displacement of 3.5 mm.

The bioreactor was fabricated with 3D-printed PETG and laser cut acrylic such that 12 scaffold samples could be loaded for simultaneous tension-compression testing. A rack-and-pinion mechanism in conjunction with linear actuation enabled the bidirectional movement that induced cyclic stress [Fig 3], and movement was calibrated to a frequency of 0.5 Hz and a maximum uniaxial displacement of 3.5 mm (with these values being programmable). This results in 7-10% tensile strain, which is comparable to physiological values [3,4]. Finite element analysis was performed to determine the stress field on the construct and predict resulting cell morphologies.

Figure 3: Exploded-view schematic of the bioreactor's internal hardware, consisting of two outer walls that move bidirectionally to the middle wall to induce stretching and compressing of the ring samples loaded around sets of arms. The rack-and-pinion system enables this movement when coupled with a linear actuator that fits into the actuator shaft.

RESULTS

Defined by the mechanical parameters of the scaffold and bioreactor, a computational model of the bioreactor-induced stress field was generated to simulate the viscoelastic deformation of the gelatin fibrin gel using the Finite Element (FE) method in COMSOL Multiphysics (COMSOL Inc., USA) [Fig. 4].

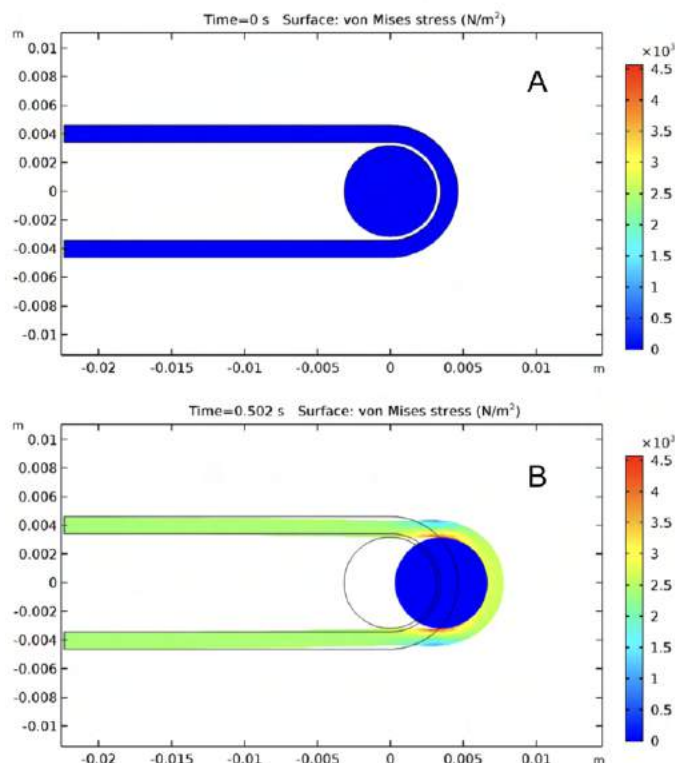

Figure 4: The stresses acting on the scaffold were visualized at

(A) time point $t = 0$ s, when uniaxial displacement across the length of the scaffold $d = 0$ mm and (B) time point $t = 0.5$ s, when displacement was at a maximum of 3.5 mm. The greatest points of stress identified were located at the tensile regions.

The reciprocating rod the samples are loaded onto was modeled as a circular solid with a uniaxial linear motion and a prescribed sinusoidal displacement. The scaffold was modeled as an elastic part that stretches on account of the movement of the rod. The geometry of the model is identical to the experimental setup, and the scaffold material properties were determined experimentally. A triangular mesh was created for the FE model, which was simulated with a time-dependent solver for two motion cycles. The stress and strain distribution inside the hydrogel part was then visualized. The stress distribution is shown in Fig. 4 at two different time points corresponding to 1) the beginning of the scaffold stretch and 2) the maximum stretch at a displacement of 3.5 mm.

DISCUSSION

The FEA model demonstrates that cells along bone/tendon constructs are subjected to a variable stress field under physiological conditions and that consequently, MSC differentiation may differ in accordance to these graded tension and compression forces. To investigate further, the cell morphologies that result from two weeks of mechanical stimulation from cell loading onto this bioreactor will be visualized to study if and how variable stress fields influence MSC differentiation. These morphologies will also be studied when such mechanical cues are delivered in conjunction with biochemical cues (eg. Sox9, Collagen1, Collagen2, Scx, Aggrecan) that are known to incite MSC growth and differentiation. In addition, a second generation bioreactor is being manufactured with anodic aluminum oxide for increased stability and durability, with bidirectional movement induced through a timing belt mechanism that provides more accurate control over displacement length. In tandem with the modelistic results of this study, these future investigations will provide insight into how bioprinted implants will integrate into native tissue, whether targeted cell differentiation can be achieved for regenerative medicine purposes by combining mechanical and biochemical stimuli, and the clinical effectiveness of printed implants in the long run.

PROBLEM STATEMENT

Patients suspected to have cancer undergo a medical procedure called biopsy where long, thin needles are used to collect a small tissue sample of the suspicious mass which is then interrogated to determine malignancy. The clinical practice of biopsy typically samples less than 1% of the tumor volume (**Fig. 1a**) whereas tumors are known to exhibit remarkable spatial heterogeneity, with considerable intratumoral variation in protein markers, gene expression, and the presence and status of immune cells [1-2]. Despite major advances in cancer diagnostics and therapy, the practice of biopsy has remained unchanged over several decades, fundamentally limiting our ability to study, understand, and treat cancer.

Several approaches have been tested to bridge this gap, including the

Fig 1. Intratumoral heterogeneity shown with different colors. **A)** Sample volume (dashed line) from conventional biopsy is miniscule. **B)** Our technology can extend the sampling volume to the entire tumor.

use of imaging tools to locally profile the tumor microenvironment or by using physical forces to improve tissue sampling [3-4]. Further translation of imaging approaches to regular clinical usage is hindered by the inability to extract tissue samples that are necessary for pathology and diagnosis. High resource requirements and considerable alteration of clinical workflow are other limiting factors. Our

proposed technology is designed to seamlessly integrate with current

image-guided biopsy procedures while dramatically increasing the data that can be derived from the tumor to guide clinical decision making.

TECHNOLOGY/SOLUTION DESCRIPTION

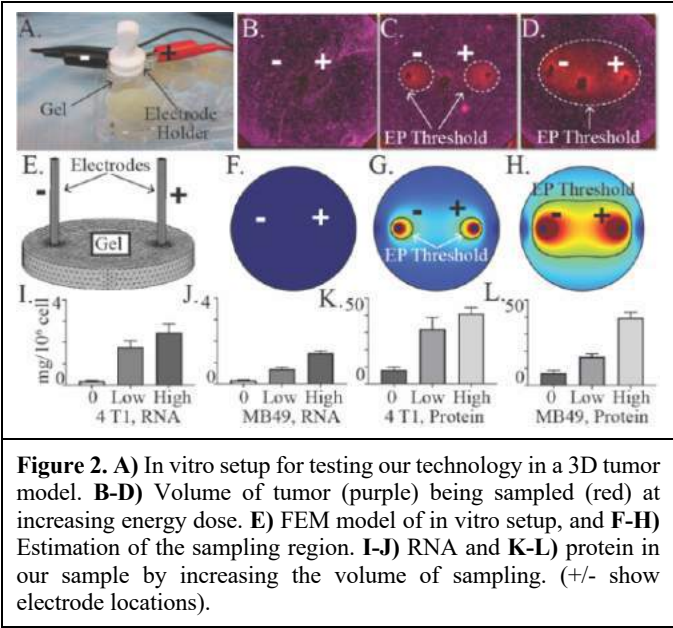

We have established devices, technology and translational techniques to produce on-demand liquid samples from large, defined tissue volumes (e.g., sphere with a 2-3 cm diameter, **Fig. 1b**). This liquid sample is enriched with intracellular material such as DNA, RNA, protein and metabolites that is otherwise inaccessible for diagnostic purposes, or is often heavily degraded due to the degradative conditions in the tumor microenvironment. This high-quality “liquid biopsy” sample can be extracted from the tumor by simple aspiration with needles, then directly fed into existing cancer diagnosis pipelines and genomic sequencing with minimal post-processing.

Our technology functions by placing a long, thin needle into the tissue of interest and delivering an electrical waveform that stimulates release of intracellular materials from cells without harming them. The medical devices we have developed has features that allow simultaneous extraction of the sample by simple aspiration. We have established computational models to guide selection of the electrical waveform based on the desired volume from which sample is to be eluted, and also volumetrically map the sample to the tumor volume from which it was derived (**Fig. 2 b-d, f-h**). For the first time, physicians will be able to extract samples from entire tumor or tissue volumes in a predictable fashion.

We have validated this technology with in vitro models (**Fig. 2 i-l**) and preclinical studies in animals bearing breast and bladder cancer, confirming that the protein and RNA extracted with our technique are representative of what can be obtained by processing the entire tumor (**Fig. 3**). Sequencing results suggest that our liquid biopsy samples have excellent correlation with matched whole tumor lysate, even without optimization. Crucially, this validates the ability for samples acquired with technology to be directly fed into next generation sequencing and

multi-omic platforms that are becoming standard of care for cancer diagnosis. Notably, existing biopsies sample require 2-3 day post-processing for subsequent multi-omic interrogation.

We are currently working on establishing of a prototype device that would be suitable for eventual clinical use and are further optimizing the electrical waveform to allow performing this procedure in an outpatient setting.

BUSINESS CASE

Our promising new technology is expected to broadly impact cancer diagnosis by upgrading clinically used biopsy techniques, specifically, that of fine needle aspirations performed during percutaneous and endoscope guided procedures. We will target prostate cancer as the first clinical indication to develop and validate our technology.

Figure 3. Comparison of protein and RNA levels in conventional (EP-) biopsy versus our technique (EP+) in breast (4T1) and bladder (MB49) tumor models in mice.

Urologists caring for men on active surveillance (AS) for prostate cancer (PCa) are our immediate and ultimate customers respectively. An estimated 50% of all men with PCa in the USA are referred to active surveillance for clinical management of their disease [5-6]. This is performed using blood tests and saturation template biopsies (using 12 – 40 needle placements) every 1-2 years for the duration of the patient’s life. This clinical paradigm for active surveillance presents known risks of under- or over-staging of PCa, and the possibility of false negative results. The current workflow also requires several days before diagnostic results are

available to patients, while being incapable of using technological advances in molecular and genetic techniques to improve precision and prognostic value of diagnosis. We anticipate our product will prove beneficial to men whose cancer is not visible on magnetic resonance imaging, have increasing prostate specific antigen levels on blood tests and are scheduled for conventional template biopsy. This would represent over half the patients on active surveillance, and close to a quarter of all non-metastatic prostate cancer patients. Eventually, we expect our product will improve diagnosis of most solid tumors (e.g., lung, colorectal, breast cancers) and patients with metastatic cancer who are eligible for immuno- or precision therapy.

For our proposed clinical indication, we anticipate our product can generate liquid biopsy samples from an entire prostate sextant with a single needle placement (Fig. 4), allowing reliable multi-omic profiling of a whole prostate gland with fewer than 4 needle placements. The entire process takes a few seconds to complete. Use of liquid biopsy samples for diagnosis would circumvent the current approach of Gleason scoring system that requires heavy involvement of pathologists and has a multi-step processing workflow. Having simultaneous access to genomic, transcriptomic, protein and metabolite sample from the entire prostate would allow creating a definitive picture of the patient’s disease status while also reducing diagnostic inaccuracies from sampling bias.

Regulatory and Commercial Strategy: The choice of preliminary evaluation in the prostate and the need for such technology was driven by input from our clinical advisors. Competing technologies are driven by imaging without acquiring tissue specimens, or are focused on minor improvements in existing biopsy devices. Both approaches lack the ability to retrieve intracellular samples from a predictable volume or seamlessly integrate with existing clinical workflows. Our product will bridge two gaps in cancer care, namely that of acquiring high-quality samples that represents an entire tumor /prostate volume with that of diagnostic capabilities by current generation genomic and molecular diagnostic technologies. Our product is based on FDA cleared predicates (for the electrical waveform) that are already in clinical use for over a decade, providing a clear pathway to regulatory approval. Our technology is positioned as a biological sample acquisition device, thereby our product would not fall under diagnostic or therapeutic categories, qualifying as a Class II device eligible for 510k approval with limited clinical trials documenting safety.

PROBLEM STATEMENT

Osteoporotic fractures commonly occur in the hip and vertebrae and are associated with a \$17 billion burden in healthcare-related costs [1]. Not simply an economic burden, osteoporotic fractures are a significant cause of morbidity and mortality in the aging population [2]. In fact, hip fractures are fatal in 20% of cases and permanently disabling in 50% of cases [3]. It is estimated that 40-46% of women over 50, and 13-22% of men over 50 will suffer an osteoporosis-related fracture [4]. With the number of persons over 60 projected to nearly triple by 2050 [5], a significant increase in at-risk populations for fracture is imminent. Thus, the need is immediate to identify those at greatest risk of bone fracture and provide timely intervention.

Over the past two decades, significant progress has been made in our understanding of bone fragility and fracture [6]. However, over the same period, little progress has been made clinically to reliably identify those at risk of fracture. This has been due in part to the narrow breadth of accessible biomarkers that indicate fracture risk. In fact, the only readily agreed upon clinical measure of fracture risk is bone mineral density (BMD). Unfortunately, since BMD only gives a coarse estimate of the amount of mineralized bone per unit volume, BMD alone has only a 30-50% success rate in predicting fractures [7]. Bone is a complex structure with an intricate microstructural organization and the characterization of this microstructure (an indicator of bone quality) provides a significantly improved estimate of bone's structural integrity [8] compared to BMD. Recently, high-resolution peripheral quantitative computed tomography (HR-pQCT) has emerged as a promising technology to clinically assess bone microstructure. Unfortunately, HR-pQCT is limited both in its low clinical availability and applicability. Only small volumes of bone at specific peripheral locations can be assessed (i.e. distal tibia, distal radius, etc.). A wealth of information describing bone's structural integrity remains inaccessible, and it has been shown that thorough, whole-bone descriptions of structure are

more predictive than single, or few measures of bone structure [9]. A robust solution for assessing bone strength and fracture risk should account for microstructural information like HR-pQCT, but should be applicable to full bone volumes at any region of interest (e.g. hip, spine, etc.) like traditional CT. To this end, we have created a software solution that uses state-of-the-art physics-based deep learning to address the limitation of existing medical image data acquisition technology.

TECHNOLOGY/SOLUTION DESCRIPTION

We have developed and submitted a patent for an algorithm that 1) improves the resolution of medical image data and 2) uses the improved medical image data in a novel fracture risk assessment. In this system, a physics-based generative adversarial neural network is used to predict high-resolution image data from low-resolution image data in a process called super-resolution. CT image data is transformed from a resolution of 250-500 microns to 50-100 microns with sharp, and accurate, delineation in the trabecular microarchitecture consistent with what is visible in a MicroCT scan (Figure 1). From these image data, the novel fracture risk algorithm considers the spatial distribution of microarchitecture. For the first time, microarchitectural parameters are obtainable at sites of frequent fracture and can assist clinicians in diagnosing osteoporotic fracture risk.

The novelty of our algorithm is threefold. 1) A novel, physics-based approach has been implemented to constrain the neural network to physiologically-plausible predictions of microarchitecture. 2) We've curated a unique dataset for training that consists of bones scanned on both a MicroCT machine, as well as traditional lower-resolution clinical CT. In past implementations of super-resolution of medical image data, high-resolution image data is artificially down-sampled to create lower-resolution input data. We've demonstrated that this approach does not faithfully reproduce data that would have originated from a clinical environment (Figure 2). Finally, 3) our fracture risk algorithm is the first

of its kind to consider the spatial distribution of microarchitecture in whole bones. The algorithm considers the same physics that govern fabric tensor-derived material properties of bone shown to accurately reflect its mechanical behavior [13-15]. Detailed bone architecture is now accessible at sites susceptible to fracture (proximal femur, spine, etc.), whereas current high-resolution imaging technology is limited to distal skeletal sites.

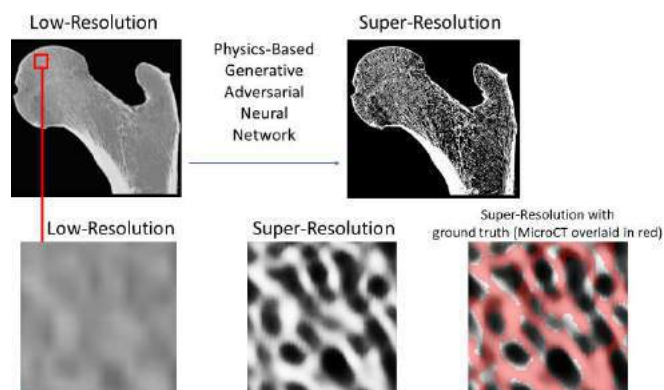

Figure 1. Top: Example of our super-resolution algorithm on the proximal femur of a bone not used in training. Bottom: 5x5 mm section of bone detailing the quality of the super-resolution algorithm compared to MicroCT (right, red overlay).

Figure 2. Example of artificial down-sampling providing similar detail to the original high-resolution image. In both the artificial down-sampling image and the clinical low-resolution image, the resolution is theoretically the same.

BUSINESS CASE

The primary use case for this technology is an opportunistic use of available image data at hospitals and imaging centers around the country. Roughly 40% of individuals over the age of 65 will have a CT scan during a typical year. Most of these scans are for reasons other than osteoporotic diagnosis (e.g. abdominal pain) but hip and spine image data are coincidentally present in these scans. The problem is that since these images are not tailored specifically to look for osteoporosis, they often do not provide high enough resolution to make informed decisions about the patient's bone strength, thus limiting any rational treatment

decision-making. We are addressing this issue with our technology that enhances low-resolution image data and can be opportunistically applied to non-osteoporosis-related image data. The value proposition is clear: fix a technological constraint to instantly gain a free, convenient, and large-scale screening tool.

Given the above, a proposed use case is: A hospital pays for our software, such that they can provide large-scale osteoporotic fracture risk screening. In the event an individual has been flagged for high risk of osteoporotic fracture, subsequent screenings and intervention may take place, which provides additional income to the hospital. Since obtaining reimbursement statutes for new medical technology is a long and cumbersome pathway, the opportunistic use case of available image data circumvents the need for reimbursement in the initial adoption of the software. As the software gains adoption through beneficial use and acceptance, the case can be made for a stand-alone practice where image data is gathered for the sole intent of detailed osteoporotic fracture risk assessment.

We are currently working with the University of Texas Health Science Center at San Antonio's department of radiology, as well as clinical partners in the university hospital system to further develop the technology, implement the solution into their medical image data processing workflow, and test the feasibility. Moreover, we are collaborating with a large medical scanner manufacturer to explore additional product opportunities.

As a non-profit research and development organization, the path to market requires a spinoff of a small, startup company. Currently, we are working toward validating our fracture risk assessment in a small, cadaveric study. If successful, a large cohort will be recruited for a clinical study that will accompany the 510(k)-device application to demonstrate the validity in the approach and its clinical utility and accuracy. A 510(k) submission is noted as a precedent has been set for medical image-based fracture risk assessment tools, as well as image enhancement software (e.g. O.N Diagnostics, FRAX, Canon's Advanced Intelligent Clear-IQ Engine, etc.). In the meantime, a Q-submission will be presented to the FDA for their initial feedback and concerns. In addition, an alternative path to market will be explored via simple licensing agreements of our patent to a CT manufacturer. In this way, an established medical device company may implement our software into their existing medical scanners and assume the risk of bringing the product to market. The largest risk of our product is an inability to predict fracture risk better than existing methodologies, such as O.N. Diagnostics, FRAX, and published algorithms in the literature. However, our alternative path to market partially ameliorates this risk, as medical scanner manufacturers are interested in the super-resolution technology alone, which we've demonstrated success with.

ACKNOWLEDGEMENTS

The authors of this submission would like to thank Canon Medical Systems, USA for their funding of the initial research and development.

SLIC-VAD: A WIRELESSLY POWERED LVAD WITH MAGNETIC LEVITATION BEARINGS

**Shweta Karnik (1), Huang Chen (1), Simon Kiang (4), Arun Kumar Kota (2), Yaxin Wang (3),

(4) Electrical and Computer Engineering, Rice University, Houston, TX, USA

PROBLEM STATEMENT

Heart failure (HF) is one of the leading causes of death, affecting nearly 6 million people in the United States (US). In 2012, HF contributed to more than 10% of the total health expenditure costs for cardiovascular diseases. These costs are projected to increase by 127% to \$69.8 billion by 2030 [1]. Other than significantly increasing the economic burden, HF greatly reduces patients' mobility and quality of life.

Heart transplantation is the optimal surgical therapy for end stage HF; however, this therapeutic option is progressively limited. Due to the limited availability of donor hearts, left ventricular assist devices (LVADs) have emerged as a primary treatment modality for HF as both bridge-to-transplantation and destination therapy. After the discontinuation of HeartMate II (Abbott labs) and HVAD (Medtronic), Abbott's HeartMate III remains as the only implantable, FDA approved LVAD on the market.

Despite the clinical success, LVAD therapy is known to have adverse effects that negatively impact patient outcomes and may result in fatalities. After LVAD implantation, the stroke rates fall anywhere between 11-47% whereas the incidence of gastrointestinal (GI) bleeding is reported to be around 11-40% [2]. LVADs are driven by percutaneous drivelines, which can cause infection and lead to rehospitalization and surgical intervention. Moreover, the inflow cannula is susceptible to thrombus formation, embolization of thrombus puts the patient at a high risk of ischemic stroke. In case of a thrombosis related LVAD failure, the patient might need undergo a second open heart surgery to replace the implanted device.

There is an urgent unmet need for a long-term, implantable LVAD to cater to the widening gap between the donors and the patients, along with the growing number of patients with end stage HF. To address this need of a reliable LVAD therapy that effectively causes no adverse events post implant, we propose the SLIC-VAD, a centrifugal pump designed using a synergistic amalgamation of material science, fluid

dynamics, wireless energy transfer, magnetic levitation, and hemodynamics.

TECHNOLOGY/SOLUTION DESCRIPTION

The SLIC-VAD is a centrifugal LVAD specifically designed to minimize the post implant complications using our team's expertise. Most of the LVADs aim to utilize one or more of fluid dynamics, magnetic levitation, hemodynamics, material science, wireless energy transfer in their design; SLIC-VAD on the other hand, is designed to be performant on all these fronts (Figure 1Figure 1).

Figure 1 SLIC-VAD with a stented inlet, wireless energy transfer and super hydrophilic (SLIC) coating

The hydrodynamic components of the SLIC-VAD are optimized to offer superior fluid dynamics performance under complex inflow conditions using a state-of-the-art machine learning algorithm. It will include a stented inlet, motivated by the transcatheter aortic valve technology, to improve the inflow hemodynamics and reduce the risk of thrombosis. Furthermore, we plan to incorporate flexible rotors which will open the possibility of low-cost manufacturing.

The blood contacting regions of the SLIC-VAD will be coated with a novel slippery and hydrophilic coating with ice-like hydration layers. This innovative coating would dramatically hinder the subsequent steps of blood coagulation cascade by imparting substantial lateral forces and dislodge adsorbed blood proteins on a molecular scale.

SLIC-VAD will incorporate magnetically levitated bearings to eliminate the contact bearings and avoid blood stasis in the narrow gaps of the device. SLIC-VAD's driveline will be replaced with wireless energy and communication transfer to dramatically reduce the infection caused by the percutaneous drivelines. The wireless communication will enable the clinicians to remotely monitor the device operation and provide real-time management of any complications that may arise.

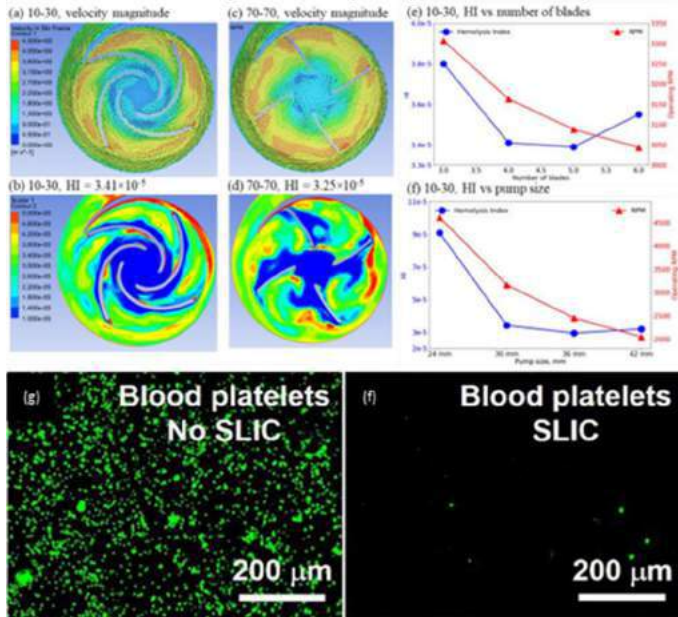

Figure 2 (a & f) Preliminary Results using a validated CFD Model. (g-f) Blood platelets adhesion without and with SLIC coating
SLIC-VAD's initial experimental and CFD analysis have shown its ability to achieve a pressure of 90 mmHg at 5 L/min and 3000 RPM. Figure 2 (a–d) shows the results from our initial design optimization, where in flow field and the hemolysis index (HI) of two rotor designs are compared. We also investigated the effects of the pump size and the number of blades on HI Figure 2 (e–f). It is observed a flow – targeted optimization is insufficient since better flow may not correlate with less blood damage. The fluorescence microscopy images indicate virtually negligible platelet adhesion with our novel SLIC coating (Figure 2(g–f)).

BUSINESS CASE

The global LVAD market is projected to grow significantly at a CAGR of 17.6% from 2021-2028, with a valuation of \$1.8 billion in 2020.

SLIC-VAD is designed to be a destination and bridge-to-transplantation therapy for end-stage HF patients, our primary end users. We also consider family members, caregivers, and healthcare professionals to be our end users. Insurance companies are expected to be the main payer, in addition to government programs covering some or all of the device's cost.

Given the high impact of our work, we plan to incorporate a targeted marketing approach to touch as many patients' lives as we can. We aim to establish a relationship with key stakeholders/decision makers of the LVAD therapy, namely, cardiac surgeons, cardiologists and medical centers specializing in heart transplantation.

SLIC-VAD is a Class III device and will follow the FDA premarket approval (PMA) pathway. The preclinical studies will include 30 day 15 GLP chronic ovine studies post implantation and *ex vivo* hemocompatibility tests. Upon successful completion of the initial

prototype evaluation, we will apply for an Investigational Device Exemption from the FDA to gather early clinical data that will be used for the PMA application.

The clinical trials evaluating the HeartMate III (NCT02224755) utilized 1000 patients in a randomized parallel assignment. We anticipate having a similar study protocol and number of patient volunteers for our SLIC-VAD's randomized trials where HeartMate III would serve as a clinical control. Key performance indicators will include the rate of survival six months after implantation, without stroke or device malfunction. Our work is currently supported by a government funding, we plan on applying for venture capitalist funding and business targeted NIH grants in future.

Bringing a novel LVAD to market successfully is a task that requires us to overcome a multitude of hurdles. Some of the ones we anticipate are related to cost, physician adoption and patient selection. Our key manufacturing concerns include ensuring precise manufacturing and usage of high-quality materials, establishing a robust tracking system for accountability, and implementing a sterilization process to mitigate infection risks.

In 2019, a new high annual volume of 3,198 LVADs implants was recorded in the registry history [3]. We estimate to achieve the design freeze and FDA approval by 2026 and 2032, respectively (Figure 3). With the rapidly increasing HF patient population, we plan to have 20% market penetration by 2035 and generating a cumulative revenue of \$2 billion in the US.

Figure 3 SLIC-VAD's financial projections

Currently the LVAD market is dominated by the companies listed below (Table 1), however, these companies fail to address the comprehensive market needs. SLIC-VAD's unique synergistic approach towards tackling the market needs is what distinguishes it from the rest of its competitors.

I-KINCOR: REVOLUTIONALIZING PEDIATRIC DUCT – DEPENDENT SURGERIES.

Luis René Mata Quiñonez (1), Shweta Karnik (1), Srujana S. Joshi (1), Leon Cheng (1), Holly Bauser-Heaton, MD, PhD(1, 2), Lakshmi Prasad Dasi, PhD(1)

(1) Wallace H Coulter Department of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, GA, USA
(2) Children's Healthcare of Atlanta, Atlanta, GA, USA

PROBLEM STATEMENT

Congenital heart disease (CHD) is present in 17.9 of every 1000 newborns representing one of the leading causes of neonate mortality [1]. The prevalence of patients with duct-dependent circulation, wherein the ductus arteriosus (DA) is the only pathway for the pulmonary blood supply, is around 8 out of 10,000 births [2][3].

For subsequent surgical repair, the palliative treatment for these patients is maintaining the patency of the DA (PDA). Traditionally, the modified Blalock–Taussig–Thomas shunt (BTTS), which is a surgical connection between the aorta and the pulmonary artery is used. However, it has a high infant mortality rate of about 20% [4]. Previous solutions include formalin infiltration, balloon angioplasty, and thermal balloon dilation, but are associated with complications like variability in the length of duct patency response [5], cardiac and pulmonary artery perforation [6] and aneurysmal dilation and stenosis [7] respectively, making them unsuitable for use.

To overcome these limitations, a minimally invasive procedure of PDA stenting has been used. It involves the percutaneous deployment of coronary stent in the DA, and allows for higher stent patency length, lower operative risks, shorter hospital stay and lower mortality rate than BTTS procedure with a risk ratio of 0.58 [4]. However, there are associated complications to PDA stenting. Meta-analysis shows higher reintervention rates in PDA stent groups when compared to surgical shunt groups with a risk ratio of 1.63 [4]. Furthermore, stenting procedures may also cause pulmonary artery isolation, stent stenosis, thrombosis and fracture [4][8].

One of the most important factors for the successful stenting of the PDA is pre-procedural planning; in which main considerations are: determining the correct stent dimensions, predicting the interaction of the stent with patient anatomy, and ultimately deciding patient candidacy. Hence, there is an unmet need for a surgical planning platform for this procedure.

TECHNOLOGY/SOLUTION DESCRIPTION

We are committed to enhance the pre-procedural planning of ductal stenting, which currently involves visualizing the patent DA and adjacent structures from CT scans to identify the required stent dimensions (length and diameter) and the most optimal surgical access. However, this process does not take into account the complex and tortuous DA anatomy, and unexpected outcomes like partial covering of the duct length, stent malapposition, migration and thrombosis, or even pulmonary isolation might occur [4][8].

Figure 1. Benefits of i-KinCor.

i-KinCor is a 3D computational modeling framework that will serve as a virtual surgical planning tool for physicians for ductal stenting, and to predict procedural outcomes and complications.

The computational framework will allow simulation of transcatheter stent deployment into patient-specific anatomies and analyze the structural interaction between the stent and native DA. We are pioneers in the application of computational simulations for pre-procedural planning of ductal stenting. Figure 1 lists the benefits of our solution.

Figure 2 presents an outline of the steps of the proposed solution. Pre-procedural chest CT/MRI scans will be analyzed, segmented and discretized for simulations using commercially available software. This process is intended to identify the stent dimensions and the most adequate access to the DA. The selected stent, balloon and guide wires will be collected from our database of CAD models. Finite element analysis (FEA) will be performed on the patient-specific 3D model of DA to simulate transcatheter deployment of the stent. Key anatomic features of the DA and deployment attributes that lead to favorable stenting outcomes will be identified. These data will help the interventional cardiologist to decide if the patient is suited for the procedure and to be aware, in advance, of potential complications that might occur. This innovative approach will revolutionize the pre-procedural planning for ductal stenting resulting into reduced procedure risk and time, selection criteria for patient candidacy, longer duration of palliation and improved communication between the interventional and surgical teams for short and long-term medical decisions. This will also pave the way for a standard solution by homogenizing the best clinical practices regarding the device selection and pre-procedural planning across medical centers.

The pathway towards the commercialization of this technology requires the replication of the computational methods in large populations of patients to contemplate the inherent variability of DA geometries and tissue properties among patients. Applying this iterative process will permit us to refine the solution.

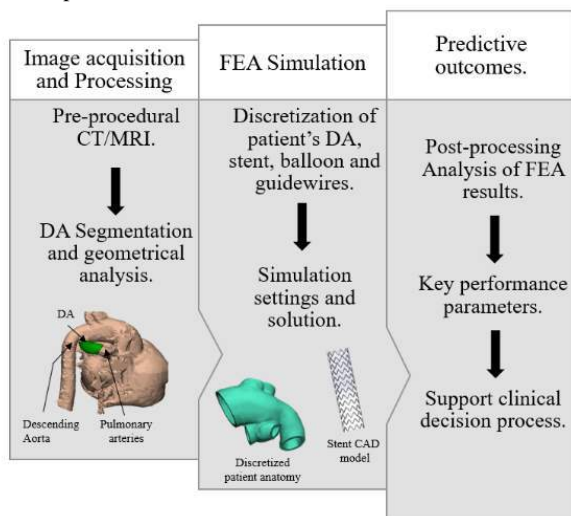

Figure 2. Workflow Schematic of i-KinCor.

BUSINESS CASE

With the increasing prevalence of CHDs in the United States, the pediatric population born with duct-dependent circulation is growing [1]. Due to the complicated patient anatomies and unforeseeable complications, the clinicians have to decide the best course of treatment within limited time frame which may lead to reinterventions and rehospitalizations in future. Currently, there is no available technology for surgical planning of ductal stenting and predicting the post-procedural outcomes. i-KinCor is a niche product which provides a personalized virtual platform to bridge this market gap.

Within the stakeholders of i-KinCor, the primary end users will be the interventional cardiologists, cardiothoracic surgeons to decide the best treatment option. Our technology could be further extended as a surgical training platform for medical residents, thereby increasing the

impact on patient outcomes as well as expanding our market. We expect the pediatric centers specializing in CHDs and the insurance companies to be our main payers.

We aim to establish a relationship with key decision makers as our marketing strategy. We will conduct demonstrations using case studies proving the efficiency of i-KinCor across different hospitals and medical centers. Additionally, we will incorporate digital marketing elements including engagement via website, professional platforms and social media and present at clinical conferences.

To commercialize our technology, we will need a facility with robust IT infrastructure including workstations, servers, access to supercomputers and software licenses. Our team will consist of highly skilled engineers and marketing and sales, finance, and IT departments. We plan on applying for venture capitalist funding and business targeted NIH SBIR and STTR grants for funding our future work.

i-KinCor is a Class II medical device and will follow the FDA 510k pathway. We will use FEops HEARTguide as our predicate device since we use a virtual surgical planning platform. We plan on achieving design freeze and 510k approval by 2025 and 2027, respectively (Figure 3). We estimate to have 20% market penetration by 2033: generating about \$65 million cumulative revenue in the US.

Some of the anticipated risks are the technology adoption, quality of patient scans, and meeting service time. The customers would need to institutionalize the usage of this technology to properly exploit the benefit of an improved planning process.

Figure 3. i-KinCor's financial projections.

PITCH COMPETITION: SOLVING THE PROBLEM OF BICYCLE HELMET FIT

William J. Makowski (1), Thomas L. Martin (2), William A. Schaudt (3)

- (1) Graduate School, Virginia Tech, Blacksburg, VA, USA
(2) Department of Electrical and Computer Engineering, Virginia Tech, Blacksburg, VA, USA
(3) Virginia Tech Transportation Institute, Virginia Tech, Blacksburg, VA, USA

PROBLEM STATEMENT

Evidence shows that the use of bicycle helmets significantly reduces the risk of head injury during a crash [1]. Sadly, the use of improperly fitting helmets and its relationship to greater risk of injury has been continually identified over the last twenty years [2], [3], [4], [5]. Common problems that relate to poor helmet fit are wearing helmets that are too wide, helmet's being too high on the forehead or helmets not being adjusted properly [3], [4], [5].

In an effort to learn about additional problems relating to helmets, I conducted primary qualitative research, through Customer Discovery (CD). For CD, I conducted 166 Problem Interviews, with pro and semipro athletes, masters riders, downhill riders, various demographics of parents and bike industry personnel. Then, I conducted another 118 interviews through the NSF I-Corps program with pediatricians, coordinators at Safe Kids, the primary volunteer for the Bicycle Helmet Safety Institute, bicycle helmet testing lab personnel, as well as researchers at various universities regarding bicycle helmet fit. The CD interviews focused on three types of risk, product risk (problem), market risk (existing alternatives) and customer risk (customer segment) [6].

During the Problem Interviews, I spoke with a group of potential early adopters who I refer to as US Bike Parents, meaning parents who bought a bike from a US kids specific bike company. I conducted thirty one Problem Interviews with US Bike Parents. I am highlighting US Bike Parents as they appear to be a viable group of early adopters, for a solution that will be described in the Technology/Solution Description section of this abstract.

Specific to US Bike Parents, for product risk, I found that eight of the parents experienced a Severe Problem of helmet fit for their child. A Severe Problem of helmet fit means a difficulty so severe, they went to multiple bike shops, returned multiple helmets and/or disregarded a buying option because "it won't work," with severe amounts of frustration expressed. This finding would lead me to believe that helmet

fit was a concern for this demographic of parents and that they are potential early adopters of a solution that would solve that problem.

TECHNOLOGY/SOLUTION DESCRIPTION

Bicycle helmets can reduce peak linear acceleration (PLA), as well as other injurious forces to the brain [7]. Historically, expanded polystyrene (EPS) has been the most commonly used material for bicycle helmets to reduce PLA to the brain in the event of a crash [8]. Due to the material's ability to reduce PLA, it is still commonly used [8], [9].

In 2014, Smith Helmets introduced the Overtake. The Overtake's helmet liner was a combination of EPS and a material called Koroyd, an extruded thermoplastic structure [10], [11]. Bontrager released the next iteration of structure-based helmets with the introduction of Wavecel. Wavecel helmets are a combination of both EPS and Wavecel, a stacked origami thermoplastic structure [12], [13]. Wavecel is a more complex structure than Koroyd and reduces both PLA and rotational acceleration [13]. In 2021, Hexr's additively manufactured hexagonal helmet, is the most recent iteration of helmets with thermoplastic structures [14]. Despite the developments in both design and manufacturing technologies, the safest commercially available bicycle helmets as of February 10th, 2023 are entirely EPS based helmets according to Virginia Tech's Helmet Ratings [15]. However, the one exception is the Bontrager Specter Wavecel helmet, just making the top 30 [15].

The goal of designing additively manufactured structures is not necessarily to produce a "safer" helmet, but rather to use additive manufacturing to create a better fitting helmet, which can be difficult with traditional injection molded foam helmets. To create such a helmet, the development process includes: 1. Designing for fit, which incorporates creating a digital surface; 2. Designing for protection, which incorporates designing a mesostructure; and finally, 3. Developing a feedback loop for evaluating mesostructure performance.

The technologies include scanning, surface generation, mesostructure design, finite element analysis (FEA) and production, resulting in new methods of product development for personal protective equipment.

For initial product development I have focused on step 2. Designing for protection. The basis for the mesostructure design process was split into two groups: Group 1: Recreating structures found in previous research and Group 2: Recreating structures currently on the market. Figure 1 shows three structures I designed in the latticing software nTopology, based on the Group 1 and Group 2 design strategies.

Figure 1: a) Group 1 using a Weaire-Phelan unit type, b) Group 1 using a Kelvin unit type, c) Group 2 using a Hexagonal Honeycomb unit type

For step 2. Designing for protection, I designed and printed several different test coupons, which have gone through four phases of impact testing. The parameters for impact testing were based on the Consumer Product Safety Commission (CPSC) standard for bicycle helmets. The parameters included using the flat anvil, headform A and ambient conditioning [16]. When impact testing, the only difference from the standard was we started with an impact velocity of 3.1m/s, and increased the velocity with each subsequent phase of testing. Recently, we tested the parts at an impact velocity of 6.2m/s, which is the highest velocity impact attenuation test for the CPSC standard [16]. In the standard, during an impact, the parts cannot experience a peak linear acceleration (PLA) above 300g [16]. During testing at 6.2m/s, one of the parts experienced a PLA of 211g, and another part experienced a PLA of 256g. We plan to move to conditioned testing soon.

Additional product development will focus on 1. Designing for fit and 3. Developing a feedback loop for evaluating mesostructure performance. When designing for fit, in order to collect cranial measurements two techniques can be leveraged, 3D scanning and using a photo based software that measures and interprets images, such as photogrammetry. When developing a feedback loop for evaluating mesostructure performance homogenization and impact testing should help determine what geometries are best suited for reducing PLA.

BUSINESS CASE

As previously mentioned in the Problem Statement section, from the Customer Discovery Interviews, US Bike Parents appear to be a viable group of potential early adopters, where the parents are the customers and the children are the end users. Based on the interviews, the value proposition is, parents who want a high quality riding experience for their child will buy a custom fit helmet to eliminate the twenty minutes per week they spend adjusting their child's helmet.

Current revenue models include direct sales through a website, channel sales through product reviewers and US children's specific bicycle companies, as well as retailer sales through bicycle retailers. It is anticipated that orders will be fulfilled through drop shipping, as each helmet is custom made. Based on Customer Discovery, specifically the Solution Interviews, we developed value and cost based pricing models, where we anticipate pricing will be \$150 per helmet.

For bicycle helmets, the primary regulatory body is the CPSC. As directed by their standard, the helmets must pass the peripheral vision test, positional stability test, dynamic strength of retention system test and impact attenuation test [16]. In regards to production, additive

manufacturing has advantages for producing complex lattice structures and customized solutions, when compared to injection molding [17]. However, as we have impact tested parts, the parts have performed inconsistently which is concerning. So we are currently navigating production strategies.

As stated in section Technology/Solution Description, additional product development will include 1. Designing for fit, which involves: developing and improving the user experience when collecting scan data and; optimizing the digital workflow from the collection of scan data to the final print. In addition, product development will include 3. Developing a feedback loop for evaluating mesostructure performance, which involves a combination of static FEA, dynamic FEA and impact testing to achieve lower PLAs and reduce the part weight. Other commercialization activities include offering a pilot program aimed at potential early adopters, as well as establishing a strategy for localized and automated production.

Other commercialization activities include, we have submitted a provisional patent application, through our technology transfer offices. Through CD, another market we identified as a viable group of early adopters are riders who have purchased a high-end or custom built bike. Finally, we have identified cranial helmets and military helmets as additional product categories for custom fit applications.

ACKNOWLEDGEMENTS

First of all we would like to thank Virginia Tech's Institute of Creativity, Arts and Technology for funding initial product development through a SEAD Grant. We thank Dominic LoPinto and Dr. Emily Kieffer for their feedback and expertise in the design process. We are thankful to Dr. Christopher Williams and Bemnet Molla at Virginia Tech's DREAMS Lab for their assistance with printing parts. We also thank Larry Rose for his help during the initial stages of testing. Finally, we would like to thank the Dr. Mark Begonia and Ethan Harris at the Virginia Tech Helmet Lab for their assistance and expertise during impact testing.

PITCH COMPETITION: FACILIFLOW: AN IMPLANTABLE DEVICE TO PREVENT THE ONSET OF BREAST CANCER-RELATED LYMPHEDEMA

A. Swarup (1), A. Vella (1), K. Rowley (2), J. Frattolin (1), J. Moore Jr. (1)

(1) Department of Bioengineering, Imperial College, London, UK
(2) Lympha Motus Ltd, London, UK

PROBLEM STATEMENT

Approximately one in seven women will develop breast cancer. In 2021, there were some 282,000 new breast cancer diagnoses in the US. The removal of lymph nodes and severing of lymphatic vessels during breast cancer surgery disrupts lymph flow and impairs normal fluid removal from the arm. This leads to debilitating and incurable swelling of the arm (breast cancer-related lymphedema; BCRL) in approximately 21% of breast cancer patients [1]. This translates to 59,220 new cases of BCRL each year, with a prevalence of 760,000.

There is no cure for BCRL, forcing patients to live with a constant reminder of their cancer as well as long term problems with pain, immune dysfunction and recurrent infections. With five-year survival rates for breast cancer now exceeding 90% [2], the incremental costs for BCRL care for the US are estimated at \$6B/year.

Despite the development of at least two surgical procedures, three pharmaceutical approaches and two devices aimed at treating BCRL, it is still considered incurable in the general setting. This is in part because the surgical procedures (which show mixed success rates) require specialized microsurgical skills, but also because once the swollen arm tissue has fibrosed, those adaptations are likely irreversible.

Current surgical BCRL strategies are predominantly aimed at treatment. Lymphovenous Anastomosis (LVA) involves connecting lymphatic vessels to veins, both of which are typically <1mm diameter thus requiring microsurgery. Autologous Lymph Node Transfer (ALNT) requires a lymph node plus surrounding tissue to be harvested from another part of the body and moving it to the axilla. Surgeons must connect the node's blood supply, also requiring microsurgery. LVA and ALNT show mixed success rates, often based on short follow up periods (<3 years). These procedures are generally not covered by insurance or national health programs.

Pharmaceutical approaches to treatment include Lymfactivin, a gene therapy version of vascular endothelial growth factor C (VEGF-C),

widely acknowledged as the most effective compound to promote lymphatic vessel growth [3,4]. Lymfactivin is infused into harvested tissue as an adjuvant to ALNT. Clinical trials showed no benefit, perhaps due to the immature form of VEGF-C produced. CellTaxis is in clinical trials with Acebilustat, targeted at treating BCRL.

The only device in clinical trials is Fibralign's BioBridge (a collagen-based surgical mesh) which aims to treat and prevent BCRL by wicking fluid out of the arm and guiding lymphatic vessel growth. BioBridge is deployed via subcutaneous injections, requiring additional training, surgery and special equipment.

In the absence of widely available, reliable means of prevention or treatment, BCRL patients at best can only manage their disease through complete decongestive therapy (CDT), comprising compression bandaging, specialized massage, skincare, and exercise. CDT requires fastidious patient compliance, and generally will at best only limit further arm swelling. Over 80% of BCRL patients take health-related leave from work, and many suffer social isolation and depression [5,6]. Physical Therapists who help patients manage their BCRL have stated that prevention should be a priority of research and development efforts [7].

We aim to develop an effective, economical means of BCRL prevention that can be easily integrated into the current standard care pathway without additional expertise or equipment.

TECHNOLOGY/SOLUTION DESCRIPTION

Our implantable medical device seeks to prevent, rather than cure, BCRL. FaciliFlow (Figure 1) would be easily implanted by any surgeon at the time of the original cancer surgery to encourage lymphatic vessel regrowth and lymph flow normalization. It is made from materials well-known to the FDA and attached to surrounding tissue with 2-4 sutures in minutes.

Its patented design [8] features multiple parallel channels to minimize resistance to fluid flow, imitating the multiple parallel pathways formed by afferent lymphatic vessels as they approach lymph nodes. It also releases VEGF-C in a controlled manner over 90 days. Fluid flow also increases VEGF-C effectiveness [9]. Preliminary data from a study in rats indicated a success rate of 55% in FaciliFlow's ability to regrow new lymphatic vessels, comparable to the success rate of ALNT + injected VEGF-C protein [10].

FaciliFlow is injection molded from medical-grade silicone, with encapsulated slow-release of fully functional VEGF-C, and a water-soluble excipient that facilitates VEGF-C release. We aim to achieve a therapeutic concentration of 100ng/mL [11] at a distance of 2 cm from the implant for 90 days, providing a consistent, locally-delivered, functional dose following lymphatic injury to elicit healing. Local release should minimize the risk of VEGF-C reaching therapeutic concentrations in tumor locations. We will be monitoring blood VEGF-C levels in preclinical and clinical trials as verification.

FaciliFlow's design is being fully verified under an ISO13485-compliant Quality Management System. Next steps are large animal trials and preparation for clinical trials.

BUSINESS CASE

The total addressable market for BCRL prevention is all breast cancer patients undergoing surgery; approximately 90% of breast cancer patients in the USA, or 253,800 patients. At an anticipated price of \$1000 (based on other medical devices of similar complexity), the USA market is approximately \$250M per year. We estimate the EU market to be of similar size to the USA market.

The device will be attractive to insurance and provider-associated payers who would also be responsible for the care of BCRL patients, costing \$7450 per year for each patient in the first two years (and slightly lesser amounts thereafter, lifelong for each patient).

The primary challenge to this device will be uptake by surgical oncologists. Surgeons may fail to appreciate the extent of the condition because patients must be followed for at least three years to confirm BCRL. The development of node-sparing procedures such as Sentinel Lymph Node Biopsy may lead to the assumption that the condition is declining but we have performed an extensive meta analysis of BCRL incidence (to be published soon) showing that the incidence rate remains at around 20%, the same as Disipio noted in 2013 [1]. We have recruited surgical oncologists and patient advocates to our advisory board and will continue to work with KOLs as we prepare for regulatory approval and reimbursement.

Remaining hurdles to market include preclinical and clinical trials, production of clinical grade VEGF-C, regulatory approval and reimbursement. Our current funding is being used to produce implants under a regulatory-compliant QMS. We are seeking funding for trials. We have received quotes for producing clinical grade VEGF-C (which is already available as research grade).

We are in discussions with regulatory bodies in the UK and US. The FDA will likely consider this a Class III combination product. Other permanent silicone implants that release drugs have been in use since the 1980s. An important determinant of the regulatory pathway will be the primary outcome. We believe that evidence of lymphatic vessel reconnection (which can be done minimally invasively with near-infrared imaging), which should occur within six months, should suffice as a primary outcome. If regulatory bodies insist on BCRL development as a primary outcome, this will greatly increase the costs of the clinical trial.

Figure 1: Illustration of lymph node removal during breast cancer surgery, followed by FaciliFlow implantation. Its flow channels are oriented in the original direction of flow and VEGF-C is released locally to promote lymphatic vessel reconnection.

The cost of manufacturing is estimated at <\$4 per device which provides a margin of >95%. The majority of the costs associated with the procedure of implantation will be borne by the underlying procedure rather than needing a separate surgical procedure, given that implantation is performed at the time of lymph node removal.

The breast cancer therapy market is growing at a CAGR of 8.3% [12], thus the US market for FaciliFlow has the potential to grow to \$370M in five years. In addition to the strong market pull for BCRL prevention, there is potential that the device would be of use in other lymphoedema such as cervical, womb, prostate, bladder, and head and neck cancers.

Route to Market and Dissemination: The route to market will likely imitate that for implantable medical devices employing a similar technology or therapeutic mode of action. Commercial exploitation will likely involve acquisition by an established MedTech company with pre-existing distribution networks.

PROBLEM STATEMENT

Musculoskeletal trauma presents a major medical and financial burden, with long bone fractures accounting for 10% of all nonfatal injuries in the US [1]. Non-union, the failure to heal, occurs in approximately 5-10% of all fractures. Non-unions are gravely concerning, as analyses of direct healthcare costs associated with non-unions have been reported to be in the range of \$20,500-\$53,500 per incident [2]. These estimates do not include the indirect costs associated with non-unions such as lost wages and productivity, which are thought to represent 67-92.3% of total costs [3]. It has been reported that 72% of patients with non-unions continue to experience pain, and 41% have not returned to work 12 months post-fracture [4].

To avoid the tremendous socioeconomical costs likely to be incurred, the ability to recognize potential non-unions early in the post-injury course is of utmost importance. It has been estimated that the deleterious effects and resultant costs can be reduced by approximately 50% if fractures at risk of non-union can be addressed during the acute four-week postoperative time period [5]. Therapies to improve healing, including osteobiologics, rehabilitation, and electromagnetic stimulation, are most effective during this early healing time period. However, the prognosis of improper bony healing remains an obstacle to the early and effective implementation of these treatments. The current gold standard for monitoring healing is via biplanar radiographs. Regrettably, radiographic evidence is unhelpful during the acute healing phase due to the delayed timeframe of visible mineralization in the fracture callus. The current standard of care results in the determination of non-union ranging from 3-9 months. Thus, there remains a profound gap in the market necessitating improved early and quantitative techniques to monitor and predict the course of fracture healing.

Due to formation and remodeling of the soft fracture callus, which occurs prior to radiographically visible mineralization, the quantification of fracture site compliance has shown the ability to accurately predict healing outcomes prior to radiographic diagnosis [6-

7]. However, there are currently no clinically available solutions on the market for monitoring fracture site compliance. Therefore, we have developed a technology that leverages the temporal fracture compliance phenomenon to monitor acute healing and provide an early prediction of non-union.

TECHNOLOGY/SOLUTION DESCRIPTION

We have developed a non-invasive system that utilizes an external radio-frequency antenna to electromagnetically couple to a fractured limb to measure deformations at the fracture site under applied loading ("direct electromagnetic coupling", DEC). The DEC technique works by measuring the resonant frequency shift between the antenna and bone/hardware, which can be calibrated to determine precise deflections of the fracture from which stiffness and/or compliance of the fracture site can be calculated. Our group has (1) established the electromagnetic foundations of the DEC technique via experiments and computational models [8], (2) experimentally demonstrated the efficacy of this technique to monitor changes in stiffness using *in vitro* fracture healing models [9], and (3) validated DEC for distinguishing between normal and non-union healing in a large animal fracture model [10].

Other similar mechanical-monitoring technologies currently in development rely on modifying fracture stabilization implants by adding an implanted sensor and associated circuitry. In contrast, our DEC technology is completely external, which provides two main advantages: (1) It can be applied universally to fractures stabilized with any existing implant(s) including plates and intramedullary nails or to fractures stabilized non-operatively, such as with functional bracing. (2) Since DEC is non-invasive and the radio sensing technology is harmless, it presents no significant risk to the patient, enabling an easier clinical implementation and relatively few regulatory hurdles.

Additionally, we have developed the DEC technology into a telemetric device that can be easily used by the fracture patient in their home, and the data are transmitted for analysis. This telemedicine

approach enables daily data collection, which is crucial for determining the temporal trends in fracture compliance during the acute healing timeframe without requiring additional clinical office visits. We have implemented this telemetric DEC system in a pilot clinical study of tibial fracture patients (Fig. 1). The results of this study have established the feasibility of the self-measurement telemetric approach. One patient out of the eight completed to date experienced a non-union and required a revision surgery 6 months following the original surgery. The temporal compliance data show promise for distinguishing between normal and non-union healing pathways in the early timeframe (Fig. 1).

The DEC technology represents a paradigm shift in the way fracture healing can be evaluated. Therefore, there is a high burden of proof for the clinical community to adopt this method in their practice. In order to advance the technology to the market, we must demonstrate efficacy in predicting non-union by using the device in a much larger patient population and establishing a predictive algorithm based on the collected data. Towards this end, we have begun planning for a large multi-site clinical study of the telemetric tibial DEC system. Additionally, we must show that the collected data are useful for improving patient care by using the predictive algorithm to prescribe treatment interventions, such as the injection of osteobiologics, to improve healing in patients determined to have a high probability of non-union. Finally, to improve the appeal of this technology as a marketable product, we plan to demonstrate efficacy in additional fracture locations. Towards this goal, we are developing humeral and femoral DEC systems and have shown efficacy in cadaveric studies of proximal and diaphyseal humeral fractures.

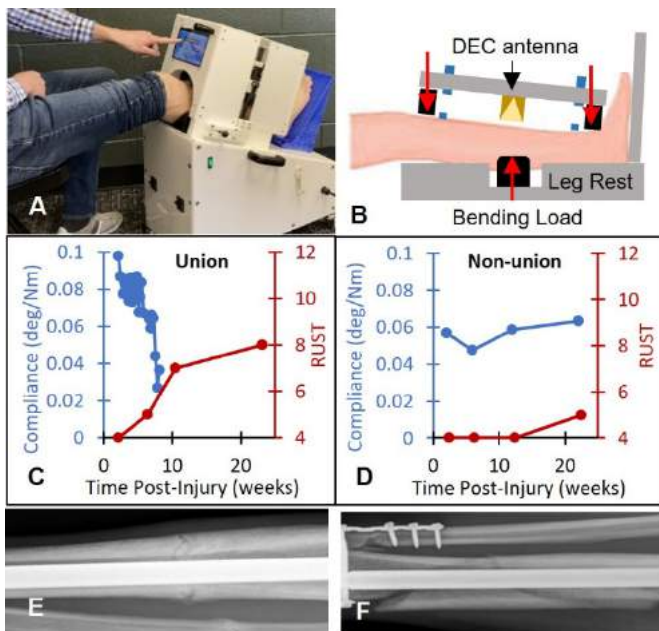

Figure 1: (A) The telemetric tibial DEC device is automated for daily self-use by the patient. (B) The device applies 3-point bending and measures deflection via a calibrated DEC antenna. Example bending compliance data (blue) and corresponding radiographs are shown for patients with (C, E) union and (D, F) non-union healing outcomes. Semiquantitative radiographic union score for tibia (RUST) data are also shown (red), demonstrating for the union patient that large changes in compliance were seen prior to radiographically visible bridging (RUST < 9).

BUSINESS CASE

Our product is an analytic service. Our business would provide the measurement devices to the fracture patients' homes, analyze the data as it is acquired, and provide weekly reports to the attending doctor. The end user is the fracture patient, and human factors studies will ensure device usability and safety. The primary customer and key decision maker for purchasing this product will be orthopaedic trauma surgeons. We plan to collect a robust set of clinical data on the efficacy of our technology in order to use a clinical evidence-based approach to sell to the customers. Since we have a novel product in a niche market, we will utilize a direct sales approach. In the United States, there are approximately 5,000 orthopaedic trauma surgeons in 800 trauma clinics treating approximately 1.5 million long bone fractures annually, 100,000 of which result in non-union. We estimate that there is a \$750 million annual market for identifying and treating problematic fractures, which represents 50% of the direct medical costs of non-union.

The feasibility of this business model will require the primary medical payors (e.g. insurance companies, Medicare, Medicaid, VA) to provide reimbursement. Accomplishing this will necessitate strong clinical evidence supporting the efficacy the technology to predict non-union and show that the overall healthcare savings from treating problematic fractures early outweighs the cost of using our product.

Prior to marketing our product, we will need to obtain regulatory approval. A clinical trial will be conducted under Good Clinical Practice (GCP) regulations, and an investigational device exemption (IDE) will be applied for through the FDA. There will be an administrative burden associated with this. However, since our technology presents no significant risk, the IDE should not be technically challenging to acquire. For FDA marketing approval, our technology would qualify as a Class I device and would be appropriate for a De Novo classification as a novel medical device. The European Union Medical Device Regulation classification is Class Im (a low-risk device with a measuring feature) and will require involvement of a notified body to receive the CE mark. For device fabrication, we will partner with a manufacturer operating under Good Manufacturing Practice (GMP) regulations.

Although we have collected strong evidence supporting the efficacy of the DEC, there remains risk associated with the additional clinical studies needed to advance the technology. There is a risk that the method may not produce a non-union prediction with a high enough confidence to make it valuable. However, we are investigating methods to combine the mechanical evidence the DEC provides with radiographic evidence and healing-related biomarkers to improve predictive analytics. Ultimately, we expect that mechanical measurements using our technology will provide a critical contribution to monitoring healing in the future of fracture care.

PITCH COMPETITION: TACKLING ANTIMALARIAL DRUG RESISTANCE IN AFRICA USING NOVEL DRUG REPURPOSING AND NANOTECHNOLOGY STRATEGIES.

Samuel W. Uzundu, Petra O. Nnamani, Anthony A. Attama.

Department of Pharmaceutics, University of Nigeria, Nsukka, Enugu State, Nigeria.

PROBLEM STATEMENT

Malaria is a global public health concern that has ravaged particularly Sub-Saharan Africa which accounts for over 90% of the global malaria burden [1]. More worrisome is the fact that Nigeria has consistently topped the chart of Countries with the highest malaria burden in the last five years [1]. Since malaria was first discovered, there has been a lot of therapeutic interventions which led to the introduction and usage of the following classes of antimalarial drugs-4-aminoquinolines eg Chloroquine etc, 8-aminoquinolines eg Primaquine etc, Aminoalcohols eg Mefloquine, Antifolates eg Sulphadoxine etc, Hydroxynaphthoquinones eg atovaquone etc Endoperoxides eg Artemether,

These classes of antimalarial drugs with the exception of the endoperoxides have been taken out by resistance from the malaria parasite; the endoperoxides are currently being threatened by resistance from the malaria parasite [2]. The above drug classes were initially active against the malaria parasite which eventually mustered resistance against them. As a result of this resistance by the malaria parasite, these drugs are no longer in clinical use; a good example is Chloroquine which was very effective against *P.falciparum* until resistance set in. Chloroquine is no longer used in treating malaria.

Resistance is the common denominator in the retirement of these drugs from clinical use. This resistance challenge is what my novel formulation addresses.

TECHNOLOGY/SOLUTION DESCRIPTION

This invention aims at tackling the challenge of antimalarial drug resistance (ADR) through the application of a novel drug combination and Nanotechnology. Chloroquine is not indicated for the treatment of Chloroquine-resistant *P.falciparum* malaria due to resistance by the malaria parasite.

To solve this problem of resistance, Chloroquine was combined with WOG19 (physical combination in a lipid matrix) and formulated into solid lipid nanoparticles and tested for clinical efficacy against the malaria parasite. This novel combination of chloroquine and WOG19 gave the highest reduction in parasitaemia in the Anka strain (resistant strain) of *P.berghei*-infected mice in the curative model (please see Figure 1) and highest average parasitaemia suppression (please see Table 1). THE COMBINATION OF CHLOROQUINE WITH WOG19 EXTENDS THE USE OF CHLOROQUINE TO THE TREATMENT (CURATIVE AND SUPPRESSIVE) OF CHLOROQUINE-RESISTANT MALARIA-WHICH BEFORE NOW WAS NOT POSSIBLE CURATIVELY! DUE TO RESISTANCE BY THE MALARIA PARASITE.

This formulation needs to be optimized in terms of targeted delivery, delivery system, safety and encapsulation efficiency to be market-ready.

BUSINESS CASE

My Antimalarial nanoformulation is novel, cheap, smart, potentially resistance-proof and very effective against resistant malaria parasites, therefore will potentially eliminate Malaria globally particularly in Sub-Saharan Africa which accounts for over 90% of the global malaria burden (World Malaria Report, 2021). Africa will be a huge market for my product (Repurposed Chloroquine for treating Chloroquine-Resistant *P.falciparum* malaria) which should be affordable (a key requirement for therapeutic interventions in Africa) for them. I do not foresee any immediate approval and manufacturing concerns (Licensing by FDA etc); Chloroquine is already an established drug in terms of its safety, efficacy, the only concern would that of WOG19 as to its safety, WOG19 is naturally occurring, results from our toxicity studies show WOG19 is safe for human consumption. I also do not foresee any immediate threat to this product (it is potentially resistance-proof).

Table 1: The Average suppression of parasitaemia in the Anka strain (P<0.05), SLN-Solid Lipid Nanoparticles.

Group	Average Parasitaemia (%)	Average Parasitaemia (%) of Reference	Average Suppression (%)
Placebo	14.000± 1.528	14.000± 1.528	100
Formulation(WOG19-loaded SLNs)	5.400 ± 0.503	14.000± 1.528	61.420 ± 1.029
Combination(Chloroquine plus WOG19-loaded SLNs)	2.200 ± 0.252	14.000± 1.528	84.300 ± 1.015
Positive control(pure Chloroquine solution)	7.600 ± 0.503	14.000 ±0.503	45.700 ± 1.079

Figure 1: Reduction in parasitaemia in the Anka strain (curative model)

PITCH COMPETITION: TAPPING INTO LIGAMENT TENSION WITH OUR LIGAMENT TENSIO-METER TO ENHANCE OUTCOMES FOLLOWING ORTHOPEDIC PROCEDURES

Lesley R. Arant (1), Kai M. Heineman (1), Josh D. Roth (2, 3)

- (1) Department of Biomedical Engineering, University of Wisconsin-Madison, Madison, WI, USA
(2) Department of Orthopedics and Rehabilitation, University of Wisconsin-Madison, Madison, WI, USA
(3) Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, USA

PROBLEM STATEMENT

Improper ligament tensioning during orthopedic procedures is associated with postoperative joint dysfunction, patient dissatisfaction, and a higher risk of revision procedures. For example, in total knee arthroplasty, under-tensioning the collateral ligaments can lead to instability and pain, while over-tensioning can lead to stiffness and pain [1]. Similarly, in cruciate ligament reconstructions, inadequate graft tension impedes graft healing and fails to reinstate normal anterior laxity [2]. Considering that total knee arthroplasty and ligament reconstructions are among the most frequently performed orthopedic procedures [3], achieving proper ligament tension is necessary to improve patient satisfaction and reduce the economic burden associated with revision procedures.

Despite the well-documented importance of proper ligament tensioning, existing solutions to gauge ligament tension intraoperatively are either subjective or fail to assess tension in an individual ligament. One common technique is a laxity assessment, in which ligament tension is indirectly inferred from joint motion and stiffness [4]. Since this assessment is commonly subjective, its outcomes vary according to a particular surgeon's training and experience [5]. Although distraction devices [6] and contact force sensors [7] provide quantitative measurements, they are unable to assess tension in an individual ligament. Thus, given the lack of adequate devices available, there is no consensus on the proper target or method of assessing ligament tension.

Accordingly, a sensor that provides direct and objective measurements of ligament tension would give orthopedic surgeons the information needed to improve patient function and satisfaction following orthopedic procedures.

TECHNOLOGY/SOLUTION DESCRIPTION

Our technology, termed a ligament tensiometer, shows promise for filling this hole in a surgeon's toolbox because it provides direct and quantitative measurements of ligament tension. The ligament tensiometer is a handheld device placed in contact with the ligament of

interest. It consists of two main components (**Figure 1**): (1) a voice coil actuator that excites low amplitude shear waves in the ligament, and (2) a piezoelectric load cell that tracks the shear wave propagation along the ligament's length. The tensiometer software computes the shear wave speed in the ligament using the time delay between the voice coil actuator and load cell signal (**Figure 1**). The tensiometer software then calibrates measured shear wave speeds to ligament tension using the linear relationship between shear wave speed squared and tension [8,9]. Thus, the output of the tensiometer is a near real-time, quantitative measurement of tension in a specific ligament.

Figure 1: Our ligament tensiometer is a handheld device that uses shear wave speed to measure tension in a particular ligament.

We performed a preliminary error analysis of our tensiometer prototype to assess its accuracy of measuring collateral ligament tension (**Figure 2**). We chose these ligaments to study because of the promising application of the tensiometer in collateral ligament balancing during total knee arthroplasty. We used our ligament tensiometer to measure shear wave speeds in the medial and lateral collateral ligaments of human cadaveric knees ($n=3$) under manually applied loads (**Figure 2a**). We used a calibration algorithm to compute the tensiometer-measured tensions from measured shear wave speeds. We computed the errors between the tensiometer-measured tensions and gold standard

tensions measured using a six degree-of-freedom robot and the principle of superposition [10]. We found that the tensiometer can directly measure ligament tension with low bias errors (**Figure 2b**). Additionally, when the tensiometer was coupled with optical motion capture to track ligament length, the tensiometer could accurately measure ligament engagement length (i.e., length at transition from toe to linear region) (**Figure 2c**). Thus, the tensiometer could be used with existing surgical navigation tools to measure other key metrics of ligament mechanics.

Figure 2: (a) We used the tensiometer to measure lateral and medial collateral ligament (LCL and MCL, respectively) tension during laxity assessments in three cadaveric knees. (b) The tensiometer measured ligament tension with low bias errors. (c) When coupled with optical motion capture, the tensiometer accurately measured ligament engagement length.

The key technical advancement required to take our tensiometer to market is to increase its precision through design optimization. Preliminary data suggests that tensiometer-measured tension is sensitive to tensiometer design factors (e.g., tip spacing, excitation frequency [11]) and use factors (e.g., application force [12], positioning of the tensiometer on the ligament [13]). Thus, we must identify the optimal combinations of these design and use factors that yield repeatable and accurate measures of ligament tension, while maintaining the tensiometer's ease-of-use. Additionally, the size of the tensiometer should be decreased so it can be placed in contact with the intraarticular surface of ligaments, thus avoiding the need for additional surgical incisions. With these key technical advancements, the ligament tensiometer would be a strong candidate for a marketable product.

BUSINESS CASE

Although orthopedic surgeons and other operating room personnel are the end users of the ligament tensiometer, there are additional customers to consider. First, the patients are those who are receiving an orthopedic procedure that involves ligament tensioning, such as total knee arthroplasty or ligament reconstruction. In the United States alone, the number of total knee arthroplasties and cruciate ligament reconstructions are projected to reach 1,272,000 [14] and 700,000 [15], respectively, by 2025. Considering that the tensiometer has potential use in many other procedures, joints, and ligaments, this should be considered a conservative estimate of the patient market size.

The payers are the hospitals, insurance agencies, and the patients who receive the surgery. Once marketed, we envision the cost structure of the tensiometer to be a one-time payment for the device, followed by the purchasing of disposables and software licenses as needed. Thus, we expect this cost to be comparable to existing sensors on the market used to gauge ligament tension. To appeal to each of these customers, we plan to acquire data that shows that tensiometer use improves patient outcomes, decreases surgical time, and/or decreases costs.

Our marketing strategy involves three phases (**Figure 3**). In phase I, we will recruit an interested “champion” surgeon to test the tensiometer on a small subset of patients at the UW Hospital. This phase

requires IRB approval before the tensiometer can be used in live patients. To fund phase I, we plan on seeking Small Business Innovation Research (SBIR) phase I funds totaling \$200,000. In phase II, we will fabricate at least ten tensiometers and send each to a different institution for use by surgeons. In this phase, we will also submit Premarket Notification 510(k) to the FDA because the tensiometer will be considered a Class II medical device. To fund phase II, we will apply for SBIR phase II funds totaling \$1 million. In phase III, we plan to acquire FDA clearance to enable widespread tensiometer use. Several companies with strong footholds in the orthopedic technology industry have already expressed interest in the tensiometer. By selling our small business and any patents to one of these companies, we aim to achieve widespread adoption of the tensiometer in hospitals.

Figure 3: Pathway to market for the ligament tensiometer.

The main hurdle to market is translating our tensiometer from a prototype to a clinically-usable device. In particular, the tensiometer components must be either sterilizable or disposable so that the tensiometer can be reused in different patients. Additionally, to decrease manufacturing cost and time, and increase product robustness, the tensiometer housing must not be made of 3D printed polymers.

The main risk to the developmental pathway of the tensiometer is the reluctance of surgeons to incorporate a new technology into their surgical procedure. If this challenge presents, then we will lean on the support of the existing early adopters to generate more data that supports the benefit of tensiometer measurements to improving patient outcomes. This may lengthen the time to commercialization, but we do not believe this will be a permanent roadblock to translation of our device.

In sum, our three-phase marketing plan aims to recruit surgeons who will fuel the generation of supporting data, which in turn will fuel market expansion. Once commercialized, the ligament tensiometer will enhance the process of ligament tensioning during orthopedic procedures, leading to more consistent, predictable, and positive surgical outcomes for patients suffering from debilitating orthopedic injuries and diseases.

ORTHOPEDIC CAST SAW

Ryan A. DeJesus (1), Nicholas J. Graham (1), Evan M. Lunney (1), Jaedan D. Morton (1)

(1) Department of Mechanical Engineering, The Pennsylvania State University - Harrisburg,
Middletown PA, United States

PROBLEM STATEMENT

In the medical industry an orthopedic cast saw is used to remove casts. A cast is a supportive device used to stabilize extremities, preventing further injury. The shortcoming with the current cast saw is that it allows the user to plunge the saw too deep causing cuts and burns. This results in an injury to 72 out of every 10,000 casts removed from patients. The Stryker® 940 is designed to minimize cuts using an oscillating blade shown in **Figure 1**. This method cuts through hard material like casting but leaves skin mostly unscathed. Beyond causing harm to the patient, these injuries can cost the company money in lawsuits, and give a bad reputation. The goal of this project, as stated, is to minimize unnecessary injuries during the cast removal process. To reduce injuries to patients, the device needs to include more safety features. The current design lacks the necessary depth control required to stop the user from causing injury. The target customer for this project is primarily orthopedic centers that perform cast removals.

Figure 1

This figure shows the OEM design of the Stryker® 940 Cast saw

TECHNOLOGY/SOLUTION DESCRIPTION

Our proposed prototype implements a modular depth control system. This is achieved by the creation of a new guard shown in **Figure 2**. It is composed of 3 ABS parts along with stainless steel hardware. This guard replaces the OEM guard shown in **Figure 1**. The purpose behind the new guard is to impose limits to the cutting depth which can be set with the knob in the back. Cutting depths are set by moving the guard parallel with the blade in 1-millimeter increments. For each full rotation of the knob, one millimeter of translation will be achieved. A clockwise rotation results in a decrease of cutting depth, while the opposite applies for counterclockwise rotation. Using a Nyloc nut embedded in the base, the knob gets progressed as it goes through the threads of the nut. This resulting motion adjusts the cutting depth.

To increase useability in the medical field, the material must be changed from ABS. Fabrication of a nylon part is critical for sterilization in the medical field. While the current 3-D printed prototypes are functional, injection molding is essential for the future of this product, as it provides a clean and professional finish. The current mechanical design shows a great proof of concept but is lacking features. An electronic design is currently being developed. This design will be controlled with buttons that adjust cutting depth while displaying the current depth of cut on a seven segment LED display. The buttons provide a more accurate method of measuring one rotation since they are paired with a stepper motor.

Figure 2

This figure shows an ABS print of the new guard design

BUSINESS CASE

The adjustable guard is a modular implementation that can be added on the Stryker® 940. By designing this guard to fit on a commonly used cast saw, we are securing a large potential customer base. In the US approximately 6.8 million fractures occur each year. When a fracture occurs, casting is a common practice of immobilization. Breaking bones will always occur, so the use of safe removal processes will always be in demand.

For each of our prototypes, the cost including the hardware was less than \$20 when printed from ABS as shown in **Figure 2**. If nylon was used along with better fabrication processes, the cost of a single product would be around 200\$. This includes electronics, stainless-steel hardware, and injection molded parts. These parts consist of the lid, base, and adjustable guard shown in **Figure 3**. When a larger order is placed, the cost per part along with the cost of electronics will decrease significantly making a more cost-effective solution. This shows the economic viability of the product for orthopedic centers and hospitals. Patients include anyone with a cast, while end users are nurses and techs along with doctors who remove casts.

The CDRH which is a subsection of the FDA controls medical devices produced in the US. Since a cast saw does not have a severe risk of illness or injury, we are not required to submit a premarket approval. The largest risk to this business is that the Striker® 940 is no longer in production. This is not an overwhelming concern since the guard can be easily modified to fit onto other existing saws. Due to the low cost and modular design of our guard, this product can be implemented into hospitals easily. The reward for using this product is high especially when considering its low cost.

PITCH COMPETITION: ARTIFICIAL MULTI-ORGAN REPLACEMENT (AMOR) SYSTEM

PROBLEM STATEMENT

Intensive care patients who are acutely ill often have at least one or multi-organ failure (MOF). During the past decades, the prevalence of MOF in critically ill patients has been increasing, and the associated mortality rate remains high. More than 5 million patients are admitted annually to US ICUs for intensive or invasive monitoring [1]. And studies have reported a high prevalence of at least one failure with 70% of the patients at some point during the ICU stay.[2] The MOF even contributes to 50% of the ICU patient deaths and this number has a dramatic increase to 341% during pandemic [3,4]. Critically ill patients are complex and require a systematic approach to ensure excellent care. They are often managed by thinking about each system in turn so that all their maladies are considered and appropriately treated. Unfortunately, MODS is a complex syndrome for which the pathophysiological mechanisms are poorly understood. Despite a physician's best efforts, patients may deteriorate to the point that multiple organs are dysfunctional and heading toward failure. When this occurs, the acuity and complexity of these patients escalates and considerable attention to the details of each system is paramount. Decades of research have ensued to treat and reverse multi-organ dysfunction syndromes (MODS) before it becomes MOF. However, aside from correcting the underlying etiology, there has been no single treatment strategy that can be used to cure all patients. Moreover, salvage therapies are lacking for severe MODS that progress to MOF. [1]

At the most recent development, when MOF happened, the solution was to create extracorporeal support for failing organ-systems by applying multiple single organ support equipment. These organ support systems include kidney dialysis, liver dialysis, fluid removal, gas exchange support, respectively. But applying those individual complex machines together on one patient is quite challenging, risky, and labor intensive. "The timing and degree of any intervention are crucial when saving MOF patients" [5]; With the interviews from nurses

who operate the organ support systems in ICUs, they all have the comments that the manual tubing setup and preparation procedure for organ support machines gave them the most pain as well as frustration. The complex and time-consuming preparation procedure puts patients waiting for treatment at danger, and this is also critical for nurses rushing for an extremely sick patient with MOF. The reliance on current priming technique creates fear for both patients and nurses. Having a solution to demonstrate safety and check for proper priming is essential.

TECHNOLOGY/SOLUTION DESCRIPTION

We are working on a modular AMOR system that can provide easier but more efficient treatment for doctors to apply on single or multi-organ failure patients. AMOR was inspired by the concept that organs do not work indecently in our body. Integrating all these systems into one will also be beneficial to the user experience and save preparation time that is critical to provide treatment. It will minimize the operation procedure, significantly reduce the preparation complexity. Furthermore, an integrated system could monitor patients online and analyze the treatment data from different organ support systems together, which will reduce the nurse workload and minimize potential human error. The modular design makes the treatment set up more flexible. Doctors can easily switch between different organ support modes based on patient situations.

Patients who developed failure of multiple organs such as kidney, central nervous system, lungs and heart with massive anasarca, needing kidney dialysis, various forms of liver support systems such as Molecular Adsorbent Recirculating System™ (MARST™) along with ventilator and vasopressor support. Kidney dialysis is usually effective in treating the biochemical abnormalities of renal failure, such as urea, creatinine, electrolyte abnormalities and metabolic acidosis. But the kidney dialysis is ineffective in treating extra-cellular fluid excess that

usually is massive and adversely affects the pulmonary, cardiac and brain functions and eventual outcome of the patient [6].

Kidney dialysis is also unable to reduce protein bound hepatic toxins such as bilirubin [7]. Several systems based on the concept of using albumin containing dialysate to remove albumin bound toxins, as a consequence of liver failure, were developed. The albumin systems that have been used include the Single-Pass Albumin Dialysis system (SPAD), and the Molecular Adsorbent Recirculating System™ (MARSTM). The MARS is the most commonly used liver support system in the USA. However, this system is expensive and has many limitations such as its ability to treat uremic abnormalities and most importantly, very limited ability to reduce fluid excess. Additional kidney dialysis treatment is required to treat uremic abnormalities. Randomized studies reviewing the results of the MARS use have shown some mortality benefit however there are also reports of hemodynamic instability with its use. For patients with acute on chronic liver failure (AOCLF), the use of MARS has not increased the probability of receiving transplantation compared to the use of standard medical treatment without MARS [8].

A recent device called the Advanced Organ Support (ADVOS) system has been used in acutely ill patients with MOF. The device is reported to provide liver, renal, and respiratory support. It is proposed that the modulation in pH regenerates the albumin in the albumin dialysate and ultrafiltration is proposed to filter out bilirubin and other solutes wastes. The modulation of pH in the dialysate circuit is proposed to help the acid base balance of patient thus supporting renal system [9,10]. Unfortunately, removal of bilirubin from the circuit by ultrafiltration for the albumin regeneration purpose has not been documented by data. Improvement in patient's biomarkers is promising however survival benefit has not been shown [11].

Past work from our group established three key observations: albumin dialysate removes protein-bound toxins across commonly used dialyzer membranes without a need for a specially designed membrane such as reported for MARS (9); charcoal columns can regenerate albumin dialysate by removing clinically relevant toxin(s) (bilirubin) (10). Our theoretical modeling showed that combining albumin dialysis with ultrafiltration produces greater solute clearance than albumin dialysis alone (11). Based on these experiments, we developed a multi-organ support system that uses recirculating regenerating albumin dialysate. Additionally, the combined hemodialysis and albumin dialysate system provides both liver and kidney dialysis simultaneously. Unlike previous systems, our device allows sorbent columns to be regenerated to maintain their functionality for a longer period.

BUSINESS CASE

The AMOR system will initially focus on ICU settings, where most MOF patients are treated while the mortality rate remains high. Follow-on opportunities for the deployment of AMOR system include Emergency Rooms, Emergency Response Unit and Military. There is also portable potential of AMOR system that can achieve home-based use for organ support treatment. The primary customers and early adopters for AMOR system will be physicians and nurses at Intensive Care Unit (ICU) in hospital settings, representing our beachhead market. They are the main potential customers since they are the primary role of treating MOF patients. In the words of the medical director of dialysis services at UW Medical Center, "A device that could maintain patient's multi-organ function would simplify decision making". Additionally, another potential market share that can be added for AMOR system is the consumables which also take up a considerable medical expense through the Medicare systems each year.

We have already filed the PCT patent (US 63/183,482, 2022) with UW CoMotion for our Kidney and Liver combined modular system. We are planning to file the full utility patent once we conduct further regulatory investigation to create a solid patent landscape. For the regulatory aspect of AMOR system to get the clinical approval and payment, we are in the process of figuring out a clear pathway with the regulatory consultants and we are also conducting search for the predicated devices and possible 510(k) pathway that we can follow for accelerating the FDA approval process. The lack of existing solutions or devices for MOF support might require our AMOR system to follow new guidelines and standard codes which would take longer period for the approval process. However, Since AMOR is also a modular platform for each organ support, the existing FDA approved organ support system for kidney, liver, heart and lung can be individually considered for assisting the FDA approval for AMOR system as well.

ACKNOWLEDGEMENTS

A NOVEL HARDWARE AND SOFTWARE DEVICE TO NON-INVASIVELY PREDICT POST THROMBOTIC SYNDROME

Cyrus J. Darvish (1), Pete H. Gueldner (1), Rabih A. Chaer (2),

 (8) Clinical and Translational Sciences Institute, University of Pittsburgh, Pittsburgh, Pennsylvania, USA

PROBLEM STATEMENT

Deep vein thrombosis (DVT) (**Figure 1A**) is a common cardiovascular disorder where a blood clot forms, typically in the lower leg or thigh. DVT affects as high as 3 in 1000 of the general population each year and can lead to a pulmonary embolism (PE), which is the third most common cause of death from a cardiovascular disease [1]. According to the CDC, 900,000 people are diagnosed with DVT in the United States each year, and approximately 300,000 of these patients will die from DVT/PE. Clinical diagnosis of DVT can be accomplished using compression duplex ultrasound and in some rarer cases computed tomography (CT) or magnetic resonance imaging (MRI) [2]. Anticoagulation and compression socks have emerged as a reliable method to treat DVT. However, approximately 50% of symptomatic DVT patients will progress to post thrombotic syndrome (PTS) [3]. PTS is a debilitating disease that is associated with chronic venous insufficiency after an episode of acute DVT. Common symptoms include chronic inflammation, pain, and venous ulcers.

Patients that suffer from PTS will experience a significant reduction in quality of life when compared to DVT patients due to persistent pain and inflammation in the lower legs. PTS is also associated with a higher prevalence in the Black community [4,5]. There are heavy costs to bear when managing PTS (\$10,300 in 1991 US dollars, estimated to be ~22,445 in 2023) and this does not include the downstream complications of the disease [6]. PTS is typically diagnosed 3-6 months after an episode of acute DVT and can only be diagnosed if the symptoms of DVT have previously subsided with treatment [7].

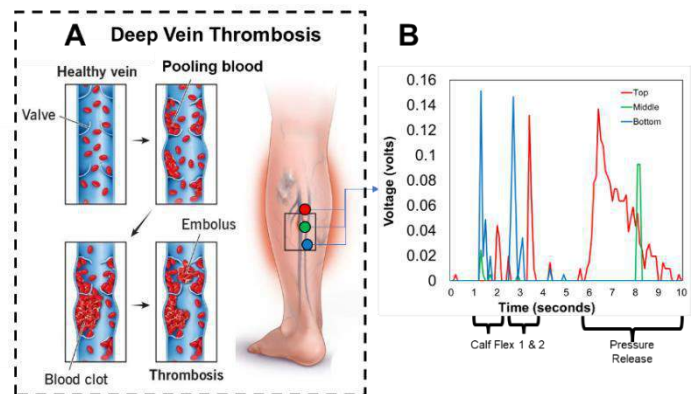

Figure 1: A) Shows the steps that lead towards deep vein thrombosis and post thrombotic syndrome. B) Preliminary data of our device output from sensor array from pressurized calf flexion and pressure release

Diagnosis of PTS is currently limited to a qualitative assessment of clinical signs and symptoms (Villalta scale) [8]. A patient is considered to have PTS if they score greater than five points on the scale, with greater than fifteen points considered severe (10-15% of patients).

An alternative method that has not been widely adopted is air plethysmography. This method tracks the overall volume change with pressure and can measure venous reflux. However, it cannot independently diagnose PTS [9] and ultrasound remains the predominant method to confirm PTS. While diagnosis and treatment of DVT is well established, there is no gold standard for diagnosing PTS or predicting its outcome in patients with acute DVT.

TECHNOLOGY/SOLUTION DESCRIPTION

The penultimate goal of this approach is to design and manufacture a non-invasive low-cost Thrombosis Differentiating Pressure (TDP) cuff that is accompanied by a machine learning (ML) model to pre-emptively identify whether a patient will transition to PTS after DVT (**Figure 2**). Development of the device will include two aims. The first aim will include developing a novel TDP cuff hardware device that will be placed on the lower leg or thigh of a patient with DVT. The cuff will contain a matrix of sensors that will be able to characterize deformations in the deep veins during

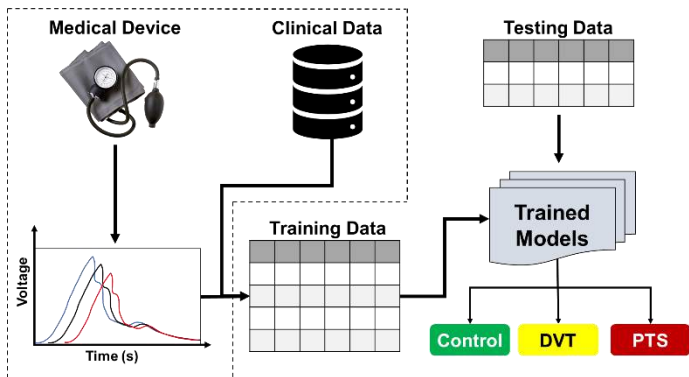

Figure 2: Illustrates the variables and steps of the approach to identify patients at high risk of developing PTS after acute DVT.

pressurization. The inflation of the pressure cuff will compress the vein wall and compliance of the vein can be measured. Gathering compliance data will be used to identify patients who are at high risk of developing PTS after the incidence of acute DVT.

The second aim is to incorporate a ML model to predict patients at risk of transitioning to PTS. The process will include training, testing, and validating a ML model to predict the likelihood of a DVT patient transitioning to PTS using the processed signals from the TDP cuff, patient survey data (Villalta score) and key patient clinical indices (age, sex, race, medications, and other co-morbidities). The device would have a wide range of applications that are not limited to DVT/PTS and could assess venous hypertension for patients during dynamic movements (e.g., walking with the TDP cuff). The approach combines vascular biomechanics and ML to develop a novel non-invasive hardware device paired with an innovative ML software system to predict whether a patient will develop PTS. Accurate predictions would allow clinicians to preemptively treat high risk patients more aggressively, reducing healthcare costs and improving quality of life for the patients.

BUSINESS CASE

As mentioned before, PTS bears a significant socioeconomic impact, increasing cost to the patient when compared to DVT treatment alone (\$10,300 vs. \$6,000 in 1991 dollars, or \$22,445 vs. \$13,074 in 2023). With the 900,000 people affected each year by DVT in the United States that gives an overall market size of nearly \$12 billion.

The purpose of the novel approach is to pre-emptively diagnose PTS before symptoms reappear, allowing clinicians to

treat the initial bout of acute DVT more aggressively. The TDP cuff will be used at the time of treatment to identify at-risk patients. This could significantly reduce costs for follow-up treatments and reduce concern for both patients and clinicians of developing debilitating PTS in the immediate future (3-6 months after a DVT episode). The TDP cuff is a low-cost solution that has the potential to replace ultrasound for patients that suffer from acute DVT.

The primary customers would be primary care offices and specialties that include vascular surgeons and cardiothoracic surgeons that regularly treat DVT patients. The TDP cuff could be used in a primary care facility without the need for a vascular surgeon. The primary advantage is that the hardware device would not add any significant clinical time (i.e., easy to use). The hardware and software approach could potentially replace the need for an ultrasound technician to measure vein functionality during follow-up visits.

The initial TDP cuff will be deployed in a clinic to measure acoustic waveforms from patients diagnosed with DVT and PTS. A pilot study will be conducted to compare the signature waveforms with ultrasound compliance measurements. The pilot study will collect ultrasound and TDP cuff data from normal, DVT, and PTS patients. A validation study will be performed to correlate the signals from the TDP cuff and train a predictive machine learning model.

Clinical adoption is key to overcoming the limitations of the current methods of managing DVT patients. The path towards commercialization includes the protection of intellectual property and regulatory approval. An invention disclosure and provisional patent has been filed by the University of Pittsburgh Innovation Institute. There are current efforts underway to develop the prototype and deploy it in a clinical setting to collect sensor data, clinical data, and ultrasound images from patients (control, DVT, and PTS). After the hardware and ML software model are completed, an FDA pre-submission meeting will be sought after to understand the regulatory path forward. The initial hardware and software approach would be classified as a Class II device with predicates (i.e., not a *de novo* device) for the hardware and Class II for the software as a medical device (SaMD) as it would inform clinical management of DVT/PTS. Lastly, a prospective clinical trial will be performed with an FDA device exemption to demonstrate the efficacy and performance of the TDP cuff in a clinical setting for 510(K) FDA approval as a safe and effective medical device.

PITCH COMPETITION: POLYMERIC TRANSCATHETER AORTIC VALVE REPLACEMENT (TAVR) FOR TREATING AORTIC STENOSIS

B. Kovarovic (1), O.M. Rotman (1), M. Slepian (2), D. Bluestein (1)

- (1) Biomedical Engineering, Stony Brook University, Stony Brook, NY, USA
(2) Sarver Heart Center, University of Arizona, Tucson, AZ, USA

PROBLEM STATEMENT

Aortic stenosis (AS) resulting from progressive calcific aortic valve disease (CAVD) is estimated to be prevalent in 5% of the elderly population above 65 years old and severe AS in 3% of the population about 75 years old [1]. Untreated severe AS is associated with a 50% mortality rate within the two years [2], and thus the highly invasive surgical replacement procedure was considered the gold standard therapy until the minimal transcatheter aortic valve replacement (TAVR) was introduced in 2011 to treat inoperable patients. SAVR held in the market with about 70,000 US patients in 2010 and the introduction of TAVR has expanded the market to about 150,000 combined SAVR/TAVR patients in 2020 [2]. Since the introduction of TAVR, it has been approved in the US to expand from inoperable patients (2011) to high risk (2012), intermediate risk (2016), and low risk/younger patients (2019) as well as for unique aortic valve anatomies such as bicuspid aortic valve. 2019 marked the first year TAVR (72,991) exceeded SAVR (57,626) procedures in the US [3], and this is due to both the experience of interventional heart teams as well as the attraction of patients to the reduced hospital costs and stay. With additional pressure from the COVID-19 pandemic, the global TAVR market reached \$4.4B and is forecasted to reach up to \$13.35B by 2030.

Despite the global acceptance of TAVR because of the minimally invasive nature of the procedure, the current commercial valves are subject to intrinsic and extrinsic structural valve degeneration (SVD) due to the inherent limitations of the chemically fixed bioprosthetic tissues used to create the functional leaflets and sleeve components. The fixed tissues are subject to degradation due to intrinsic inflammatory responses that can lead to thrombosis, endocarditis, and eventually lead to formation of calcific masses within the bioprosthetic tissue. Due to the crimping procedure, in which the metal stent frame is compressed radially onto the delivery catheter for the transcatheter approach to the aortic valve, the bioprosthetic tissue is compressed and is prone to mechanical damage. The damage incurred diminishes the durability and

wear resistance of the prevailing tissue-based valves in the market, leading to increased rates of wear and tear damage. With the recent advancements in TAVR technology, the in vivo durability lifetime of tissue TAVR valves remains uncertain or inconclusive, thereby posing a significant risk to younger patients who opt for TAVR devices instead of surgical alternatives with an established durability record.

The present polymeric valve technology has the potential to rectify the various shortcomings of the prevailing tissue-based TAVR devices, as well as exceed the performance, hemocompatibility, safety, and manufacturability of tissue valves. The idea of using elastic polymer material to cast or mold leaflet structures, known as polymeric valves, has been explored since the 1950s, starting with polyurethane valves. However, the demanding conditions of the aortic valve environment and the limitations of polymer technologies have hindered their success. The polymer properties, in combination with leaflet design that is very limited for tissue valves, has to be able to easily open during systolic forward flow, close and seal during diastole while resisting the largest pressure gradient in the cardiovascular system, and maintain this function at a constant rate of approximately 72 beats per minute throughout the patient's remaining lifespan. In recent years a few materials have been identified to be suitable for polymeric valves and

Fig 1: PolyNova Cardiovascular Inc timeline of polymeric TAVR development to the PolyV-2 design.

companies or research groups are beginning the process of study, validation, animal trials, and final approval from the FDA for novel polymeric valve systems. The regulatory approval process will be especially rigorous as the device is a Class III device without 510k pathway due to the novel material. Nevertheless, the prospect of a material that offers an engineered platform with reduced patient risk, along with the rapidly growing TAVR market, is highly appealing to both startup companies and potential investors.

TECHNOLOGY/SOLUTION DESCRIPTION

Our company, PolyNova Cardiovascular Inc (Stony Brook, NY), has been researching and developing polymeric valve technologies since 2014 with the initial focus on surgical valves, and since transitioning to the more attractive TAVR devices (Fig 1). The polymeric material has undergone development into a now cross-linked form of Poly(Styrene-block-IsoButylene-block-Styrene) or xSIBS that we have termed “Flexamer” technology. SIBS based devices have been used in cardiovascular devices for paving coronary stents, Boston Scientific, Marlborough, MA) and for glaucoma shunts. Initial testing involved study of proper material stiffness, degree of cross-linking, and benefits or shortcomings of composite materials. This polymer has been shown to be hemocompatible and thromboresistant, as well as resilient to calcification, crimping damage and wear and tear that has plagued tissue valves [3]. One of the advantages of the “Flexamer” material compared to the competitors, is that the polymer is a thermoset material and utilizes a encased casting/molding platform with either compression, transfer or even injection molding systems. This gives the advantage that our valve can be cast in virtually any shape, configuration, or size with a highly repeatable molding system. Compared to tissue valve, which are hand sutured to the stent frame over numerous days of manual labor and is fraught with human error, we are able to cast the valve on top or around the stent frame, creating the leaflets and attachment simultaneously, in a matter of hours, drastically reducing the error and cost of the final product. The main polymeric valve competitor (Foldax Inc, Salt Lake City, UT), who is currently in first-in-man trials for their surgical valve, utilizes a “dip-coating” system in which a mandrel is coated via controlled dipping and drying process, which requires a robotic arm to reach repeatable products and they lose the ability to finely control the resulting design.

This fine control of the leaflet structure has given us the ability to iterate on the device design, with significant utilization of *in silico* models and optimization from the initial surgical valve design to the current second generation TAVR valve design. The casting technology unlocked the ability to cast variable thickness leaflets in a semi-open configuration via the simulation results informing the design where the largest cycle stresses occur and increases the thickness in this region (Fig 2, Provisional patent UA 22-059 Pro, U.S.S.N. 63/315,286 – March 2022). The variable thickness optimization reduces the peak cycle stress far below the fatigue limit of the polymer, offering a known large factor of safety, as well as increasing the performance of the valve. The first generation TAVR device, PolyV-1, was subjected to a battery of *in vitro* testing in order to confirm the strength of the polymer and functionality as a valve. The polymer offered reduced platelet activation compared to commercial devices, increased performance in both idealized [4] and patient-specific platforms [5], no risk of calcific salts depositions, no risk of crimping damage over long periods [6], and achieving the ultimate benchmark of durability with no performance loss over 1B cycles (25 year *in vivo* equivalent, exceeding the FDA required 200M limit) [7]. The PolyV-1 was designed to evaluate the polymer and the second generation PolyV-2 was redesigned for proper TAVR deployment and on-going animal (ovine) trials. PolyV-2 was scaled up, designed, and optimized [7] To demonstrate the *in vivo* performance and compatibility of the polymeric valve, the valves need

to be properly deployed in an ovine model using an 18F delivery system that minimizes the stent and polymer volume.

BUSINESS MODEL

The current TAVR market is rapidly expanding due to the aging of the “baby boomer” generation, combined with the attractive nature of the risk involved in this minimally invasive procedure, its lower cost and decreased hospital stay. However, the “double-edge” nature of TAVR rapid expansion is demonstrated by the many failing tissue based valves leading to Valve-in-Valve (ViV) rescue operations to correct the failing valves. This creates a situation where there is a requirement to rectify numerous currently deployed devices while

continuing to employ flawed tissue technologies, which puts the patients at risk. Polymer valve technologies have the potential to be disruptive as they offer a viable long-term solution that can overcome the shortcomings of current TAVR tissue valve technology by allowing engineering solution of optimized designs. Consequently, the continued use of tissue valves would offer no clear benefits. With proper design and testing polymer TAVR technologies can replace the need for most surgical valve replacements since only current advantage of surgical valves is their established longer-term durability as compared to tissue TAVR devices. The polymeric valve technology of PolyNova Cardiovascular Inc will effectively address the needs of AS patients as well as the expansion to unique anatomies such as Bicuspid Aortic Valve (BAV) specific devices, and can address the challenges and economic burden of developing nations such as rheumatic heart disease with lower cost polymeric valves. Manufacturing can be completed in a small lab/ clean factory setting without need to massive scale up since the device manufacturing time would be reduced from days to hours. The main hurdle to market is the lengthy and in-depth regulatory process of a complex new Class III device with new material by the FDA. Performing the needed validation testing (ISO 5840) and animal trials is a challenging and costly process. Earlier companies that developed polymeric valves attempted to rush to clinical trials without fully optimizing the design, resulting in resource depletion. We have taken the approach of careful and continued improvement of the device design to mitigate these risks before finally arriving at our current stage of animal trials.

PROBLEM STATEMENT

In addition to lifestyle factors and coexisting conditions, pathogens and other extrinsic harmful substances have become increasingly recognized as contributors to and direct causes of vasculopathies in humans. Highly common bacterial (e.g., by *Chlamydia pneumoniae*, *Helicobacter pylori*, and *Streptococcus pneumoniae*) and viral infections (e.g., by herpes viruses, hepatitis B and C, influenza, and human immunodeficiency virus) have been linked to cardiovascular diseases including coronary artery disease [1–4], vascular dementia [5,6], endothelial dysfunction [7–9], and thrombosis [10–12]. Most recently, endothelial dysfunction and venous thromboembolism have been identified as major contributors to the risk and severity of coronavirus disease 2019 (COVID-19), cited as having contributed to up to one-third of deaths in some clinical reports [13].

Human vascular pathologies are highly complex diseases that result from a convergence of factors, and many mechanisms of these diseases remain poorly understood [14]. Traditionally, basic biology research and preclinical drug discovery and development testing has been performed using animal (predominantly, murine) research models. However, due to inherent differences between animals and humans ranging from inconsistent genetic profiles to large differences in macroscopic tissue environments and behaviors, these research models do not mimic human physiology sufficiently for understanding the complexities of vascular pathologies [15]. As a result, little is known about many mechanisms of pathogen-induced vascular diseases, and new approaches to treatment have been difficult to identify. Furthermore, drug candidate screening and efficacy and toxicity testing efforts remain limited in their prediction of human drug response. Finally, variabilities in vascular physiology and drug response caused by genetic stochasticity and lifestyle factors result in significant differences in manifestations of disease and responses to therapeutics across populations. In fact, the U.S. Food and Drug Administration

(FDA) recently announced new requirements for greater representation in diverse clinical trials to achieve approval of new therapeutics [16]. Resolving these differences is one of the major challenges in design and execution of clinical trials as many potential adverse effects are not captured during limited clinical trials [17].

In addition to the broad challenges associated with accurately modeling human disease and drug response, studies that must be conducted in hazardous containment environments present unique problems. Recently, the COVID-19 pandemic has highlighted these challenges as biosafety level 3 and 4 (BSL-3 and 4) containment requirements [18] have significantly slowed research into and treatment of severely damaging secondary effects of the disease. These facilities require strict safety measures to be considered for sufficient protection of personnel, and traditional in vitro and animal models are difficult or, in some cases, impossible to implement in accordance with rules and regulations.

Microphysiological systems (MPS) represent a leading candidate technology for addressing the challenges outlined above. These platforms integrate advantages of modern tissue engineering and microfluidics technologies including use of human cells (e.g., primary or iPSC-derived), control of tissue architectures, tunability of tissue microenvironments, perfusion of nutrient-containing solutions and biological fluids, and facile observation of cell and tissue responses sufficient for providing deep mechanistic insights. We have demonstrated novel MPS platforms to model key aspects of vascular physiology and pathology. We have shown inflammation-induced clotting relevant to various systemic human diseases [19, 20]. We have reproduced physiologically relevant hemodynamics and shown their role in formation of deep vein thrombosis [21]. We have also implemented blood-derived endothelial progenitors on these model platforms as a rapid option for developing patient-specific in vitro vascular models [22]. However, despite these and many other advancements in MPS models of human diseases, standard methods and

platform configurations for fluid handling, sample input, and outcome observation do not meet the requirements for use in hazardous containment environments. As a result, there is a significant need for new technologies to translate MPS and similar technologies for applications in studying human pathogens, hazardous materials, and others requiring special research environments.

TECHNOLOGY/SOLUTION DESCRIPTION

To address the challenges associated with studying human physiology and testing drugs in hazardous containment environments, we have developed a platform integrating four key components. First, a pumping system has been constructed with a minimized footprint for easy accommodation in cell culture incubators of various sizes. This instrumentation provides advantages over commercially available platforms in its ability to tightly control fluid flow at the resolutions required to reproduce patterns directly from clinical patient data across the range of flow rates seen in various kinds of cardiovascular regimes while occupying less volume than traditional fluid delivery instruments. Second, an automated three-way valve with a sample injection port is included to alternate between media or biological fluid flow streams and pathogen (or other test case) solutions. This unit provides users the ability to introduce test samples such as pathogens of interest into the vascular tissue model system using only standard operation of a syringe. Third, a MPS vascular tissue model (which can easily be exchanged for other models) is interfaced directly with the fluid handling elements for reliable control of fluid perfusion. This system can include human endothelial cells from a range of sources to model various sections of the human cardiovascular system for research at various scales ranging from pooled experiments for high-level uniformity to single patient resolution for population representation or treatment pre-screening. Finally, a small, inexpensive fluorescent microscope is included within the platform for easy real-time monitoring of cell and tissue responses to test conditions. Additionally, a collection reservoir is provided to allow for cell or lysate extraction with sufficient sample concentration for downstream genomics, transcriptomics, and proteomics assays. Collectively, the components of the platform are packaged in such a way that sterilization and integration into controlled environments is easily achievable even with extensive personnel protection equipment (PPE). Furthermore, operation and sample collection requirements have been optimized so that users need only perform conventionally simple tasks.

The capabilities of this system have been demonstrated both individually and collectively. The fluid handling component has been proven capable of matching human cardiovascular flows in arterial and venous systems with accuracy less than 0.13 mmHg and resolution of 20 ms. The three-way valve is operable using a simple button press. The MPS component has been published previously as an impactful model of human vasculature both as a representation of disease (i.e., deep vein thrombosis) and drug testing (both to test anti-thrombotic therapeutics and to screen for off-target effects). As a prototype platform has been constructed and applied for research at a biosafety level 2 by untrained users (technology readiness level – TRL – 5), future development will be dedicated to addressing user input from alpha and beta testing to maximize ease of use. Additionally, durability testing is currently ongoing to identify the time and number of operations that the platform can withstand reliably.

BUSINESS CASE

The user groups for this technology include researchers studying vascular pathologies induced by harmful pathogens or other substances requiring experimentation in hazardous containment environments.

Such users include academic and medical basic science researchers, drug discovery and early-stage development researchers, pharmaceutical companies, and contract research organizations (CROs) conducting both preclinical and clinical testing. Furthermore, stakeholder interviews have revealed interest by government agencies including the Food and Drug Administration (FDA) for the data offered by a human-representative in vitro model, the Centers for Disease Control (CDC) for the ability to conduct rapid response experimentation in the event of pathogen outbreaks, and the National Aeronautics and Space Administration (NASA) for the ability to deploy these platforms in space to study the effects of anti-gravity environments and aging on the human cardiovascular system.

Because this is an entirely in vitro platform, regulation occurs at the site of deployment based on safety requirements for each use case. Although this system has been developed based on feedback from such safety officers, the lack of a standardized set of requirements between containment facilities and separate use cases will need to be addressed more extensively. Additionally, although manufacturing and distribution companies with proven capabilities in generating individual components for the platform exist and have been identified, the most financially feasible large-scale platform assembly mechanism remains to be determined. Finally, despite the proven capabilities of the individual components of the platform, the initial lack of market awareness and general inertia associated with the use of traditional research strategies will provide initial resistance. This challenge will be addressed using a strategic publication strategy with reputed partners across our prospective user groups both to demonstrate product feasibility and to gain widespread awareness.
